**Abstract.** The 8.2 ka Event was a prominent climate anomaly that occurred approximately 8,200 years before present (8.2 ka) with implications for understanding the mechanisms and characteristics of abrupt climate change. We characterize the tropical hydroclimate response to the 8.2 ka Event based on a multiproxy compilation of 61 tropical hydroclimate records and assess the consistency between the proxy synthesis and simulated hydroclimate anomalies in a new 8.2 ka Event experiment performed using the isotope-enabled Community Earth System Model (iCESM1.2). We calculate the timing and duration of the hydroclimate anomalies in our proxy reconstruction using two event detection methods, including a new changepoint detection algorithm that explicitly accounts for age uncertainty. Using these methods, we find significant hydroclimate anomalies associated with the 8.2 ka Event in 30% of our proxy compilation, with a mean onset age of  $8.28 \pm 0.12$  ka ( $1\sigma$ ), mean termination age of  $8.11 \pm 0.09$  ka ( $1\sigma$ ), and mean duration of  $152 \pm 70$  years ( $1\sigma$ ), comparing well with previous estimates. Notably, these anomalies are not hemispherically uniform, but display a rich regional structure with pronounced drying and/or isotopic enrichment across South and East Asia, the Arabian Peninsula, and in southern Central America, with wetter conditions and/or isotopic depletion in northeastern South America. In contrast, we find no signature of the 8.2 ka Event over the Maritime Continent.

The simulated hydroclimate response to the 8.2 ka Event generally agrees with the proxy reconstructions. In iCESM, the North Atlantic meltwater forcing causes a southward shift of the tropical rain bands in the zonal mean, resulting in a generally drier Northern Hemisphere and wetter Southern Hemisphere, but with large regional variations in precipitation amount and the isotopic composition of precipitation. Over the oceans, precipitation  $\delta^{18}\text{O}$  ( $\delta^{18}\text{O}_p$ ) anomalies are generally consistent with the "amount effect," wherein  $\delta^{18}\text{O}_p$  is inversely correlated with precipitation amount. However, the  $\delta^{18}\text{O}_p$  anomalies are more decoupled from changes in precipitation amount over land. iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic enrichment pattern in  $\delta^{18}\text{O}_p$  in South and East Asia and the Arabian Peninsula, drying and isotopic enrichment in  $\delta^{18}\text{O}_p$  in southern Central America, isotopic depletion in parts of northeastern South America, and a muted hydroclimate response over the Maritime Continent.

We decompose the simulated precipitation  $\delta^{18}\text{O}$  response to identify the mechanisms driving these isotopic anomalies in the tropics, finding that changes in amount-weighted  $\delta^{18}\text{O}_p$  arise primarily from seasonal changes in the isotopic composition of precipitation rather than changes in precipitation seasonality. However, the mechanisms of the isotope anomalies vary regionally, with the local amount effect dominant in northeastern South America and the northeastern tropical Pacific; while changes in moisture source, circulation patterns, and/or upstream rainout control the response in East Asia; and the addition of isotopically depleted meltwater to the North Atlantic directly contributes to reduced, but substantially depleted, wet season precipitation through the Caribbean. Overall, this study provides new insights into the tropical hydroclimate response to the 8.2 ka Event, emphasizing the importance of accounting for age uncertainty in proxy-based hydroclimate reconstructions and the value of using isotope-enabled model simulations for data-model intercomparison.

**Abstract.** The 8.2ka Event, a prominent climate anomaly that occurred approximately 8,200 years before present (8.2ka), has been the subject of extensive research due to its potential implications for understanding the characteristics and mechanisms of abrupt climate change events. We characterize the tropical hydroclimate response to the 8.2ka Event based on a multiproxy compilation of 61 tropical hydroclimate records and assess the consistency between the reconstructed hydroclimate changes and those simulated by a new isotope-enabled climate model simulation of the 8.2ka Event with iCESM. The timing and duration of the hydroclimate anomalies is calculated using two event detection methods, one of which uses a new changepoint detection algorithm to account for age uncertainty. When age uncertainties are explicitly accounted for, significant hydroclimate anomalies associated with the 8.2ka Event are detected in 30% of the records in the compilation, with a mean onset age of  $8.28 \pm 0.12\text{ ka}$  ( $1\sigma$ ), mean termination age of  $8.11 \pm 0.09\text{ ka}$  ( $1\sigma$ ), and mean duration of  $152 \pm 70$  years ( $1\sigma$ ; with a range of 50–289 years), comparing well with previous estimates, and lending support to a regionally variable tropical hydroclimate response to the 8.2ka Event, with events that span decadal to multi-centennial timescales in the proxy record. Notably, the hydroclimate anomalies are not hemispherically uniform, but rather display rich regional structure. Anomalous conditions are characterized by pronounced isotopic enrichment across East Asia, South Asia, and the Arabian Peninsula. In the Americas, drying and isotopic enrichment occurred in southern Central America, contrasting with isotopic depletion in central/eastern Brazil. In contrast, no robust signatures of the 8.2ka Event were found over the Maritime Continent. Many of these regional patterns generally agree with the new set of iCESM simulations of the 8.2ka Event. In iCESM, the North Atlantic meltwater forcing leads to a broad southward shift in tropical rainfall, resulting in a generally drier Northern Hemisphere and wetter Southern Hemisphere, but with large regional variations in precipitation amount and the isotopic composition of precipitation. Over the oceans, the precipitation  $\delta^{18}\text{O}$  anomalies are generally consistent with the "amount effect", wherein areas characterized by drying have more isotopically enriched precipitation and areas of wetting have more isotopically depleted precipitation. However, the precipitation  $\delta^{18}\text{O}$  anomalies are more decoupled from changes in precipitation amount over land. iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large scale isotopic enrichment pattern in precipitation  $\delta^{18}\text{O}$  in South and East Asia and the Arabian Peninsula, drying and isotopic enrichment in precipitation  $\delta^{18}\text{O}$  in southern Central America, isotopic depletion in

parts of northeastern South America, and a muted hydroclimate response in the Maritime Continent. Overall, this study  
65 provides new insights into the tropical hydroclimate response to the 8.2ka Event, emphasizing the importance of accounting  
for age uncertainty in the hydroclimate reconstructions and the value of using isotope-enabled model simulations for data-  
model intercomparison.

Abstract. The 8.2ka Event, a prominent climate anomaly that occurred approximately 8,200 years before present  
(8.2ka), has been the subject of extensive research due to its potential implications for understanding the  
70 characteristics and mechanisms of abrupt climate change events. We characterize the tropical hydroclimate response  
to the 8.2ka Event based on a multiproxy compilation of 61 tropical hydroclimate records and assess the consistency  
75 between the reconstructed hydroclimate changes and those simulated by a new isotope-enabled climate model  
simulation of the 8.2ka Event with iCESM. The timing and duration of the hydroclimate anomalies is calculated using  
two event detection methods, one of which uses a new changepoint detection algorithm to account for age  
80 uncertainty. When age uncertainties are explicitly accounted for, significant hydroclimate anomalies associated with  
the 8.2ka Event are detected in 30% of the records in the compilation, with a mean onset age of  $8.28 \pm 0.12$  ka (1 $\sigma$ ),  
mean termination age of  $8.11 \pm 0.09$  ka (1 $\sigma$ ), and mean duration of  $152 \pm 70$  years (1 $\sigma$ ; with a range of 50–289 years),  
85 comparing well with previous estimates, and lending support to a regionally variable tropical hydroclimate response  
to the 8.2ka Event, with events that span decadal to multi-centennial timescales in the proxy record. Notably, the  
hydroclimate anomalies are not hemispherically uniform, but rather display rich regional structure. Anomalous  
90 conditions are characterized by pronounced isotopic enrichment across East Asia, South Asia, and the Arabian  
Peninsula. In the Americas, drying and isotopic enrichment occurred in southern Central America, contrasting with  
isotopic depletion in central/eastern Brazil. In contrast, no robust signatures of the 8.2ka Event were found over the  
Maritime Continent. Many of these regional patterns generally agree with the new set of iCESM simulations of the  
95 8.2ka Event. In iCESM, the North Atlantic meltwater forcing leads to a broad southward shift in tropical rainfall,  
resulting in a generally drier Northern Hemisphere and wetter Southern Hemisphere, but with large regional  
variations in precipitation amount and the isotopic composition of precipitation. Over the oceans, the precipitation  
 $\delta^{18}\text{O}$  anomalies are generally consistent with the "amount effect", wherein areas characterized by drying have more  
isotopically enriched precipitation and areas of wetting have more isotopically depleted precipitation. However, the  
99 precipitation  $\delta^{18}\text{O}$  anomalies are more decoupled from changes in precipitation amount over land. iCESM captures  
many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic  
enrichment pattern in precipitation  $\delta^{18}\text{O}$  in South and East Asia and the Arabian Peninsula, drying and isotopic  
enrichment in precipitation  $\delta^{18}\text{O}$  in southern Central America, isotopic depletion in parts of northeastern South  
America, and a muted hydroclimate response in the Maritime Continent. Overall, this study provides new insights  
into the tropical hydroclimate response to the 8.2ka Event, emphasizing the importance of accounting for age  
uncertainty in the hydroclimate reconstructions and the value of using isotope-enabled model simulations for data-  
model intercomparison.

## 1 Introduction

The tropics play a fundamental role in Earth's climate variability, acting as a heat source that drives global weather  
100 patterns via complex atmospheric teleconnections. A key component of the tropical climate system is the Intertropical  
Convergence Zone (ITCZ). From a zonal mean perspective, the ITCZ represents the ascending branch of the Hadley cell,  
and is characterized by converging the convergence of the convergence of low-level trade winds, ascent, and heavy  
precipitation near the equator. Regionally On a regional basis On a regional basis, ITCZs exist over the Atlantic and eastern

105 | Pacific Ocean, where strong ~~strong~~ sea surface temperature (SST) gradients drive convergence, ascent, and narrow, well-defined rainbands. Distinct processes govern the large-scale circulation and precipitation in other regions of the tropics like monsoon systems and the Indian Ocean. Throughout the tropics, rainfall patterns migrate on a seasonal basis, following the warmer hemisphere. The migrations are regionally variable, with the Atlantic and Pacific ITCZs migrating between 9°N and 2°N in boreal summer/fall and winter/spring, respectively, while rainfall over the Indian Ocean and adjacent land masses swings more dramatically between 20°N and 8°S (Schneider et al., 2014). These fluctuations drive distinct wet and dry 110 | seasons through many regions of the tropics, providing critical access to water for roughly 40% of Earth's population ([State of the Tropics](#)~~Penny~~[Penny](#), 2021). As the tropics comprise some of the most densely populated areas on Earth, it is ~~essential~~[critical](#)~~critical~~ to understand how tropical precipitation patterns may change in the near future. However, there is currently no agreement across models on how the ITCZ and monsoons will change with continued greenhouse gas forcing 115 | (Biasutti et al., 2018; Geen et al., 2020), in part due to persistent biases in the representation of the tropical mean state in global climate models (Li & Xie, 2014). Therefore, improving our understanding of how tropical rainfall patterns respond to external forcing is a ~~key~~[critical](#)~~critical~~ target in the climate modeling community.

120 | ~~Our ability to make robust predictions about the climate system is also limited by the relatively short instrumental record. Paleoclimate proxy records extend the observational record beyond the instrumental era, helping to illuminate the linkages between climate forcings and the response of the climate system to forcing. Such data are critical for ground-truthing climate models to observations outside of the short period of direct observational data.~~

130 | ~~Our ability to make robust predictions about the climate system is also limited by the relatively short instrumental record. Paleoclimate proxy records extend the observational record beyond the instrumental era, illuminating the linkages between climate forcings and the response of the climate system. Such data are crucial for ground-truthing climate models to observations outside of the short period of direct observational data. Examining past periods of abrupt — Past periods of abrupt climate change are especially important to examine in the context of evaluating future — Past periods of abrupt climate change are especially important to examine in the context of evaluating future climate change also provides important context for evaluating future climate risk, as we lack modern analogues of have no modern analogue with which to compare have no modern analogue with which to compare these events and cannot preclude the occurrence we cannot rule out the possibility we cannot rule out the possibility of such abrupt events in the future. Evidence from paleoclimate records (Arbuszewski et al., 2013; Koutavas & Lynch-Stieglitz, 2004; Rhodes et al., 2015) and model simulations of past climates (Chiang & Bitz, 2005; Roberts and Hopcroft, 2020) suggest that the location of the tropical rain bands may have shifted significantly and abruptly in the past (upwards of 7° latitude in certain regions) associated with changes in ice sheet~~

extent and meltwater forcing (e.g., during Heinrich Events). The most recent such period of rapid, global climate reorganization occurred approximately 8,200 years before present day (the 8.2 ka 2ka 2ka Event; Alley et al., 1997) and is thought to have lasted over a period of 100 to 200 years based on oxygen isotopic data from Greenland ice cores and tropical speleothems (Morrill et al., 2013). This event period occurred during the otherwise stable Holocene epoch (11,700 years ago to present) and is thought to have been driven by the discharge of ~1.63×105 km<sup>3</sup> of meltwater from proglacial Lakes Ojibway and Agassiz (remnants of the Laurentide Ice Sheet) into the North Atlantic, triggering which triggered which triggered a large-scale salinity anomaly and resultant reduction in the strength of the Atlantic Meridional Overturning Circulation (AMOC; e.g., Barber et al., 1999; Ellison et al., 2006). The precise source, routing, and strength of the freshwater perturbation are still under discussion (e.g. Törnqvist and Hijma, 2012), ranging from an upper limit of 27.1×105 km<sup>3</sup> of freshwater released from the retreating Laurentide Ice Sheet (LIS) between 9 ka and 8 ka (Peltier 2004), to a smaller but more abrupt discharge of 5.3×105 km<sup>3</sup> between 8.31 ka and 8.18 ka (Li et al., 2012). Recent data-model comparisons from Aguiar et al. (2021) suggest that an additional 8.2×105 km<sup>3</sup> of freshwater may have flowed into the Labrador Sea after the collapse of the Hudson Bay due to the routing of river discharge over the western Canadian Plains (Carlson et al., 2009). Proxy data and dynamical theory (e.g., Kang et al., 2008; Kang et al., 2009; Schneider et al., 2014) link this event to widespread cooling of the Northern Hemisphere (1 to -6°C; e.g., Ellison et al., 2006; Kobashi et al., 2007) and an associated southward shift of tropical rainfall patterns, with hydroclimate anomalies lasting anywhere from decades to centuries (e.g., Rohling and Palike, 2005; Morrill et al., 2013).

Morrill et al. (2013) published the most recent multiproxy compilation of high-resolution paleoclimate data related to the 8.2 ka 2ka 2ka Event, incorporating 262 paleoclimate records from 114 global sites. Their synthesis demonstrated a regionally variable hydroclimate response to the 8.2 ka Event characterized by 2ka Event. Some of the robust regional hydroclimate changes included 2ka Event. Some of the robust regional hydroclimate changes included drying in Greenland, the Mediterranean, the Maritime Continent (Ayliffe et al., 2013; Chawchai et al., 2021), and across Asia (Wang et al., 2005; Dykoski et al., 2005; Cheng et al., 2009; Liu et al., 2013); while wetter conditions prevailed over northern Europe, Madagascar (Voarintsoa et al., 2019), and northeastern South America (Aguiar et al., 2020). Together, these data provide evidence for an anti-phased hemispheric precipitation response, with a strengthening of the South American summer monsoon (SASM), and a weakening of the Asian (AM) and East Asian summer monsoons (EASM).

Building on this work, Parker and Harrison (2022) used a statistical technique called breakpoint analysis to identify the timing, duration, and magnitude of the 8.2 ka 2ka 2ka Event in 73 high-resolution, globally distributed speleothem  $\delta^{18}\text{O}$  records from the Speleothem Isotope Synthesis and Analysis database (SISALv2; Comas-Bru et al., 2020). They identified significant isotopic excursions near 8.2 ka 2ka 2ka in over 70% of their records and determined a median duration of global hydroclimate anomalies of approximately 159 years. Parker and Harrison (2022) inferred several regionally coherent tropical hydroclimate anomalies from their synthesis, based on broad patterns of isotopic depletion

170 across South America and southern Africa and isotopic enrichment in Asia, from which they inferred a weakening of Northern Hemisphere monsoons, strengthening of Southern Hemisphere monsoons, and a mean southward shift of the ITCZ as the most plausible mechanism for transmitting the effects of the 8.2 ka Event throughout the tropics.

175 There are several limitations to these studies which are addressed in the updated proxy compilation presented here. Chiefly, Morrill et al. (2013) rely upon an a priori event window in classifying the climate response to the 8.2 ka Event, and do not take radiometric age uncertainty of the proxy records into account. While Parker and Harrison (2022) consider the effects of age uncertainties on their compilation, they did not propagate these uncertainties through their breakpoint analyses. ~~Neither study includes comparisons with isotope-enabled climate model simulations, a critical tool for validating proxy record interpretations. Neither study includes comparisons with isotope-enabled climate model simulations, a critical tool for validating proxy record interpretations.~~ Further, tropical records 180 comprise less than half of each compilation and since the publication of those studies, many new records have been generated in data-sparse regions that are key to understanding the complexities of tropical precipitation variability. Finally, recent studies (e.g., Atwood et al., 2020) have demonstrated significant regional variability in the tropical precipitation response to a variety of forcings, including North Atlantic meltwater events, calling into question the usefulness of invoking a southward shift in the zonal mean ITCZ as the primary mechanism driving hydroclimate changes in response to the 8.2 185 ka Event, as invoked in the reconstructions of Morrill et al. (2013) and Parker and Harrison (2022).

190 This study seeks to provide new insights into the tropical hydroclimate response to the 8.2 ka Event, by compiling an updated set of hydroclimate-sensitive proxy records complete with age model uncertainty and integrating them with new statistical tools to quantitatively evaluate how tropical rainfall patterns responded to this period of abrupt global climate change. We further assess how well the proxy reconstructions compare to a new isotope-enabled model simulation of the 8.2 ka Event. ~~Such model simulations provide dynamical context to the sparse proxy data and, by tracking water isotopes through the hydrologic cycle, enable more direct comparisons between proxy and model data than conventional climate models. Such data-model comparisons facilitate improved~~ ~~In doing so, we hope to improve our~~ ~~In doing so, we hope to improve our~~ ~~understanding of the tropical hydroclimate response to abrupt AMOC disruptions and provide a necessary critical benchmark for climate models that are used in projections of future climate change.~~

## 195 2 Methods

### 2.1 Synthesis of ~~published datasets~~ ~~Published Datasets~~ ~~Published Datasets~~

200 To assess the tropical hydroclimate response to the 8.2 ka Event, we developed an updated compilation of published, high-resolution, continuous, ~~and~~ well-dated proxy datasets. ~~We collated records spanning 7 ka-10 ka, covering~~ ~~collating records that span the period 7ka-10ka, cover~~ ~~collating records that span the period 7ka-10ka, cover~~ latitudes from 30°N to 30°S, and which are sensitive to some aspect of hydroclimate variability. Records were

identified through an in-depth literature review, searches of public data repositories (e.g., the NOAA National Centers for Environmental Information and World Data Center PANGAEA databases), and incorporation of previous compilations (e.g., Morrill et al., 2013). All records were reformatted into the Linked Paleo Data framework (LiPD; McKay and Emile-Geay, 2016) to facilitate analyses of age uncertainty and quantitative event detection.

To constrain the timing and duration of the abrupt hydroclimate anomaly associated with the 8.2 ka Event, the datasets in this compilation were screened to meet the following criteria: (i) data resolution of 50 years or better over the period of 7 ka-10 ka; (ii) based on hydroclimate-sensitive proxy data interpreted by authors as reflecting precipitation amount or intensity, the isotopic compositions of environmental water (including precipitation, lake water, and seawater), effective moisture, lake level, fluvial discharge, or sea surface salinity (SSS); and (iii) contain at least three radiometric dates over the 7 ka-10 ka interval. Emphasis was placed on collecting water isotope-based records to enable more direct comparison with isotope-enabled climate model simulations.

The compilation was organized into three categories based on the climate interpretation of the various proxy records (Fig. 1): proxies which reflect the isotopic composition of precipitation ( $P_{iso}$ ), proxies which reflect effective moisture (EM; P-E), and proxies which reflect precipitation amount and/or intensity ( $P_{amt}$ ). This categorization scheme enables more robust interpretations of the proxy records and facilitates data-model comparison as our understanding of water isotopes and their manifestations in paleoclimate archives continues to advance (Konecky et al., 2020).

## 2.2 Age model development

Published radiometric age data were used to develop age-depth model ensembles for each dataset using Bayesian methods. Where available (Table A1), we employed the age ensembles developed by the Past Global Changes (PAGES) Speleothem Isotope Synthesis and Analysis (SISAL) working group version 2 of their database (Comas-Bru et al., 2020). For records for which these age ensembles were not available due to lack of inclusion in the SISALv2 database or comprising a lacustrine or marine sediment archive, we developed age-depth models using the geoChronR package in R version 4.2.1 (McKay et al., 2021).

All radiometric dates were obtained from the original publications and screened for updated age data where available. For records originating from the Northern Hemisphere tropics, radiometric dates were calibrated using the Northern Hemisphere calibration curve, IntCal20. Dates of records originating from the Southern Hemisphere tropics were calibrated using the Southern Hemisphere calibration curve, SHCal20. For each record, 1000 age-depth model iterations were run to generate a Markov Chain Monte Carlo (MCMC) age ensemble, which produces median age values and quantile age ranges, enabling the propagation of age-model uncertainties through subsequent analyses.

In order to reduce uncertainty arising from the differences in age modeling algorithms offered through geoChronR, we prioritized the use of BACON (Blaauw and Christen, 2011) across our records, including those in the SISALv2 database,

where available. If a BACON age ensemble was not constructed for a SISALv2 dataset, we employed the Behron (Haslett and Parnell, 2008) or copRA (Breitenbach et al., 2012) ensembles instead.

235 In order to reduce uncertainty arising from the differences in age modeling algorithms offered through geoChronR, we prioritized the use of BACON (Blaauw and Christen, 2011) across our records, including those in the SISALv2 database, where available. If a BACON age ensemble was not constructed for a SISALv2 dataset, we employed the Behron (Haslett and Parnell, 2008) or copRA (Breitenbach et al., 2012) ensembles instead.

240 To reduce uncertainty arising from the differences in age modeling algorithms offered through geoChronR, we prioritized the use of BACON (Blaauw and Christen, 2011) across our records, including those in the SISALv2 database, where available. If a BACON age ensemble was not constructed for a SISALv2 dataset, we employed the Behron (Haslett and Parnell, 2008) or copRA (Breitenbach et al., 2012) ensembles instead.

## 2.3 Detection of the 8.2 ka Event

245 Two event detection methods were used in this study, as detailed below. The start, end, and duration of the hydroclimate anomalies associated with the 8.2 ka Event were calculated for all records where both methods detected in which in which events of the same sign were detected in both event detection methods were detected in both event detection methods. This was done to leverage the strengths of each detection method and provide a more robust reconstruction of the hydroclimate response to the 8.2 ka Event.

### 2.3.1 Modified Morrill methodMethodMethod

250 For each record's published time series, we applied apply apply a modified version of the event detection methods described in Morrill et al. (2013) as a control for comparison with to compare against to compare against our actR results (hereafter referred to as MM; Fig. B1). Using 7.4 ka-7.9 ka the period from 7.4ka to 7.9ka the period from 7.4ka to 7.9ka as a reference period, we calculate the mean and the standard deviation over that interval. Then From there, we define the upper and lower bounds by the two-sigma level. We repeat this process for a second reference period from 8.5 ka-9.0 ka 5ka to 9.0ka 5ka to 9.0ka. We take the final upper and lower bounds as the most extreme values between the two reference periods. Then we use the 7.9 ka-8.5 ka-8.5ka-8.5ka period as the 8.2 ka 2ka 2ka Event detection window.

255 Over this period, any values which exceed the upper or lower bound are marked as the 8.2 ka 2ka 2ka Event, with the timing of the event defined by the ages of the proxy values that exceed those bounds. For In order for In order for an excursion to be considered part of the 8.2 ka 2ka 2ka Event, the excursions must last at least 10 years. If multiple events are detected within the 7.9 ka-8.5 ka-8.5ka-8.5ka window, they are combined into a single event if there are no more than three data points, or thirty years, separating the different excursions. This modification is necessary to account for the varying sampling resolutions present within and between several of the records in our compilation. If multiple events of differing signs are detected within the 8.2 ka 2ka 2ka Event window, the event with the largest z-score is chosen as the

representative hydroclimate response. The magnitude of the event is defined by the largest absolute value z-score within the  
265 event detection period.

—The MM method differs from the methodology presented in Morrill et al. (2013) in two additional aspects: (i) we do not perform the "leave one out" standard deviation calculation that Morrill et al. (2013) employed to account for noisy data and outliers in each reference window, and (ii), while Morrill et al. (2013) use a moving two-tailed z-test to define the duration of their detected events, we consider only the time between the initial and final anomalous data point in our  
270 calculation. We elected to simplify this method as it is primarily intended to supplement results using our actR methodology.

### 2.3.2 actR methodMethodMethod

—A second event detection method was used to account for age model uncertainties in the proxy records. Past studies (e.g., Morrill et al., 2013) ~~of the 8.2ka Event~~ employed statistical techniques to detect excursions in ~~the~~ proxy records using the ana priori assumption that the North Atlantic meltwater perturbation propagated globally at exactly 8.2 ka 2ka 2ka and lasted no more than 200 years. To better constrain the timing, duration, and magnitude of the 8.2 ka 2ka 2ka Event in this study, we employed an event detection algorithm based on the changepoint package in the newly developed Abrupt Change Toolkit in R (actR; McKay and Emile-Geay, 2022). This algorithm detects abrupt shifts in the mean of a time series based on a prescribed number of age model ensembles (generated in geoChronR), the minimum length of a segment (in years) over which mean shifts in the time series are detected, and and a user-defined  
275 changepoint detection method, and a and and weighting penalty function (Fig. 2). ...A minimum segment length of 50 or  
280 100 years was assigned for each record in the proxy compilation to minimize short-lived transitions in the noisy proxy records, with the assumption that the 8.2 ka 2ka 2ka Event signal in each of the records lasts at least 50 years. For all but one  
record in our compilation, the 100-year minimum segment length optimally captured the major shifts in the data sets while  
minimizing the

285 ~~Detected changepoints were summarized over 10-year long windows. The Pruned Exact Linear Time (PELT; Killieck et al., 2012) changepoint detection method was chosen for its computational efficiency and dynamic programming approach to accurately identify the location and number of changepoints in time series data. The Modified Bayesian Information Criterion (MBIC; Zhang and Siegmund, 2007) was chosen as the penalty weighting function to balance the goodness of fit of the model to the data with the complexity of the model and the number of changepoints. These methods effectively minimize the~~

290 ~~Detected changepoints were summarized over 10-year long windows. The Pruned Exact Linear Time (PELT; Killieck et al., 2012) changepoint detection method was chosen for its computational efficiency and dynamic programming approach to accurately identify the location and number of changepoints in time series data. The Modified Bayesian Information Criterion (MBIC; Zhang and Siegmund, 2007) was chosen as the penalty weighting function to balance the goodness of fit of the model to the data with the complexity of the model and the number of changepoints. These methods~~

effectively minimize the detection of spurious short-lived shifts. The exception was the speleothem record of Cheng et al. (2009; PAD07; Fig. C5), for which it was necessary to reduce the minimum segment length to 50 years to capture the clear isotopic depletion near 8.2 ka that was otherwise missed. Each time series ensemble was tested against a robust null hypothesis using surrogate proxy data generated by an isospectral noise model. By construction, the surrogate data have the same power spectrum as the original data, but phase scrambling destroys any autocorrelation that was present in the original time series. If autocorrelation is detected in a segment of the original time series ensemble, it fails the null hypothesis test, and any changepoint detected within that segment is excluded from the result. This test helps to ensure that the detected changepoints are statistically significant and not just the result of random variation. Both age and proxy data uncertainties are propagated through each ensemble, improving the robustness of the result. For each record, 1000 age model ensembles were generated and tested against 100 surrogate time series changepoints within each ensemble. Each time series ensemble was tested against a robust null hypothesis using surrogate proxy data generated by an isospectral noise model. By construction, the surrogate data have the same power spectrum as the original data, but phase scrambling destroys any autocorrelation that was present in the original time series. If autocorrelation is detected in a segment of the original time series ensemble, it fails the null hypothesis test, and any changepoint detected within that segment is excluded from the result. This test helps to ensure that the detected changepoints are statistically significant and not just the result of random variation. Both age and proxy data uncertainties are propagated through each ensemble, improving the robustness of the result. For each record, 1000 age model ensembles were generated and tested against 100 surrogate time series.

Detected changepoints were summarized over 10-year-long windows. The Pruned Exact Linear Time (PELT; Killick et al., 2012) changepoint detection method was chosen for its computational efficiency and dynamic programming approach to accurately identify the location and number of changepoints in time series data. The Modified Bayesian Information Criterion (MBIC; Zhang and Siegmund, 2007) was chosen as the penalty weighting function to balance the goodness of fit of the model to the data with the complexity of the model and the number of changepoints. These methods effectively minimize the detection of spurious changepoints within each ensemble. Each time series ensemble was tested against a robust null hypothesis using surrogate proxy data generated by an isospectral noise model. By construction, the surrogate data have the same power spectrum as the original data, but phase scrambling destroys any autocorrelation that was present in the original time series. If autocorrelation is detected in a segment of the original time series ensemble, it fails the null hypothesis test, and any changepoint detected within that segment is excluded from the result. This test helps to ensure that the detected changepoints are statistically significant and not just the result of random variation. Both age and proxy data uncertainties are propagated through each ensemble, improving the robustness of the result. For each record, 1000 age model ensembles were generated and tested against 100 surrogate time series.

The actR event detection algorithm can be compromised by variable sampling resolution. Therefore, for records with highly variable resolution, we used the MM method to determine event onset, termination, and duration. This applies to

only two records: the speleothem record from Dykoski et al. (2005; D4Dykoski, Fig. C7) and the speleothem record from Neff et al. (2001; H5; Fig. C10).

330 Two types of events were characterized based on the actR results. 'Significant events' are defined by the presence of two consecutive changepoints with  $p < 0.05$  over the 7.9 ~~ka-8.3 ka -8.3ka-8.3ka~~-window ("start" and "end"). If more than two consecutive changepoints exist over that window, the two with the lowest p-values and highest probability are used. The difference between "start" and "end" dates is used to calculate event duration, which we assume to be ~~between a minimum of 20 and a maximum of no greater than no greater than~~ 300 years. The magnitude of "events" is 335 determined by the greatest absolute value z-score in each record's median age ensemble time series between the actR-derived "start" and "end" dates, with interpretation based on the sign of the z-score corresponding to the interpretation direction of the original authors. 'Tentative events' are defined by the presence of two consecutive changepoints with  $p < 0.1$  over ~~an extended 7.7 ka-8.5 ka window~~~~the 7.7-8.5ka window ("start" and "end")~~~~the 7.7-8.5ka window ("start" and "end")~~. Events lasting more than ~~~~~300 years are removed from consideration. If more than two events are detected within that window, the 340 event with the start date closer to ~~8.2 ka 2ka 2ka~~ is chosen as the final ~~8.2 ka Event~~~~2ka event~~~~2ka event~~.

## 2.4 iCESM ~~simulations~~~~Simulations~~~~Simulations~~

345 The National Center for Atmospheric Research's (NCAR) water isotope-enabled Community Earth System Model (iCESM1.2; Brady et al., 2019) is a state-of-the-art, fully ~~—~~-coupled GCM designed to simulate water isotopes across all stages of the global hydroclimate cycle. It employs the CAM5.3 atmospheric model, with a gridded resolution of  $1.9^\circ$  latitude x  $2.5^\circ$  longitude and 29 vertical levels. Land processes are modeled by CLM4, at the same nominal  $2^\circ$  resolution. CLM is coupled to a River Transport Model which routes runoff from the land into oceans and/or marginal seas. Both the POP2 ocean model and the CICE sea ice model have a common grid size of 320 x 384 with a nominal  $1^\circ$  resolution near the equator and in the North Atlantic. While iCESM faithfully captures the broad quantitative and qualitative features of precipitation isotopes, it is known to have a global bias toward depleted precipitation  $\delta^{18}\text{O}$  ( ~~$\delta^{18}\text{O}_\text{p}$~~ ; 350 median bias of -2.5%; Brady et al., 2019).

355 We performed a new ~~8.2 ka 2ka 2ka~~ Event meltwater-forced ("hosing") simulation and an early Holocene control simulation ("ctrl") using iCESM1.2. iCESM enables explicit tracking of water isotopes throughout the global water cycle, facilitating quantitative comparisons between model output and water isotope-based proxy records. These simulations ~~were based on the freshwater forcing scenario recommended by Otto-Bliesner et al. (2017) for their proposed~~  
~~were based on the freshwater forcing scenario recommended by Otto-Bliesner et al. (2017) for their proposed~~ Paleoclimate Modeling Intercomparison Project 4-Coupled Model Intercomparison Project 6 (PMIP4-CMIP6) ~~8.2 ka simulation parameters~~  
~~(2ka simulation. The climate of the early Holocene is characterized by different orbital configurations, including a larger obliquity and slightly higher eccentricity than present day. In addition, precession resulted in increased seasonality of insolation in the Northern Hemisphere, with greatest insolation receipt in boreal summer (Wu et al., 2018; Hu et al.,~~

360 2019). These factors produced warmer Northern Hemisphere summers, especially in mid to high latitudes, which are thought to have promoted the retreat of the remnant Laurentide Ice Sheet (LIS) (2ka simulation. The climate of the early Holocene is characterized by different orbital configurations, including a larger obliquity and slightly higher eccentricity than present day. In addition, precession resulted in increased seasonality of insolation in the Northern Hemisphere, with greatest insolation receipt in boreal summer (Wu et al., 2018; Hu et al., 2019). These factors produced warmer Northern Hemisphere summers, especially in mid to high latitudes, which are thought to have promoted the retreat of the remnant Laurentide Ice Sheet (LIS) (Otto-Bliesner et al., 2017), with two exceptions: (1) the freshwater flux (and references therein).  
365  
370 To simulate early Holocene climate, the model was forced with prescribed greenhouse gas concentrations ( $\text{CH}_4 = 658.5 \text{ ppb}$ ,  $\text{CO}_2 = 260.2 \text{ ppm}$ , and  $\text{N}_2\text{O} = 255 \text{ ppb}$ ), orbital configurations (eccentricity =  $0.019524^\circ$ , obliquity =  $24.2030^\circ$ , and longitude of perihelion =  $99.228^\circ$ ), and a reconstruction of the ice sheet extent (Peltier et al., 2015) representative of conditions at 9ka. A control simulation (“ctrl”) was initialized from an earlier 400-year long 9ka simulation and was run for 100 model years using these parameters. The 8.2ka Event simulation (“hose”) was branched from year 100 of this control run. Initially, a simulated 2.5Sv meltwater flux (meltwater  $\delta^{18}\text{O} = -30\text{\textperthousand}$ ; Zhu et al., 2017) (and references therein).  
375 To simulate early Holocene climate, the model was forced with prescribed greenhouse gas concentrations ( $\text{CH}_4 = 658.5 \text{ ppb}$ ,  $\text{CO}_2 = 260.2 \text{ ppm}$ , and  $\text{N}_2\text{O} = 255 \text{ ppb}$ ), orbital configurations (eccentricity =  $0.019524^\circ$ , obliquity =  $24.2030^\circ$ , and longitude of perihelion =  $99.228^\circ$ ), and a reconstruction of the ice sheet extent (Peltier et al., 2015) representative of conditions at 9ka. A control simulation (“ctrl”) was initialized from an earlier 400-year long 9ka simulation and was run for 100 model years using these parameters. The 8.2ka Event simulation (“hose”) was branched from year 100 of this control run. Initially, a simulated 2.5Sv meltwater flux (meltwater  $\delta^{18}\text{O} = -30\text{\textperthousand}$ ; Zhu et al., 2017) was applied across the entire northern North Atlantic (in our simulations (instead of just in the Labrador Sea as in PMIP4) in order to limit the sensitivity 380 of the subsequent AMOC and climate response to poorly resolved deepwater formation regions in the model, and (2) our hosing experiment branches from 9 ka boundary conditions (instead of 9.5 ka as in PMIP4), and thus uses slightly different orbital and GHG configurations from PMIP4. However, the impact of these marginally different boundary conditions is expected to be minimal (50–70°N) for 1 year, followed by 0.13Sv flux for 99 years to approximate the abrupt drainage 385 of Lakes Agassiz and Ojibway and eventual collapse of the LIS at Hudson Bay (Otto-Bliesner et al., 2017). Monthly surface air temperature, precipitation amount, and precipitation  $\delta^{18}\text{O}$  variables were extracted from each simulation for analysis. To isolate the global response to the simulated 8.2ka Event in the model, yearly time series of temperature (°C), precipitation amount (mm/day) and precipitation amount weighted precipitation  $\delta^{18}\text{O}$  (‰) were obtained. Anomalies for each variable 390 were calculated by subtracting the final 50 years of the “ctrl” simulation from the final 50 years of the “hose” simulation (50–70°N) for 1 year, followed by 0.13Sv flux for 99 years to approximate the abrupt drainage of Lakes Agassiz and Ojibway and eventual collapse of the LIS at Hudson Bay (Otto-Bliesner et al., 2017). Monthly surface air temperature, precipitation amount, and precipitation  $\delta^{18}\text{O}$  variables were extracted from each simulation for analysis. To isolate the global response to the simulated 8.2ka Event in the model, yearly time series of temperature (°C), precipitation

amount (mm/day) and precipitation amount-weighted precipitation  $\delta^{18}\text{O}$  (‰) were obtained. Anomalies for each variable were calculated by subtracting the final 50 years of the “ctrl” simulation from the final 50 years of the “hose” simulation.

395 For the 9 ka control simulation, the model was forced with prescribed greenhouse gas concentrations ( $\text{CH}_4 = 658.5$  ppb,  $\text{CO}_2 = 260.2$  ppm, and  $\text{N}_2\text{O} = 255$  ppb), orbital configurations (eccentricity = 0.019524°, obliquity = 24.2030°, and longitude of perihelion = 99.228°), and a reconstruction of the ice sheet extent (Peltier et al., 2015) representative of conditions at 9 ka. The orbital configuration is characterized by larger obliquity, slightly higher eccentricity, and a change in the longitude of perihelion relative to present day that resulted in increased seasonality of insolation in the Northern 400 Hemisphere (Wu et al., 2018; Hu et al., 2019). These factors produced warmer Northern Hemisphere summers, especially in mid to high latitudes, which promoted the retreat of the remnant Laurentide Ice Sheet (LIS) (Otto-Bliesner et al., 2017 and references therein). The control simulation (“ctrl”) was initialized from an earlier 400-year-long 9 ka simulation and run for 100 model years using these parameters.

405 The 8.2 ka Event simulation (“hose”) was branched from year 100 of the 9 ka control run. Initially, a simulated 2.5Sv meltwater flux (meltwater  $\delta^{18}\text{O} = -30\text{\textperthousand}$ ; Zhu et al., 2017) was applied across the northern North Atlantic Ocean (50–70°N) for 1 year, followed by 0.13Sv flux for 99 years to approximate the abrupt drainage of Lakes Agassiz and Ojibway and eventual collapse of the LIS at Hudson Bay (Otto-Bliesner et al., 2017). Monthly surface air temperature, precipitation 410 amount, and  $\delta^{18}\text{O}_p$  variables were extracted from each simulation for analysis. To isolate the global response to the simulated 8.2 ka Event, yearly time series of temperature (°C), precipitation amount (mm d<sup>-1</sup>), and amount-weighted  $\delta^{18}\text{O}_p$  (‰) were obtained. Anomalies for each variable were calculated by subtracting the final 50 years of the “ctrl” simulation from the final 50 years of the “hose” simulation.

## 2.5 Decomposition of changes in precipitation $\delta^{18}\text{O}$

We decomposed the changes in amount-weighted  $\delta^{18}\text{O}_p$  following Liu and Battisti (2015) to assess whether the changes arise 415 from variations in the monthly isotopic composition of precipitation or changes in the seasonality of precipitation (i.e., changes in monthly precipitation amount). The difference in amount-weighted  $\delta^{18}\text{O}_p$  between the hosing and control simulations is:

$$\delta \square_{p,hose} - \delta \square_{p,ctrl} = \frac{\sum_j \delta \square_{j,hose} P_{j,hose}}{\sum_j P_{j,hose}} - \frac{\sum_j \delta \square_{j,ctrl} P_{j,ctrl}}{\sum_j P_{j,ctrl}}, \quad (1)$$

where  $\delta^{18}\text{O}_j$  is the monthly isotopic composition of precipitation and  $P_j$  is the monthly precipitation rate (in mm day<sup>-1</sup>). The importance of changes in precipitation seasonality to changes in  $\delta^{18}\text{O}_p$  is then given by:

$$420 \quad \frac{\sum_j \delta \square_{j,ctrl} P_{j,hose}}{\sum_j P_{j,hose}} - \frac{\sum_j \delta \square_{j,ctrl} P_{j,ctrl}}{\sum_j P_{j,ctrl}}. \quad (2)$$

and the importance of changes in the monthly isotopic composition of precipitation to changes in total  $\delta^{18}\text{O}_p$  is given by:

$$425 \quad \frac{\sum_j \delta \square_{j,hose} P_{j,ctrl}}{\sum_j P_{j,ctrl}} - \frac{\sum_j \delta \square_{j,ctrl} P_{j,ctrl}}{\sum_j P_{j,ctrl}}. \quad (3)$$

Note that Eqs. (2) and (3) do not sum to the total change in  $\delta^{18}\text{O}_p$  due to nonlinearity in the definition of  $\delta^{18}\text{O}_p$ .

### 3 Results

#### 425 3.1 Data compilation

61 tropical hydroclimate proxy records have been compiled in this study, covering 17 IPCC-designated scientific regions (Fig. A1; Iturbide et al., 2020). Compared to the compilation in Morrill et al. (2013), there is substantial improvement in hydroclimate proxy data coverage across the Caribbean, Central America, South America, South and East Asia, and the Maritime Continent.

430 61 tropical hydroclimate proxy records have been compiled in this study, covering 17 IPCC-designated scientific regions (Fig. A1; Iturbide et al., 2020). Compared to the compilation in Morrill et al. (2013), there is substantial improvement in hydroclimate proxy data coverage across the Caribbean, Central America, South America, South and East Asia, and the Maritime Continent.

This study compiled 61 tropical hydroclimate proxy records covering 17 IPCC-designated climate regions (Fig. B2; 435 Iturbide et al., 2020). Compared to Morrill et al. (2013), our compilation substantially improves hydroclimate proxy data coverage across the Caribbean, Central America, South America, South and East Asia, and the Maritime Continent.

The compilation comprises 42 speleothem records (~69%), 14 lacustrine records (~23%), and 5 marine records (~8%; Table 2). When categorized by hydroclimate interpretation into the three hydroclimate interpretation groups, the compilation includes 43  $P_{iso}$  records (70.5%), 11 EM 440 records (18%), and 7  $P_{amt}$  records (11.5%; Fig. 1; Table 2). For the purpose of this study, records which fully meet all inclusion criteria are designated as Tier 1 records ( $n = 50$ , 82%), forming the basis for the data-model intercomparison. Records which fail to meet either the minimum paleodata resolution or radiometric date requirements are classified as Tier 2 records and are included as supporting datasets ( $n = 10$ , 16%). One record (MWS1; Dutt et al., 2015) failed to meet both of these requirements, thus it is designated as a Tier 3 record, and has been excluded from further analysis.

### 3.2 Timing, magnitude~~Magnitude~~, and duration~~Duration~~ of the 8.2 ka 2ka 2ka Event in the proxy compilation~~Proxy Compilation~~

The approximate start, end, and duration of hydroclimate anomalies associated with the 8.2 ka event were calculated for all records ~~where both our MM and actR event detection methods detected in our compilation in which in our compilation in which events of the same sign (wetter, drier, or no change) were detected in both our modified MM and actR event detection methods~~. This ~~approach provides was done to provide was done to provide~~ approach provides a more robust reconstruction of the hydroclimate response to the 8.2 ka 2ka 2ka Event than ~~that which that which~~ either method would achieve ~~in isolation alone alone~~. This final set of records comprises 30 of the 61 records (49%) in our compilation. The remaining 31 records ~~displayed disagreement between the two detection methods and were in our compilation displayed a lack of agreement in the sign or presence of an event and are in our compilation displayed a lack of agreement in the sign or presence of an event and are~~ thus excluded from further analysis.

Of the 30 records that exhibit agreement between the two detection methods, significant hydroclimate events were detected in 18 records (34% of all Tier 1 and 10% of all Tier 2 records), with the remaining 12 records showing no event in either detection method (14% of all Tier 1 records and 50% of all Tier 2 records). ~~The lower event detection frequency in Tier 2 compared to Tier 1 records highlights the importance of using high resolution records with good age constraints for the detection of abrupt climate events, as the threshold for event detection is rarely exceeded. Globally, the detected hydroclimate anomalies had an average start age of 8.28ka, and average termination age of 8.13ka, and an average duration of 152 years. The longest events occurred in the foraminifera  $\delta^{18}\text{O}$  record from the Gulf of Mexico (LoDico et al., 2006; MD022550; Fig. A39; 289 years) and the speleothem record from Chongqing, China (Yang et al., 2019; HF01; Fig. A23; 259 years). The Chinese lacustrine magnetic susceptibility record of Hillman et al. (2021; F14; Fig. A17) has the earliest event onset age of 8.49ka, with a termination at 8.34ka, for a total duration of 152 years, while the Chinese speleothem record of Dykoski et al. (2005; D4Dykoski; Fig. A15) has the latest event onset age at roughly 8.11ka, terminating near 8.04ka, for an event duration of 62 years. Because the event detection algorithm in actR can be compromised by highly variable sampling resolution, Globally, the detected hydroclimate anomalies had an average start age of 8.28ka, and average termination age of 8.13ka, and an average duration of 152 years. The longest events occurred in the foraminifera  $\delta^{18}\text{O}$  record from the Gulf of Mexico (LoDico et al., 2006; MD022550; Fig. A39; 289 years) and the speleothem record from Chongqing, China (Yang et al., 2019; HF01; Fig. A23; 259 years). The Chinese lacustrine magnetic susceptibility record of Hillman et al. (2021; F14; Fig. A17) has the earliest event onset age of 8.49ka, with a termination at 8.34ka, for a total duration of 152 years, while the Chinese speleothem record of Dykoski et al. (2005; D4Dykoski; Fig. A15) has the latest event onset age at roughly 8.11ka, terminating near 8.04ka, for an event duration of 62 years. Because the event detection algorithm in actR can be compromised by highly variable sampling resolution, in records that are low resolution and/or have large age uncertainty (i.e., Tier 2 records), with highly variable resolution, we used the MM method to determine the event~~

onset, termination, and duration. This applies to only two records: the speleothem record from Dykoski et al. (2005; D4Dyeski, Fig. A15) and the speleothem record from Neff et al. (2001; H5; Fig. A21). with highly variable resolution, we used the MM method to determine the event onset, termination, and duration. This applies to only two records: the speleothem record from Dykoski et al. (2005; D4Dyeski, Fig. A15) and the speleothem record from Neff et al. (2001; H5; Fig. A21).-

Globally, detected hydroclimate anomalies had average onset at 8.28 ka, average termination at 8.13 ka, and average duration of 152 years. The longest events occurred in the Gulf of Mexico sedimentary foraminifera  $\delta^{18}\text{O}$  record (LoDico et al., 2006; MD022550; Fig. C4; 289 years) and the Chongqing, China speleothem record (Yang et al., 2019; HF01; Fig. C11; 259 years). The Chinese lacustrine magnetic susceptibility record of Hillman et al. (2021; F14; Fig. C8) has the earliest event onset age of 8.49 ka, with a termination at 8.34 ka, for a total duration of 152 years, while the Chinese speleothem record of Dykoski et al. (2005; D4Dykoski; Fig. C7) has the latest event onset age at roughly 8.11 ka, terminating near 8.04 ka, for an event duration of 62 years.

In the final set of 30 records (that agree on the sign of the event between the MM and actR methods), drier and/or isotopically enriched events were detected in 13 of those 30 records (Table 5), including six records from East Asia (Fig. 5), with the largest events ( $+3.0\sigma$ ,  $+5.8\sigma$ ) detected in the speleothem record of Yang et al. (2019; HF01; Fig. C11) and the magnetic susceptibility record of Hillman et al. (2021; F14; Fig. C8). Similarly, drying/isotopic enrichment was seen in three speleothem records from the Arabian Peninsula, with the largest event ( $+3.5\sigma$ ) detected in the record of Cheng et al. (2009; H14; Fig. C9) between 8.08 ka and 8.21 ka. The two speleothem records of Chawchai et al. (2021) from Klang Cave, Thailand (TK07, Fig. C15; TK20, Fig. C16) showed similarly high levels of isotopic enrichment ( $+3.1\sigma$  and  $+2.5\sigma$ ) between approximately 8.16 ka and 8.30 ka. Two large drying/enrichment events were also detected in central America, including a positive isotopic excursion of  $+3.4\sigma$  in the Costa Rican speleothem record of Lachniet et al. (2004; V1; Fig. C17) from 8.05 ka and 8.19 ka and a negative excursion ( $-4.0\sigma$ ) in titanium content (indicative of a drying event) in the Guatemalan lake sediment record of Duarte et al. (2021; Core5LI; Fig. C6) from 8.09 ka and 8.16 ka, suggesting a regional hydroclimate response to the 8.2 ka Event in southern Central America, south of the Yucatan Peninsula (Fig. 7).

Drier and/or isotopically enriched events were detected in 13 of the 30 records in the final compilation, including six records from East Asia (e.g. D4Dykoski ( $+2.8\sigma$ ) and F14 ( $+5.8\sigma$ )). Similarly, drying/isotopic enrichment was seen in three speleothem records from the Arabian Peninsula, with the largest shift ( $+3.5\sigma$ ) detected in the record of Cheng et al. (2009; H14; Fig. A22) between 8.08-8.21ka. The two speleothem records of Chawchai et al., 2021 from Klang Cave, Thailand (TK07, Fig. A57; TK20, Fig. A58) showed similarly high levels of isotopic enrichment ( $+3.1\sigma$  and  $+2.5\sigma$ ) between approximately 8.16-8.30ka. Finally, an isotopic enrichment of  $+3.4\sigma$  between 8.05-8.19ka in the Costa Rican speleothem record of Lachniet et al. (2004; V1; Fig. A61) and a negative excursion in titanium content indicative of a drying event ( $-4.0\sigma$ ) in the Guatemalan lake sediment record of Duarte et al. (2021; Core5LI; Fig. A10) from 8.09-8.16ka suggests a hydroclimate response to the 8.2ka Event in southern Central America (south of the Yucatan Peninsula; Fig. 6).

Drier and/or isotopically enriched events were detected in 13 of the 30 records in the final compilation, including six records from East Asia (e.g. D4Dykeski (+2.8 $\sigma$ ) and F14 (+5.8 $\sigma$ )). Similarly, drying/isotopic enrichment was seen in three speleothem records from the Arabian Peninsula, with the largest shift (+3.5 $\sigma$ ) detected in the record of Cheng et al. (2009; H14; Fig. A22) between 8.08–8.21 ka. The two speleothem records of Chawehai et al., 2021 from Klang Cave, Thailand (TK07, Fig. A57; TK20, Fig. A58) showed similarly high levels of isotopic enrichment (+3.1 $\sigma$  and +2.5 $\sigma$ ) between approximately 8.16–8.30 ka. Finally, an isotopic enrichment of +3.4 $\sigma$  between 8.05–8.19 ka in the Costa Rican speleothem record of Lachniet et al. (2004; V1; Fig. A61) and a negative excursion in titanium content indicative of a drying event (-4.0 $\sigma$ ) in the Guatemalan lake sediment record of Duarte et al. (2021; Core5LI; Fig. A10) from 8.09–8.16 ka suggests a hydroclimate response to the 8.2 ka Event in southern Central America (south of the Yucatan Peninsula; Fig. 6).

Wetter and/or isotopically depleted events were detected in five of the 30 records in the final compilation. Namely, the Madagascar speleothem records of Voarintsoa et al. (2017; ANJB2; Fig. C2A4A4) and Duan et al. (2021; ABC1; Fig. C1) showed negative isotopic excursions of -3.0 $\sigma$  and -2.5 $\sigma$ , respectively, while the two Brazilian speleothem records from Lapa Grande Cave (Strikis et al., 2011; LG11; Fig. C3A32A32) and Padre Cave (Cheng et al., 2009; PAD07; Fig. C5A43A43) exhibited negative isotopic excursions of -2.9 $\sigma$  and -2.7 $\sigma$ , respectively (Table 5). In addition, a large isotopic depletion event (-3.8 $\sigma$ ) was detected in the foraminifera  $\delta^{18}\text{O}$  record from the Gulf of Mexico (LoDico et al., 2006; MD022550; Fig. C4). A39.

We found no significant hydroclimate response in the remaining 12 records of our compilation, with both the MM and actR event detection methods in agreement that no event occurred. This category included three lake sediment records from the Yucatan Peninsula (Fig. 6; LC1 [Hodell et al., 1995; Fig. A31], Curtis6VII93 [Curtis et al., 1998; Fig. A13], LagoPuertoArturo [Wahl et al., 2014; Fig. A29]), two speleothem records from Southeast Asia/the Maritime Continent (Fig. 7; KMA [Berkelhammer et al., 2012; Fig. A27], SSC01 [Carolin et al., 2016; Fig. A53]), and two speleothem records from Brazil (Fig. 5; RN1 [Cruz et al., 2009; Fig. A49], TM6 [Ward et al., 2019; Fig. A59]). A39.

We found no significant hydroclimate response in the remaining 12 records of our compilation, with both the MM and actR event detection methods in agreement that no event occurred. This category included three lake sediment records from the Yucatan Peninsula (Fig. 6; LC1 [Hodell et al., 1995; Fig. A31], Curtis6VII93 [Curtis et al., 1998; Fig. A13], LagoPuertoArturo [Wahl et al., 2014; Fig. A29]), two speleothem records from Southeast Asia/the Maritime Continent (Fig. 7; KMA [Berkelhammer et al., 2012; Fig. A27], SSC01 [Carolin et al., 2016; Fig. A53]), and two speleothem records from Brazil (Fig. 5; RN1 [Cruz et al., 2009; Fig. A49], TM6 [Ward et al., 2019; Fig. A59]).

We found no significant hydroclimate response in the remaining 12 records of our compilation, with both the MM and actR event detection methods in agreement that no event occurred. This category included three lake sediment records from the Yucatan Peninsula (Fig. 7c and Fig. B7c; LC1 [Hodell et al., 1995; Fig. C25], Curtis6VII93 [Curtis et al., 1998; Fig. C20], LagoPuertoArturo [Wahl et al., 2014; Fig. C24]), two speleothem records from Southeast Asia/the Maritime Continent (Fig. 8 and Fig. B8; KMA [Berkelhammer et al., 2012; Fig. C23], SSC01 [Carolin et al., 2016; Fig. C29]), and

545 two speleothem records from Brazil (Fig. 6 and Fig. B6; RN1 [Cruz et al., 2009; Fig. C28], TM6 [Ward et al., 2019; Fig. C30]).

### 3.3 Regional coherency~~Coherency~~~~Coherency~~ of the reconstructed hydroclimate changes~~Reconstructed Hydroclimate Changes~~~~Reconstructed Hydroclimate Changes~~

550 The — There is substantial regional coherency in the — There is substantial regional coherency in the spatial pattern of reconstructed hydroclimate anomalies shows substantial regional coherency (Fig. 322), though it does not strictly they do not they do not conform to the anticipated anticipated hemispheric dipole pattern typically typically associated with the 8.2 ka Event (2ka Event, 2ka Event, i.e., a generally drier/isotopically enriched Northern Hemisphere and a a wetter/isotopically depleted Southern Hemisphere). Both Under both Under both the MM and actR event detection methods indicate, prominent drying/enrichment occurred occurred across East and Southeast Asia, as well as the Arabian Peninsula. These dry conditions are interspersed with areas of no change in parts of the Maritime Continent and eastern 555 India/Tibetan Plateau. No robust signatures of the 8.2 ka 2ka 2ka Event are observed over the Maritime Continent. Central and South America display more of a hemispheric dipole pattern, with dry/enrichment events occurring north of the equator in Costa Rica and Guatemala, contrasting with wet/depletion events south of the equator in central/eastern Brazil. However, there are also regions in northern and central Brazil that exhibit no hydroclimate response. The proxy records thus present a far more complex, regionally-specific hydroclimate response to the 8.2 ka2ka2ka Event than a simple hemispheric dipole 560 pattern.

565 In several regions (including East Asia, Fig. 5; and northeastern South America, Fig. 6), records with no detected change are located near records with clear event signals. These regional differences could arise from several factors, including localized hydroclimate responses to the event, age uncertainty, and proxy interpretation uncertainties. For example, speleothem  $\delta^{18}\text{O}$  records have been interpreted as representing a range of different climate processes, often within the same region, including changes in regional precipitation amount, monsoon strength, moisture source location, upstream rainout, seasonal frontal shifts, and temperature (e.g. Hu et al., 2019), reflecting the complexity of processes that impact  $\delta^{18}\text{O}_\text{p}$  and speleothem  $\delta^{18}\text{O}$ . Because of the inherently regional nature of rainfall patterns and the uncertainties in the proxy records, we focus our interpretation on regional hydroclimate signals that are supported by multiple records, often across different aspects of hydroclimate. In this way, we focus on the most robust aspects of the tropical hydroclimate response to the 8.2 ka 570 Event.

### 3.4 Global signature~~Signature~~~~Signature~~ of the 8.2 ka Event in iCESM

575 — We now compare these reconstructed hydroclimate patterns to those simulated by iCESM under 8.2 ka 2ka 2ka meltwater forcing. The surface temperature response in iCESM exhibits the characteristic "bipolar seesaw" is characteristic of the "bipolar seesaw" is characteristic of the "bipolar seesaw" pattern (i.e., a colder northern hemisphere and a a warmer southern hemisphere, that is that is most pronounced in the Atlantic Ocean), consistent with reduced a reduction

in a reduction in northward heat transport by AMOC (Fig. B3A2A2). Anomalously cool surface temperatures, reaching as low as -20°C where the freshwater forcing was applied, stretch across the northern North Atlantic Ocean, southward along the western coasts of Europe and North Africa, and into the tropical Atlantic via the North Atlantic Subtropical Gyre. Surface air temperatures across the Southern Hemisphere show a positive anomaly of up to 3°C, with the largest warming occurring in the South Atlantic. Over the continents, surface air temperatures cool in all regions except localized parts of northern South America, West Africa, and the southernmost regions of South America and Australia. -

Accompanying these temperature anomalies are notable anomalies in precipitation amount,  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$ , and effective moisture (Fig. 433). Precipitation decreases while effective moisture increases throughout much of the North Atlantic, with the responses most pronounced in the regions with greatest cooling. The increase in effective moisture in this region indicates that the evaporation reduction outpaces the precipitation reduction (Fig. 4c3e3e). In the tropics, the largest precipitation anomalies appear in the tropical Pacific and Atlantic basins, with a southward shift of the Pacific and Atlantic ITCZs occurring in response to the freshwater forcing (Fig. 4b3b3b). These shifts are characterized by a weakening of the northern extent of the ITCZs and an enhancement of the southern extent. The most pronounced drying occurs over central America and the northeasterneasterneastern tropical Pacific, including Costa Rica and Panama, while the largest wet anomalies occur across the southern tropical Pacific. A notable hemispheric dry/wet dipole pattern is also observed in the tropical Atlantic, extending over northeastern South America. This pattern is less pronounced but still present over the tropical Indian Ocean and Africa. In contrast, no such dipole occurs over the western Pacific or Maritime Continent. Notably, the simulated pattern in  $\delta^{18}\text{O}_p$  in iCESM under 8.2 ka meltwater forcing is remarkably similar to that in GISS ModelE-R under Heinrich forcing (Fig. 4a), indicating a robust inter-model response in  $\delta^{18}\text{O}_p$  to North Atlantic meltwater forcing (aside from Africa and Antarctica, where the inter-model agreement breaks down).

These temperature and precipitation anomalies project strongly onto the amount-weighted  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  values (Fig. 4a3a3a). The greatest  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies occur in the northern reaches of the North Atlantic Ocean, reaching up to -8‰ in association with the strong regional cooling of the North Atlantic, as well as the addition of highly depleted (-30‰) meltwater to the surface ocean of the “hosing” site, and subsequent evaporation and rainout. In the tropics,  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies closely follow the changes in precipitation amount over the tropical Atlantic and central/eastern Pacific Oceans, with negative  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies south of the equator and positive  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies north of the equator. A pronounced dipole pattern is also evident over northern South America, where anomalously increased (decreased) rainfall amounts correspond to negative (positive)  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies in the southeastern (northwestern) region of South America. In the Middle East, India, Tibetan Plateau, and parts of Southeast Asia, modest drying is accompanied by pronounced positive  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  anomalies. However, not all regions are well described by the amount effect. In the Caribbean and Central America, there is a positive relationship between  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}}$  and precipitation amount, characterized by strong drying and isotopic depletion (associated with the strong upwind cooling and meltwater addition in the North Atlantic). There also

610 | appears to be no clear relationship between precipitation amount and  $\delta^{18}\text{O}_{\text{precipitation}}$ - $\delta^{18}\text{O}_{\text{precipitation}}$ - $\delta^{18}\text{O}$  anomalies over Africa, East Asia, the Western Pacific, and Maritime Continent.

### 3.4.1 Mechanisms driving the response of precipitation $\delta^{18}\text{O}$ to North Atlantic freshwater forcing

615 | To assess whether the simulated hydroclimate changes are due to changes in the seasonality of  $\delta^{18}\text{O}_{\text{p}}$  or changes in the seasonality of precipitation amount, we decomposed the changes in amount-weighted  $\delta^{18}\text{O}_{\text{p}}$  following Liu and Battisti (2015; Fig. 9). In East Asia, the change in amount-weighted  $\delta^{18}\text{O}_{\text{p}}$ , including the east-west dipole pattern with isotopic depletion off the coast of China into the North Pacific and isotopic enrichment inland, is driven by the seasonal changes in the isotopic composition of precipitation (Fig. 10b,c). Under meltwater forcing,  $\delta^{18}\text{O}_{\text{p}}$  inland is more enriched throughout the year, particularly in the dry season from December to April (Fig. 12c). While  $\delta^{18}\text{O}_{\text{p}}$  off the coast is more depleted throughout the year, particularly during the wet season from June to November (Fig. 12d). Consistent with previous studies on Heinrich events, these results suggest that the meltwater-induced enrichment in Chinese speleothem  $\delta^{18}\text{O}$  records is not driven by changes in local precipitation and/or the strength of the EASM, but rather driven by changes in moisture source, circulation, and/or upstream rainout (Chiang et al., 2020; Pausata et al., 2011, Lewis et al., 2010). That the largest changes in  $\delta^{18}\text{O}_{\text{p}}$  over China occur during the winter season is consistent with the results from Lewis et al. (2010), which found that increased moisture provenance in the Bay of Bengal during winter yielded enriched  $\delta^{18}\text{O}_{\text{p}}$  over China during Heinrich events. The large zonal asymmetry observed in the  $\delta^{18}\text{O}_{\text{p}}$  response to meltwater forcing between China and the North Atlantic was also identified in the Heinrich simulations of Lewis et al. (2010) and Pausata et al. (2011).

620 | In northeastern South America and southern Central America, the change in amount-weighted  $\delta^{18}\text{O}_{\text{p}}$  is also dominated by the seasonal changes in  $\delta^{18}\text{O}_{\text{p}}$  and not the seasonality of precipitation (Fig. 10e-f,h-i), however the mechanisms of the response seem to differ from those in East Asia. In northeastern Brazil, precipitation increases under meltwater forcing and becomes more isotopically depleted during the wet season from December to July (Fig. 11c,d). These changes are consistent with a Type-1 control on  $\delta^{18}\text{O}_{\text{p}}$  (Lewis et al., 2010), wherein the local amount effect dominates the  $\delta^{18}\text{O}_{\text{p}}$  response. In southern Central America, the change in amount-weighted  $\delta^{18}\text{O}_{\text{p}}$  is characterized by a distinct SW-NE dipole with isotopic enrichment in the northeastern tropical Pacific and over Panama and isotopic depletion over the Caribbean and the remainder of southern Central America. This pattern is also driven by the seasonal changes in  $\delta^{18}\text{O}_{\text{p}}$  under meltwater forcing (Fig. 10h,i). In the northeastern tropical Pacific, wet season precipitation is substantially weakened and isotopically enriched (Fig. 625 | 13a,c), consistent with a Type-1 site (Lewis et al., 2010), wherein the local amount effect dominates the  $\delta^{18}\text{O}_{\text{p}}$  response. Past studies on the hydroclimate response to Heinrich events have shown that regional precipitation changes in northeastern Brazil and the eastern Pacific are associated with a southward shift of the Atlantic and northeastern tropical Pacific ITCZs (Lewis et al., 2010; Roberts et al., 2020; Atwood et al., 2020). However, the  $\delta^{18}\text{O}_{\text{p}}$  response over the Caribbean and southern Central America is notably different. In this region, the wet season precipitation decreases under hosing, essentially eliminating the wet season, while the precipitation becomes substantially more isotopically depleted throughout the year

(Fig. 13b,d), in association with the strong surface cooling of the tropical Atlantic Ocean and the addition of isotopically depleted meltwater into the North Atlantic. Thus, the  $\delta^{18}\text{O}_p$  response in this region would be classified as Type-5 according to the categorization of Lewis et al. (2010), with the mechanisms driving the  $\delta^{18}\text{O}_p$  response governed by processes outside of the local or nonlocal amount effect, moisture source, or seasonality of precipitation.

645 | **3.5 Data-model comparisons** **Model Comparisons** **Model Comparisons**

The proxy locations span ~~17 a total of 15 a total of 15~~ IPCC scientific regions (Fig. B2A1A1). The regions with densest ~~coverage of coverage of~~ Tier 1 proxy data ~~coverage are southern are are~~ Central America, northeastern South America, East Asia, and Southeast Asia/Maritime Continent. These four regions were ~~therefore thus thus~~ targeted for ~~the the~~ data-model comparisons. The proxy records within each region were compared to ~~the the~~ model-simulated ~~anomalies in anomalous anomalous~~ annual mean precipitation amount, amount-weighted  $\delta^{18}\text{O}_{\text{precipitation}}$ ,  $\delta^{18}\text{O}_{\text{precipitation}}$ , and effective moisture (P-E) to investigate ~~the the~~ data-model agreement in the four target regions.

In East Asia (Fig. 5; Tables 3 and 4), five speleothem records display isotopic enrichment events broadly corresponding to the large-scale enrichment pattern in  $\delta^{18}\text{O}_p$  simulated by iCESM across South Asia and the Arabian Peninsula (Fig. 5a,b). This modeled enrichment pattern corresponds well with the broad isotopic enrichment found in proxy reconstructions spanning East Asia, the Arabian Peninsula, and southern Thailand. In iCESM, the Chinese speleothem records are located near the node of an east-west dipole pattern in  $\delta^{18}\text{O}_p$  in eastern China, which is part of a larger zonal pattern of  $\delta^{18}\text{O}_p$  anomalies, characterized by isotopic enrichment in the Middle East and Asia, and isotopic enrichment in the subtropics and extratropics of the North Pacific, extending into the eastern coast of China (Fig. 4a). This pattern was also noted in the 8.2 ka and Heinrich meltwater events performed with GISS ModelE-R (LeGrande and Schmidt, 2008; Lewis et al., 2010). Using vapor source distribution tracers, Lewis et al. (2010) identified changes in circulation, moisture source, and upwind processes as the dominant processes underpinning the  $\delta^{18}\text{O}_p$  response in the East Asian monsoon region in their Heinrich simulations. In agreement with their results, the enriched  $\delta^{18}\text{O}_p$  anomalies over Asia in the iCESM meltwater simulations do not appear to be driven by a weakened monsoon via a local amount effect, as the rainfall changes in the region are weak and spatially variable.

665 Northeastern South America displays only moderate proxy-model agreement (Fig. 6). Two of the four speleothem records there contain large  $\delta^{18}\text{O}$  depletion events, corresponding with the large-scale isotopic depletion signal in  $\delta^{18}\text{O}_p$  in iCESM across northeastern South America. However, two other speleothem records in the region—one in the Nordeste region of Brazil and one in central Brazil—show no significant hydroclimate anomalies during the 8.2 ka Event, in contrast with the results from iCESM.

670 In East Asia (Fig. 4; Table 3; Table 4), five speleothem records display an isotopic enrichment event that broadly corresponds to the simulated large scale isotopic enrichment pattern in precipitation  $\delta^{18}\text{O}$  that stretches across South Asia and the Arabian Peninsula in iCESM (Fig. 4a,b). This broad enrichment pattern in the model corresponds well with the

similarly broad isotopic enrichment pattern found in the reconstructions, spanning East Asia, the Arabian Peninsula and southern Thailand. In iCESM, the Chinese speleothem records are located near the node of an east-west dipole pattern in precipitation  $\delta^{18}\text{O}$  in eastern China, which is part of a larger pattern of isotopic depletion in South Asia and isotopic enrichment in the subtropics and extratropics of the North Pacific. In addition to these speleothem records, there is a single lake sediment record in southern China that displays a notable drying event, indicative of reduced precipitation, however this record contrasts with the results from iCESM, which show no notable change in precipitation in this region (Fig. 4b,e).

Northeastern South America displays only moderate proxy model agreement (Fig. 5). Two of the four speleothem records there contain large  $\delta^{18}\text{O}$  depletion events, corresponding with the large scale isotopic depletion signal in precipitation  $\delta^{18}\text{O}$  in iCESM across northeastern South America. However, two other speleothem records in the region one in the Nordeste region of Brazil and one in central Brazil show no significant hydroclimate anomalies during the 8.2ka Event, in contrast with the results from iCESM.

In East Asia (Fig. 4; Table 3; Table 4), five speleothem records display an isotopic enrichment event that broadly corresponds to the simulated large scale isotopic enrichment pattern in precipitation  $\delta^{18}\text{O}$  that stretches across South Asia and the Arabian Peninsula in iCESM (Fig. 4a,b). This broad enrichment pattern in the model corresponds well with the similarly broad isotopic enrichment pattern found in the reconstructions, spanning East Asia, the Arabian Peninsula and southern Thailand. In iCESM, the Chinese speleothem records are located near the node of an east-west dipole pattern in precipitation  $\delta^{18}\text{O}$  in eastern China, which is part of a larger pattern of isotopic depletion in South Asia and isotopic enrichment in the subtropics and extratropics of the North Pacific. In addition to these speleothem records, there is a single lake sediment record in southern China that displays a notable drying event, indicative of reduced precipitation, however this record contrasts with the results from iCESM, which show no notable change in precipitation in this region (Fig. 4b,e).

Northeastern South America displays only moderate proxy model agreement (Fig. 5). Two of the four speleothem records there contain large  $\delta^{18}\text{O}$  depletion events, corresponding with the large scale isotopic depletion signal in precipitation  $\delta^{18}\text{O}$  in iCESM across northeastern South America. However, two other speleothem records in the region one in the Nordeste region of Brazil and one in central Brazil show no significant hydroclimate anomalies during the 8.2ka Event, in contrast with the results from iCESM.

In southern Central America, the simulated and reconstructed hydroclimate anomalies broadly agree (Fig. 7), with the dry event in the Guatemalan lake sediment record of Core5LI (Duarte et al., 2021) corresponding with the reduced precipitation throughout southern Central America simulated in iCESM. The lack of a detected event in three lake sediment records from the Yucatan Peninsula (LagoPuertoArturo, Curtis6VII93, LC1) also agrees with the simulated weak EM response in that region in iCESM. While a positive  $\delta^{18}\text{O}_p$  event in the Costa Rican speleothem record (V1; Lachniet et al., 2004) contrasts with the weak simulated change in  $\delta^{18}\text{O}_p$  at the overlapping model grid box, it is notable that the cave site sits at the nodal point of a pronounced east-west dipole pattern in  $\delta^{18}\text{O}_p$  in iCESM, with widespread isotopic enrichment in  $\delta^{18}\text{O}_p$  in the eastern tropical Pacific and widespread isotopic depletion in the tropical North Atlantic that stretches into the

Caribbean and Mesoamerica. Using this regional context, the isotopic enrichment event in Costa Rica is consistent with the simulated enrichment in  $\delta^{18}\text{O}_p$  that extends from southernmost Central America to the northeastern tropical Pacific.

Subject to the small sample size in Central America (Fig. 6), broad agreement is found between the simulated and reconstructed hydroclimate anomalies, with the dry event detected in the Guatemalan lake sediment record of Core5LI (Duarte et al., 2021) corresponding with the reduced precipitation simulated throughout central America in iCESM. In addition, a positive (enriched) precipitation  $\delta^{18}\text{O}$  event found in the Costa Rican speleothem record (V1) is not inconsistent with the simulated isotopic enrichment in precipitation  $\delta^{18}\text{O}$  in the southernmost extent of Central America in iCESM, forming part of the wide enrichment signal that stretches across the eastern Pacific. However, like the East Asian records, this speleothem record sits at the nodal point of a pronounced east west dipole pattern in precipitation  $\delta^{18}\text{O}$  in iCESM, characterized by isotopic enrichment in the eastern tropical Pacific and widespread isotopic depletion in the tropical North Atlantic that stretches into the Caribbean and Mesoamerica. Lastly, the lack of a detected event in three lake sediment records from the Yucatan Peninsula (Lago Puerto Arturo, Curtis6VII93, LC1) also agrees with the simulated weak EM response in that region in iCESM.

Subject to the small sample size in Central America (Fig. 6), broad agreement is found between the simulated and reconstructed hydroclimate anomalies, with the dry event detected in the Guatemalan lake sediment record of Core5LI (Duarte et al., 2021) corresponding with the reduced precipitation simulated throughout central America in iCESM. In addition, a positive (enriched) precipitation  $\delta^{18}\text{O}$  event found in the Costa Rican speleothem record (V1) is not inconsistent with the simulated isotopic enrichment in precipitation  $\delta^{18}\text{O}$  in the southernmost extent of Central America in iCESM, forming part of the wide enrichment signal that stretches across the eastern Pacific. However, like the East Asian records, this speleothem record sits at the nodal point of a pronounced east west dipole pattern in precipitation  $\delta^{18}\text{O}$  in iCESM, characterized by isotopic enrichment in the eastern tropical Pacific and widespread isotopic depletion in the tropical North Atlantic that stretches into the Caribbean and Mesoamerica. Lastly, the lack of a detected event in three lake sediment records from the Yucatan Peninsula (Lago Puerto Arturo, Curtis6VII93, LC1) also agrees with the simulated weak EM response in that region in iCESM.

Broad data-model agreement is also found in Southeast Asia and the Maritime Continent (Fig. 877), where one speleothem record in the Thailand peninsula contains a notable isotopic enrichment event, in agreement with the simulated large scale enrichment signal in  $\delta^{18}\text{O}_p$  in precipitation  $\delta^{18}\text{O}$  in iCESM in precipitation  $\delta^{18}\text{O}$  in iCESM in South Asia (Fig. 8 and Fig. B87a,d7a,d). Two other speleothem records in Sumatra and Borneo show no significant hydroclimate anomalies, in general agreement with the weak simulated  $\delta^{18}\text{O}_{\text{precipitation}}$   $\delta^{18}\text{O}_{\text{precipitation}}$   $\delta^{18}\text{O}$  anomalies in iCESM in this region, which reflect the weak response in  $\delta^{18}\text{O}_{\text{precipitation}}$   $\delta^{18}\text{O}_{\text{precipitation}}$   $\delta^{18}\text{O}$  throughout the western Pacific and Maritime Continent (Fig. 4a3a3a).

These results suggest that iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic enrichment pattern in  $\delta^{18}\text{O}_p$  in South and East Asia and the Arabian Peninsula, the muted hydroclimate response in the Maritime Continent, the drying and isotopic enrichment in southern

740 Central America, and the isotopic depletion in  $\delta^{18}\text{O}_p$  in parts of northeastern South America. Similar hydroclimate features also appear in simulations of the Younger Dryas cold event from Renssen et al (2018). While qualitative, these areas of agreement between the proxies and model demonstrate that the tropical hydroclimate response to North Atlantic meltwater forcing during the 8.2 ka Event was not a simple hemispheric dipole pattern, but is instead characterized by rich regional structure.

745 While qualitative agreement exists between many of the reconstructed and simulated regional hydroclimate anomalies during the 8.2 ka Event, our data-model comparisons are subject to several limitations. First, our regional analyses are limited by small sample sizes. In some regions like East Asia, point-to-point agreement between proxy and model data is low even though regional hydroclimate patterns offer more nuanced context. In addition, our data-model comparisons are necessarily qualitative as many of the proxy records in our compilation are carbonate  $\delta^{18}\text{O}$  records, which do not solely reflect changes in  $\delta^{18}\text{O}_p$ . Rather, these archives incorporate a combination of the isotopic composition of groundwater (for 750 speleothem  $\delta^{18}\text{O}$  records; Lachniet, 2009) or seawater (for marine  $\delta^{18}\text{O}$  records; Konecky et al., 2020) as well as the environmental temperature, among other factors (LeGrande and Schmidt, 2009; Bowen et al., 2019; Konecky et al., 2019). Thus, future work should integrate proxy system models with water isotope-enabled climate model simulations to develop 755 more quantitative data-model comparisons of the 8.2 ka Event. In addition, quantitative metrics like the weighted Cohen's kappa statistic could be used to quantitatively compare the proxy reconstructions to the pseudoproxy data derived from climate models (Cohen, 1960; Cohen, 1968; Landis and Koch, 1977; DiNezio and Tierney, 2013).

760 However, even when attempting to bridge the gap between models and proxy data using proxy system models and quantitative metrics, robust comparisons remain challenging. Characterizing the point-to-point agreement between the observed and simulated climate anomalies fails to address the well-known hydroclimate biases that exist in GCMs, which arise from factors like coarse model resolution, idealized topography, and the unresolved physics of cloud formation and convection. Furthermore, proxy data often capture localized climate signals which may not be representative of regional 765 conditions. In contrast, model data are averaged over the area of a grid cell, which can be large in coarse-resolution models. This can lead to non-trivial biases, particularly in coastal regions and regions of complex topography. Ultimately, these data-model comparisons would be improved by the integration of additional well-dated proxy records that resolve different aspects of hydroclimate, and employing ensembles of high-resolution water isotope-enabled climate model simulations of the 8.2 ka Event paired with proxy system models.

## 4 Discussion

### 4.1 Comparison to previous hydroclimate compilations ~~Previous Hydroclimate Compilations~~ ~~Previous Hydroclimate Compilations~~

770 The spatial pattern of the hydroclimate responses to the 8.2 ka Event presented in this study broadly agrees with those presented in Morrill et al. (2013) and Parker and Harrison (2022). All

three studies document Both sets of reconstructions, as well as the present study, find Both sets of reconstructions, as well as the present study, find large-scale drying across East Asia and the Arabian Peninsula, alongside robust wet and/or isotopic depletion signals as well as a robust wet/depletion signal as well as a robust wet/depletion signal in central and eastern Brazil. These signals coincide with drying and/or isotopic enrichment event eastern Brazil; in Morrill et al. (2013) and Parker and Harrison (2022) this signal coincides with a dry/enrichment event eastern Brazil; in Morrill et al. (2013) and Parker and Harrison (2022) this signal coincides with a dry/enrichment event in northern South America, aligning in agreement in agreement with the simulated hydroclimate response in iCESM (Fig. 433). All three reconstructions also agree on drying/enrichment in southern Central America, while both the present study and Parker and Harrison (2022) find a dipole pattern of wet/isotopically depleted conditions in the Caribbean/Gulf of Mexico and dry/isotopically enriched conditions in southern Central America (Fig. 4a3a3a-c).

Timing and duration estimates also show reasonable agreement across compilations. Our age ensembles yield a mean start age of  $8.28 \pm 0.12$  ka ( $1\sigma$ ), a termination age of  $8.11 \pm 0.09$  ka ( $1\sigma$ ), and an average duration of  $152 \pm 70$  years ( $1\sigma$ ; 50-289 years). These results agree, within age uncertainty, to the initiation and termination of the global event estimated from northern Greenland ice core data (8.09 ka-8.25 ka; Thomas et al., 2007). Previous studies report comparable findings. Using eight absolutely dated speleothems from China, Oman, and Brazil, Cheng et al. (2009) estimated the onset of the 8.2 ka Event at 8.21 ka, termination at 8.08 ka, and a total duration of 130-150 years. Parker and Harrison (2022) refined these estimates using 275 absolutely dated speleothems, calculating the global onset at  $8.22 \pm 0.01$  ka, termination at  $8.06 \pm 0.01$  ka, and a duration of 159-166 years. While our range of event durations exceeds those in Cheng et al. (2009) and Parker and Harrison (2022), it is consistent with the estimated range of 40-270 years from the multiproxy compilation of Morrill et al. (2013). Importantly, the present study is the first to comprehensively account for age uncertainty by propagating age ensembles through all phases of event detection. Our larger uncertainties and duration range likely stem from this explicit treatment of age uncertainty, combined with the inclusion of lower-resolution lake and marine sediment records alongside higher-resolution speleothems in our compilation. In all cases, the average event duration in the hydroclimate records closely resembles that in the layer-counted Greenland ice core records ( $160.5 \pm 5.5$  years; Thomas et al., 2007), providing further support of the global and synchronous nature of the 8.2 ka Event.

One striking difference between our compilation and previous studies is the relatively low percentage of records with detected 8.2 ka Events (e.g., only 30% of our records, compared to 70% in Parker and Harrison's [2022] global speleothem compilation). This difference may arise from several factors. We focus exclusively on tropical proxy data, which are likely to record weaker anomalies than proxies from the North Atlantic and Europe, regions more directly impacted by proximity to the meltwater forcing. More importantly, our explicit accounting of age uncertainty reveals that many records lack sufficient age constraints, precluding the generation of age ensembles to pass the robust null hypothesis test in actR, and thereby fail to identify abrupt anomalies attributable to the 8.2 ka Event.

There is a reasonable level of agreement among all three compilations regarding the timing and duration of the hydroclimate anomalies. The age ensembles produced in the current analysis yield a mean start age of  $8.28 \pm 0.12$  ka (1 $\sigma$ ) and a termination age of  $8.11 \pm 0.09$  ka (1 $\sigma$ ) for the tropical hydroclimate response to the event. This timing agrees within age uncertainty to the timing of the event established from northern Greenland ice core data (8.25 ka to 8.09 ka; Thomas et al., 2007). In a compilation of eight absolutely dated speleothems from South America and East Asia, Cheng et al. (2009) calculated an event onset at 8.21 ka and termination at 8.08 ka. Similarly, Parker and Harrison (2022) used a compilation of 275 absolutely dated speleothems to calculate the start of the global event at  $8.22 \pm 0.01$  ka and its termination at  $8.06 \pm 0.01$  ka. Importantly, the present study is the first to adopt a more comprehensive approach to age uncertainty in the proxy records through the generation of age ensembles in our analysis. The larger uncertainty in the timing of the event identified in this study is likely due to the inclusion of the age ensembles, as well as the multiproxy nature of our dataset, which includes lower resolution lake and marine sediment records, in addition to the higher resolution speleothem records.

The duration of the hydroclimate anomalies identified in this study is also consistent with previous estimates. Parker and Harrison (2022) estimate durations ranging from 159 to 166 years, while Cheng et al. (2009) report a duration of 150 years, both of which fall within the range estimated from layer-counted Greenland ice cores ( $160.5 \pm 5.5$  years; Thomas et al., 2007). In their multi-proxy dataset, Morrill et al. (2013) report a larger range in event duration, spanning from 40 to 270 years. In the present compilation, the mean duration of the tropical hydroclimate anomalies is  $152 \pm 70$  years (1 $\sigma$ ), with a range of 50–289 years, lending support to the multi-decadal to multi-centennial range of timescales found in earlier studies. Importantly, this work is the first to explicitly account for age uncertainty through all phases of the event detection analysis.

The multiproxy nature of this compilation, the explicit accounting of age uncertainties, and a geographic focus on the tropics likely contributed to a lower percentage of records which show robust signals of the 8.2 ka Event (30%) relative to previous studies (e.g., 70% of the global speleothem records compiled by Parker and Harrison, 2022). Proxy datasets from the tropics are likely to record lower magnitude climate anomalies relative to those observed in the North Atlantic and Europe, which experienced more pronounced climatic impacts from their proximity to the meltwater forcing that caused the 8.2 ka Event. Moreover, while certain records may exhibit significant changes between 7.9 ka and 8.3 ka, the lack of sufficient age constraints in some records preclude the identification of robust events that can be tied to the 8.2 ka Event (as these records display wide ranging age ensembles that fail the null hypothesis test in *aetR*).

830 There is a reasonable level of agreement among all three compilations regarding the timing and duration of the hydroclimate anomalies. The age ensembles produced in the current analysis yield a mean start age of  $8.28 \pm 0.12$  ka ( $1\sigma$ ) and a termination age of  $8.11 \pm 0.09$  ka ( $1\sigma$ ) for the tropical hydroclimate response to the event. This timing agrees within age uncertainty to the timing of the event established from northern Greenland ice core data (8.25 ka to 8.09 ka; Thomas et al., 2007). In a compilation of eight absolutely-dated speleothems from South America and East Asia, Cheng et al. (2009) calculated an event onset at 8.21 ka and termination at 8.08 ka. Similarly, Parker and Harrison (2022) used a compilation of 275 absolutely-dated speleothems to calculate the start of the global event at  $8.22 \pm 0.01$  ka and its termination at  $8.06 \pm 0.01$  ka. Importantly, the present study is the first to adopt a more comprehensive approach to age uncertainty in the proxy records through the generation of age ensembles in our analysis. The larger uncertainty in the timing of the event identified in this study is likely due to the inclusion of the age ensembles, as well as the multiproxy nature of our dataset, which includes lower resolution lake and marine sediment records, in addition to the higher resolution speleothem records.

835 840 The duration of the hydroclimate anomalies identified in this study is also consistent with previous estimates. Parker and Harrison (2022) estimate durations ranging from 159 to 166 years, while Cheng et al. (2009) report a duration of 150 years, both of which fall within the range estimated from layer-counted Greenland ice cores ( $160.5 \pm 5.5$  years; Thomas et al., 2007). In their multi-proxy dataset, Morrill et al. (2013) report a larger range in event duration, spanning from 40 to 270 years. In the present compilation, the mean duration of the tropical hydroclimate anomalies is  $152 \pm 70$  years ( $1\sigma$ ), with a range of 50–289 years, lending support to the multi-decadal to multi-centennial range of timescales found in earlier studies. Importantly, this work is the first to explicitly account for age uncertainty through all phases of the event detection analysis.

845 850 The multiproxy nature of this compilation, the explicit accounting of age uncertainties, and a geographic focus on the tropics likely contributed to a lower percentage of records which show robust signals of the 8.2 ka Event (30%) relative to previous studies (e.g., 70% of the global speleothem records compiled by Parker and Harrison, 2022). Proxy datasets from the tropics are likely to record lower-magnitude climate anomalies relative to those observed in the North Atlantic and Europe, which experienced more pronounced climatic impacts from their proximity to the meltwater forcing that caused the 8.2 ka Event. Moreover, while certain records may exhibit significant changes between 7.9 ka and 8.3 ka, the lack of sufficient age constraints in some records preclude the identification of robust events that can be tied to the 8.2 ka Event (as these records display wide-ranging age ensembles that fail the null hypothesis test in aETR).

## 855 | 4.2 Comparison Simulation Simulation of the simulated 8.2 ka Event across models in iCESM in iCESM

860 Proxy data play a crucial role in reconstructing local climate, but such data are often sparsely distributed, particularly through the tropics and the Southern Hemisphere, prohibiting a complete global picture of the 8.2 ka Event. Ocean-atmosphere-coupled General Circulation Models (GCMs) provide an invaluable tool for testing the response of the climate system to various forcings, and provide an estimate of the climate response in regions with scarce proxy data. Moreover, climate model simulations that track water isotopes through the hydrologic cycle facilitate more direct comparisons between proxy and model data.

865 Proxy data play a crucial role in reconstructing local climate, but such data are often sparsely distributed, particularly through the tropics and the Southern Hemisphere, prohibiting a complete global picture of the 8.2 ka Event. Ocean-atmosphere-coupled General Circulation Models (GCMs) provide an invaluable tool for testing the response of the climate system to various forcings, and provide an estimate of the climate response in regions with scarce proxy data. Moreover, climate model simulations that track water isotopes through the hydrologic cycle facilitate more direct comparisons between proxy and model data.

Two lower-resolution isotope-enabled GCM simulations have previously been conducted to investigate the 8.2 ka Event. LeGrande and Schmidt (2008) used the Goddard Institute for Space Studies ModelE-R (GISS

870 ModelEModelIEModelIE-R) to evaluate the response of global temperatures, precipitation amount, and  $\delta^{18}\text{O}_{\text{precipitation}}$  values to a slowdown of the AMOC. GISS ModelIE-R is a fully coupled GCM from the IPCC AR4 era, featuring a  $4^\circ \times 5^\circ$  horizontal resolution atmosphere model coupled with an ocean model of the same resolution, comprising 20 and 13 vertical layers, respectively. LeGrande and Schmidt (2008) performed a 1,000-year preindustrial control simulation and a suite of twelve meltwater forced experiments, applying a range of forcings (1.25 Sv to 10 Sv) over the 875 Hudson Bay for 0.25 to 2 years. They found that this range of meltwater forcings inhibited North Atlantic Deep Water (NADW) formation and reduced the strength of the AMOC for up to 180 years.

In agreement with the results from iCESM, LeGrande and Schmidt (2008) found large  $\delta^{18}\text{O}_{\text{precipitation}}$  anomalies over the meltwater source area in the North Atlantic in the decade following the meltwater forcing, which they similarly attributed to the evaporation and rainout of the isotopically depleted meltwater in the region. They observed 880 reasonable agreement between their simulations and proxy records of temperature and hydroclimate, with the simulations containing larger meltwater forcing exhibiting better agreement with the proxies (emphasizing the importance of considering an ensemble of simulations to find the best fit to proxy reconstructions). Regarding the tropical hydroclimate response, they identified bands of enriched (depleted)  $\delta^{18}\text{O}_{\text{precipitation}}$  anomalies in the northern (southern) tropics as a result of a southward shift in tropical rainfall. Notable patterns of  $\delta^{18}\text{O}$  enrichment were identified in 885 northeastern Africa, through the Middle East, south Asia, and the Thailand peninsula, which they attributed to large-scale changes in the hydrologic cycle, including shifts in moisture source and moisture transport pathways.

In a more recent set of simulations, Aguiar et al. (2021) used the University of Victoria Earth System Climate Model version 2.9 (UVic ESCM2.9) with the addition of oxygen isotopes to test proxy-model agreement under a range of 890 empirically derived freshwater forcing scenarios. UVic ESCM2.9 uses the Modular Ocean Model version 2, with a horizontal resolution of  $3.6^\circ \times 1.8^\circ$  and 19 vertical levels. The version of the UVic ESCM2.9 model used in this study possesses a simple two-dimensional atmospheric energy moisture balance model, which limits its ability to accurately represent  $\delta^{18}\text{O}_{\text{precipitation}}$  values. Aguiar et al. (2021) compared the sea surface temperatures and seawater  $\delta^{18}\text{O}$  values from 28 simulations with 35 proxy records to place new constraints on the amount and rate of freshwater forcing in 895 the North Atlantic. Their analysis revealed that a two-stage meltwater experiment with a background flux of 0.066 Sv over 1,000 years (8 ka-9 ka9-8ka9-8ka), followed by an intensification to 0.19 Sv over 130 years (8.18 ka-8.31 ka31-8.18ka31-8.18ka), best replicated the anomalies observed in the proxy records.

The iCESM simulation illustrates clear signatures of the global 8.2 ka-2ka-2ka Event that, at the largest scales, are broadly consistent with the GISS and UVic simulations described above, including the hemispheric dipole pattern in 900 temperature and associated southward shift of the tropical rainbands. On regional scales, the tropical rainfall patterns display substantial regional heterogeneity, with a southward shift of the tropical ocean rain bands, drying in the major NH monsoon regions of South Asia and West Africa, and wetting in parts of the South American Summer Monsoon. Tropical  $\delta^{18}\text{O}_{\text{precipitation}}$

905  $\delta^{18}\text{O}_{\text{precipitation}}$  values display strong signatures of the 8.2 ka Event, including opposing patterns of  $\delta^{18}\text{O}_{\text{precipitation}}$  values between northern South America and northeastern Brazil (e.g., Zhu et al., 2017) and large  $\delta^{18}\text{O}_{\text{precipitation}}$  anomalies over the meltwater region (e.g., LeGrande and Schmidt, 2008; Bowen et al., 2019). Dry (wet) anomalies correspond with enriched (depleted)  $\delta^{18}\text{O}_{\text{precipitation}}$  values in some tropical regions, implicating the “amount effect” as the driving force behind the isotopic signal, but a decoupling of precipitation amount and  $\delta^{18}\text{O}_{\text{precipitation}}$  anomalies occurs over many tropical continental regions, indicating that other processes such as changes in moisture source, moisture transport pathways, water recycling over land, and/or changes in precipitation 910 seasonality, dominate the isotopic signal in those regions. The model simulations lend support to the proxy reconstructions in demonstrating that the tropical hydroclimate response to the 8.2 ka Event cannot be described as a simple hemispheric dipole pattern, particularly over continental regions, and that the rich regional structure of the precipitation amount and  $\delta^{18}\text{O}_{\text{precipitation}}$  responses must be considered in order to understand the full picture of the tropical hydroclimate response to this event.

## 915 | 4.3 Data-Model Comparisons

Subject to the small sample sizes found in the regional data-model comparisons, the results suggest that iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic enrichment pattern in precipitation  $\delta^{18}\text{O}$  in South and East Asia, the muted hydroclimate response in the Maritime Continent, the drying and isotopic enrichment in southern Central America, and the isotopic depletion in precipitation  $\delta^{18}\text{O}$  in parts of 920 northeastern South America. While qualitative, these areas of agreement between the proxies and model demonstrate that the tropical hydroclimate response to North Atlantic meltwater forcing during the 8.2ka Event was not a simple hemispheric dipole pattern, but is instead characterized by rich regional structure.

However, while there is some qualitative agreement between many of the reconstructed and simulated regional hydroclimate anomalies during the 8.2ka Event, our data-model comparisons are subject to a variety of limitations. For 925 starters, our regional analyses are limited by small sample sizes and in some regions like East Asia, the point-to-point agreement between the proxy and model data is low even as the regional hydroclimate patterns offer more nuanced context. In addition, our data-model comparisons are necessarily qualitative as many of the proxy records in our compilation are carbonate  $\delta^{18}\text{O}$  records, which do not solely reflect changes in precipitation  $\delta^{18}\text{O}$ . Rather, these archives incorporate a combination of the isotopic composition of groundwater (for speleothem  $\delta^{18}\text{O}$  records; Lachniet, 2009) or seawater (for 930 marine  $\delta^{18}\text{O}$  records; Konecky et al., 2020) as well as the environmental temperature, among other factors (LeGrande and Schmidt, 2009; Bowen et al., 2019; Konecky et al., 2019). Thus, future work should integrate proxy system models with water isotope-enabled climate model simulations to develop more quantitative data-model comparisons of the 8.2ka Event. In addition, quantitative metrics like the weighted Cohen’s kappa statistic could be used to quantitatively compare the proxy

reconstructions to the pseudoproxy data derived from climate models (Cohen, 1960; Cohen, 1968; Landis and Koch, 1977; 935 DiNezio and Tierney, 2013).

However, even when attempting to bridge the gap between models and proxy data using proxy system models and quantitative metrics, robust comparisons remain challenging. Characterizing the point-to-point agreement between the observed and simulated climate anomalies fails to address the well-known hydroclimate biases that exist in GCMs, which arise from factors like coarse model resolution, idealized topography, and the unresolved physics of cloud formation and convection. Furthermore, proxy data often captures localized climate signals which may not be representative of regional conditions. In contrast, model data is averaged over the area of a grid cell, which can be large in coarse resolution models. This can lead to non-trivial biases, particularly in coastal regions and regions of complex topography. Ultimately, the incorporation of additional well-dated proxy records that resolve different aspects of hydroclimate, paired with proxy system models, and ensembles of water isotope-enabled climate model simulations of the 8.2ka Event will notably improve our 940 understanding of the characteristics and mechanisms of the tropical hydroclimate response to abrupt climate change events. 945

#### 4.3 Data-Model Comparisons

Subject to the small sample sizes found in the regional data-model comparisons, the results suggest that iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic enrichment pattern in precipitation  $\delta^{18}\text{O}$  in South and East Asia, the muted hydroclimate response in the Maritime Continent, the drying and isotopic enrichment in southern Central America, and the isotopic depletion in precipitation  $\delta^{18}\text{O}$  in parts of northeastern South America. While qualitative, these areas of agreement between the proxies and model demonstrate that the tropical hydroclimate response to North Atlantic meltwater forcing during the 8.2ka Event was not a simple hemispheric dipole pattern, but is instead characterized by rich regional structure.

However, while there is some qualitative agreement between many of the reconstructed and simulated regional hydroclimate anomalies during the 8.2ka Event, our data-model comparisons are subject to a variety of limitations. For starters, our regional analyses are limited by small sample sizes and in some regions like East Asia, the point-to-point agreement between the proxy and model data is low even as the regional hydroclimate patterns offer more nuanced context. In addition, our data-model comparisons are necessarily qualitative as many of the proxy records in our compilation are carbonate  $\delta^{18}\text{O}$  records, which do not solely reflect changes in precipitation  $\delta^{18}\text{O}$ . Rather, these archives incorporate a combination of the isotopic composition of groundwater (for speleothem  $\delta^{18}\text{O}$  records; Lachniet, 2009) or seawater (for marine  $\delta^{18}\text{O}$  records; Konecky et al., 2020) as well as the environmental temperature, among other factors (LeGrande and Schmidt, 2009; Bowen et al., 2019; Konecky et al., 2019). Thus, future work should integrate proxy system models with water isotope-enabled climate model simulations to develop more quantitative data-model comparisons of the 8.2ka Event. In addition, quantitative metrics like the weighted Cohen's kappa statistic could be used to quantitatively compare the proxy 950 955 960

965 reconstructions to the pseudoproxy data derived from climate models (Cohen, 1960; Cohen, 1968; Landis and Koch, 1977; DiNezio and Tierney, 2013).

970 However, even when attempting to bridge the gap between models and proxy data using proxy system models and quantitative metrics, robust comparisons remain challenging. Characterizing the point-to-point agreement between the observed and simulated climate anomalies fails to address the well-known hydroclimate biases that exist in GCMs, which arise from factors like coarse model resolution, idealized topography, and the unresolved physics of cloud formation and convection. Furthermore, proxy data often captures localized climate signals which may not be representative of regional conditions. In contrast, model data is averaged over the area of a grid cell, which can be large in coarse resolution models. This can lead to non-trivial biases, particularly in coastal regions and regions of complex topography. Ultimately, the incorporation of additional well-dated proxy records that resolve different aspects of hydroclimate, paired with proxy system models, and ensembles of water isotope-enabled climate model simulations of the 8.2 ka Event will notably improve our understanding of the characteristics and mechanisms of the tropical hydroclimate response to abrupt climate change events.

975

## 5 Conclusions

980 This study has investigated the tropical hydroclimate response to the 8.2 ka Event in a new multi-proxy data compilation and state-of-the-art isotope-enabled model simulation. Two event detection methods were used in this study. The first method relies on the original age model of each record and uses the 7.9 ka-8.5 ka-8.5 ka-8.5 ka period as the detection window. The second method implements a changepoint detection algorithm that explicitly accounts for age uncertainties in each proxy record. In order to leverage the strengths of each method and provide a more robust reconstruction of the hydroclimate response to the 8.2 ka Event, only records in which events were detected in both event detection methods were used to characterize the hydroclimate response to the 8.2 ka Event.

985 Robust hydroclimate anomalies were detected in 18 records across the 7.9 ka-8.5 ka interval, with z-scores ranging between  $+5.8\sigma$  and  $-4.0\sigma$  in East Asia and southern Central America, respectively. 12 records showed no evidence of a hydroclimate anomaly associated with the 8.2 ka Event. Across the records with a detected hydroclimate event, the remaining records had conflicting results based on the two event detection methods and were excluded from further analysis. Across the records, a mean onset age of  $8.28 \pm 0.12$  ka, mean termination age of  $8.11 \pm 0.09$  ka, and mean duration of  $152 \pm 70$  years ( $1\sigma$ ; with a range of 50 to 289 years) was found, comparing well with previous estimates, and lending support to a regionally variable tropical hydroclimate response to the 8.2 ka Event, with events that span decadal to multi-centennial timescales, and lending support to a regionally variable tropical hydroclimate response to the 8.2 ka Event.

990

995

with events that span decadal to multi-centennial timescales. Importantly, this work is the first to explicitly account for age uncertainty through all phases of the event detection analysis.

The results demonstrate that the tropical hydroclimate response to the North Atlantic meltwater forcing was not a simple hemispherically uniform dipole pattern but is better characterized by rich regional structure. Coherent regional hydroclimate changes identified in the proxy records include pronounced isotopic enrichment across East Asia, South Asia, and the Arabian Peninsula. In the Americas, drying and isotopic enrichment occurred in southern Central America, contrasting with isotopic depletion in central/eastern Brazil. In contrast, no signatures of the 8.2 ka Event were found over the Maritime Continent.

Broad agreement is observed between the reconstructions and iCESM model simulations and the results demonstrate that the tropical hydroclimate response to the North Atlantic meltwater forcing was not a simple hemispherically uniform dipole pattern, but is better characterized by rich regional structure. Coherent regional hydroclimate changes identified in proxy records include pronounced isotopic enrichment across East Asia, South Asia, and the Arabian Peninsula. In the Americas, drying and isotopic enrichment occurred in southern Central America, contrasting with isotopic depletion in central/eastern Brazil. In contrast, no signatures of the 8.2ka Event were found over the Maritime Continent.

Broad agreement is observed between the reconstructions and iCESM model simulations and the results demonstrate that the tropical hydroclimate response to the North Atlantic meltwater forcing was not a simple hemispherically uniform dipole pattern, but is better characterized by rich regional structure. Coherent regional hydroclimate changes identified in proxy records include pronounced isotopic enrichment across East Asia, South Asia, and the Arabian Peninsula. In the Americas, drying and isotopic enrichment occurred in southern Central America, contrasting with isotopic depletion in central/eastern Brazil. In contrast, no signatures of the 8.2ka Event were found over the Maritime Continent.

The isotope-enabled model simulation with iCESM illustrates clear signatures of the global 8.2 ka 2ka 2ka Event that are largely consistent with the proxy records. Large-scale cooling in the Northern Hemisphere and warming in the Southern Hemisphere drives a The characteristic north-south dipole pattern in surface temperature is accompanied by an associated The characteristic north-south dipole pattern in surface temperature is accompanied by an associated southward shift of tropical rainfall but with highly variable regional patterns. On regional scales, however, the tropical rainfall changes are highly variable. On regional scales, however, the tropical rainfall changes are highly variable. Major features include a southward shift of the tropical ocean rain bands in the tropical Atlantic, Central and Eastern Pacific, and Indian Oceans (characterized by a weakening of the northern extent and enhancement of the southern extent of the rainbands), as well as drying in Central America and northern South America and wetter conditions in northeastern Brazil. Modest drying also occurs in the Northern Hemisphere monsoon regions of South Asia and West Africa. The simulated

The isopic composition of tropical precipitation also displays strong signatures of the 8.2 ka 2ka 2ka Event. Over land,  $\delta^{18}\text{O}_{\text{precipitation}}$  displays a pronounced dipole pattern in South America, with isotopic enrichment in

northern South America and isotopic depletion in northeastern Brazil. Large-scale isotopic depletion also occurs over the Arabian Peninsula and South Asia. Over the tropical oceans (namely the tropical Atlantic, Central and Eastern Pacific, and Indian Oceans), a pronounced north-south dipole pattern occurs in  $\delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}_{\text{precipitation}} - \delta^{18}\text{O}$ , with isotopic enrichment corresponding with drier conditions north of the equator and isotopic depletion corresponding with wetter conditions south of the equator. Precipitation amount and  $\delta^{18}\text{O}_{\text{p}} - \delta^{18}\text{O}$  anomalies are more muted in the Western Pacific, Maritime Continent, and Africa. We decompose the simulated  $\delta^{18}\text{O}_{\text{p}}$  response to identify the mechanisms driving these isotopic anomalies in the tropics, finding that changes in amount-weighted  $\delta^{18}\text{O}_{\text{p}}$  arise primarily from seasonal changes

To quantify data model agreement, the proxy records were compared to simulated precipitation  $\delta^{18}\text{O}$ , precipitation amount, and effective moisture (P-E) from co-located sites in four regions with the densest coverage of proxy data: Central America, northeastern South America, East Asia, and Southeast Asia. Subject to the small sample sizes found in the regional data-model comparisons, the results suggest that iCESM captures many of the regional hydroclimate responses observed

To quantify data model agreement, the proxy records were compared to simulated precipitation  $\delta^{18}\text{O}$ , precipitation amount, and effective moisture (P-E) from co-located sites in four regions with the densest coverage of proxy data: Central America, northeastern South America, East Asia, and Southeast Asia. Subject to the small sample sizes found in the regional data-model comparisons, the results suggest that iCESM captures many of the regional hydroclimate responses observed in the isotopic composition of precipitation rather than changes in precipitation, including the large-scale isotopic enrichment pattern in precipitation reconstructions, including the large-scale isotopic enrichment pattern in precipitation seasonality. However, the mechanisms of the seasonal changes in  $\delta^{18}\text{O}_{\text{p}}$  vary regionally, with the local amount effect dominant in  $\delta^{18}\text{O}_{\text{p}}$  in South and East Asia and the Arabian Peninsula, the drying and isotopic enrichment in precipitation  $\delta^{18}\text{O}_{\text{p}}$  in southern Central America, the isotopic depletion in parts of  $\delta^{18}\text{O}_{\text{p}}$  in South and East Asia and the Arabian Peninsula, the drying and isotopic enrichment in precipitation  $\delta^{18}\text{O}_{\text{p}}$  in southern Central America, the isotopic depletion in parts of  $\delta^{18}\text{O}_{\text{p}}$  in northeastern South America, and the northeastern tropical Pacific; while changes in moisture source, circulation patterns, and/or upstream rainout control the response in East Asia; and the addition of isotopically depleted meltwater to the North Atlantic directly contributes to reduced, but isotopically depleted, wet season precipitation through the Caribbean. muted hydroclimate response in the Maritime Continent.

These results serve as a first step toward more quantitative data-model comparisons. Recommendations for future studies include adding more well-dated proxy records that resolve different aspects of hydroclimate during the 8.2ka Event, and quantitatively comparing these records with ensembles of water isotope-enabled climate model simulations of the 8.2ka Event paired with proxy system models. Future work should also investigate the mechanisms of the observed hydroclimate changes and their isotopic signatures to improve our understanding of the characteristics and mechanisms of the tropical hydroclimate response to abrupt climate change events. muted hydroclimate response in the Maritime Continent.

These results serve as a first step toward more quantitative data-model comparisons. Recommendations for future studies include adding more well-dated proxy records that resolve different aspects of hydroclimate during the 8.2ka Event,

and quantitatively comparing these records with ensembles of water isotope-enabled climate model simulations of the 8.2 ka Event paired with proxy system models. Future work should also investigate the mechanisms of the observed hydroclimate changes and their isotopic signatures to improve our understanding of the characteristics and mechanisms of the tropical hydroclimate response to abrupt climate change events.

The proxy records were compared to simulated  $\delta^{18}\text{O}_p$ , precipitation amount, and effective moisture (P-E) from co-located sites in four regions with the densest coverage of proxy data: southern Central America, northeastern South America, East Asia, and Southeast Asia. Subject to the small sample sizes found in the regional data-model comparisons, the results suggest that iCESM captures many of the regional hydroclimate responses observed in the reconstructions, including the large-scale isotopic enrichment pattern in  $\delta^{18}\text{O}_p$  in South and East Asia and the Arabian Peninsula, the drying and isotopic enrichment in  $\delta^{18}\text{O}_p$  in southern Central America, the isotopic depletion in parts of northeastern South America, and the muted hydroclimate response in the Maritime Continent.

These results serve as a first step toward more quantitative data-model comparison studies. Recommendations for future studies include adding more well-dated proxy records that resolve different aspects of hydroclimate during the 8.2 ka Event, and quantitatively comparing these records with ensembles of water isotope-enabled climate model simulations of the 8.2 ka Event paired with proxy system models. Future work should also investigate the physical mechanisms of the simulated hydroclimate responses and their isotopic signatures to improve our understanding of the tropical hydroclimate response to abrupt climate change events.

1080 *Author contributions.* ARA and ALM conceptualized the study, with ARA securing funding and providing supervision. ALM performed proxy data curation and led the proxy data analysis with contributions from RP. ALM performed the iCESM simulations and led the writing of the manuscript and the design of figures with contributions from ARA.

Competing interests. The authors declare that they have no conflict of interest.

1085 *Acknowledgements.* This work was supported by NSF-EAR 2002444 to ARA. Computing resources were provided to ALM by the Climate Simulation Laboratory at NCAR's Computational and Information Systems Laboratory (CISL). We gratefully acknowledge Julian Sachs for providing early inspiration for the project as well as Jiang Zhu at NCAR for his assistance setting up the iCESM simulations. We also gratefully acknowledge the PMIP4 Community and the Linked Earth team, including Nick McKay and Julien Emile-Geay, for providing access to and invaluable assistance with actR (<https://github.com/LinkedEarth/actR>).

| **Figures**

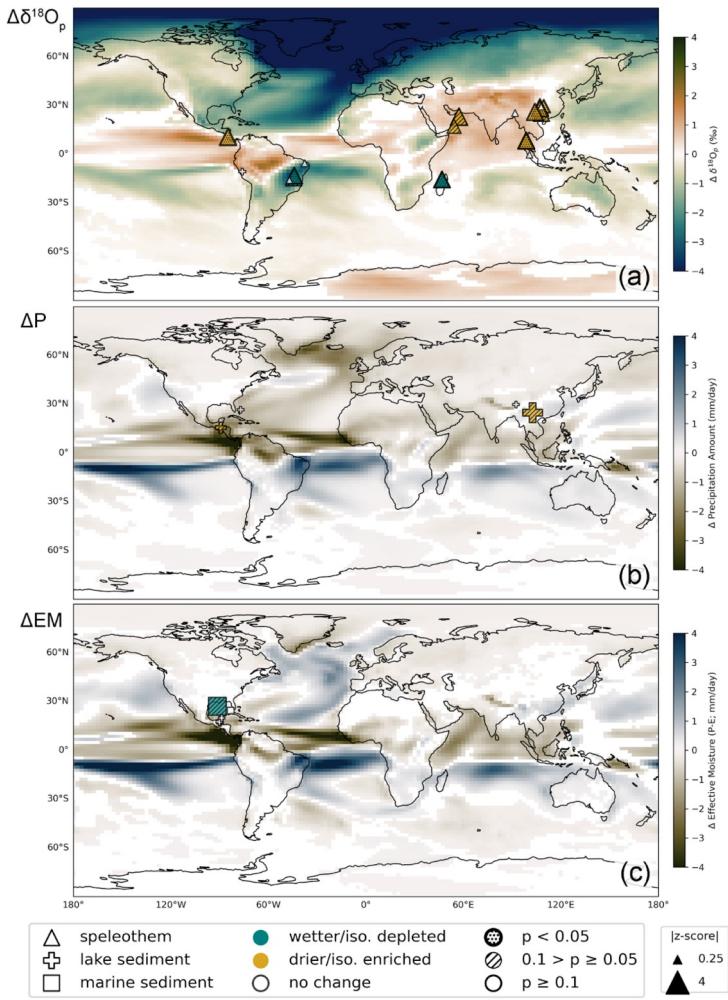

| **Figure 1.** The location of the proxy records comprising each hydroclimate interpretation group included in this study.

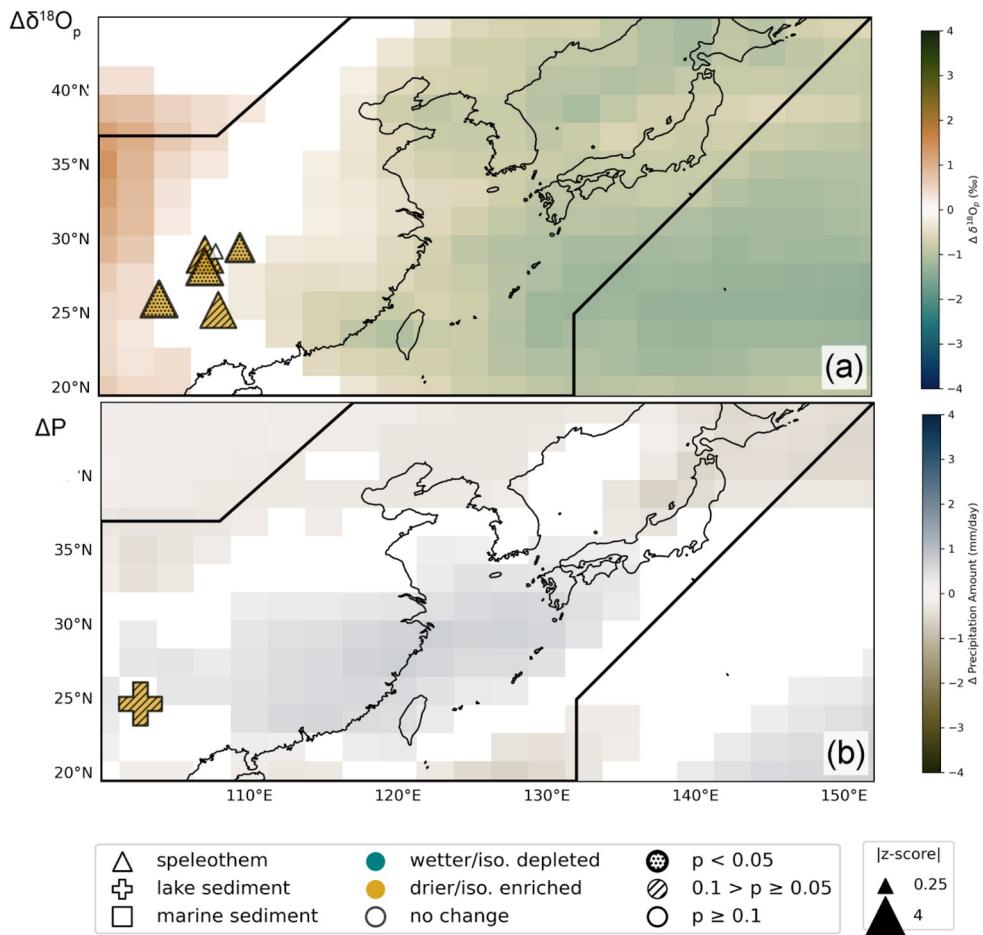

**Figure 2.** A schematic illustration of the actR analysis process. Step 1: Relevant records are identified and collated into our compilation based on the criteria outlined in the Methods (see Tables 1 and 2). Records are then converted to the LiPD file format for analysis. Step 2: A 1000-member age model ensemble is developed using geoChronR, or, where available for the speleothem records, drawn from the ensembles presented in version 2 of the SISAL database (Comas-Bru et al., 2020). This allows us to propagate age uncertainties through each successive analysis step. Step 3: The resulting 1000-member ensemble time series is then plotted, where at each time step, the median is represented by the black line, the outermost (lighter) bands represent extreme quantile values (0.025, 0.975) and the innermost (darker) bands the central quantile values (0.25, 0.75). The data are fit to a Gaussian distribution, and the change point analyses are conducted across this ensemble to determine the timing of change points in the proxy data. Step 4: The significance of the detected change points is tested by performing the same change point analyses against 100 isospectral surrogate time series, and the frequency of shifts is plotted as a histogram summarized in 10-year-long bins. The 90% and 95% confidence intervals are plotted as light and dark orange lines, respectively, and the p-value is indicated when the frequency of shifts exceeds the 90% confidence interval.

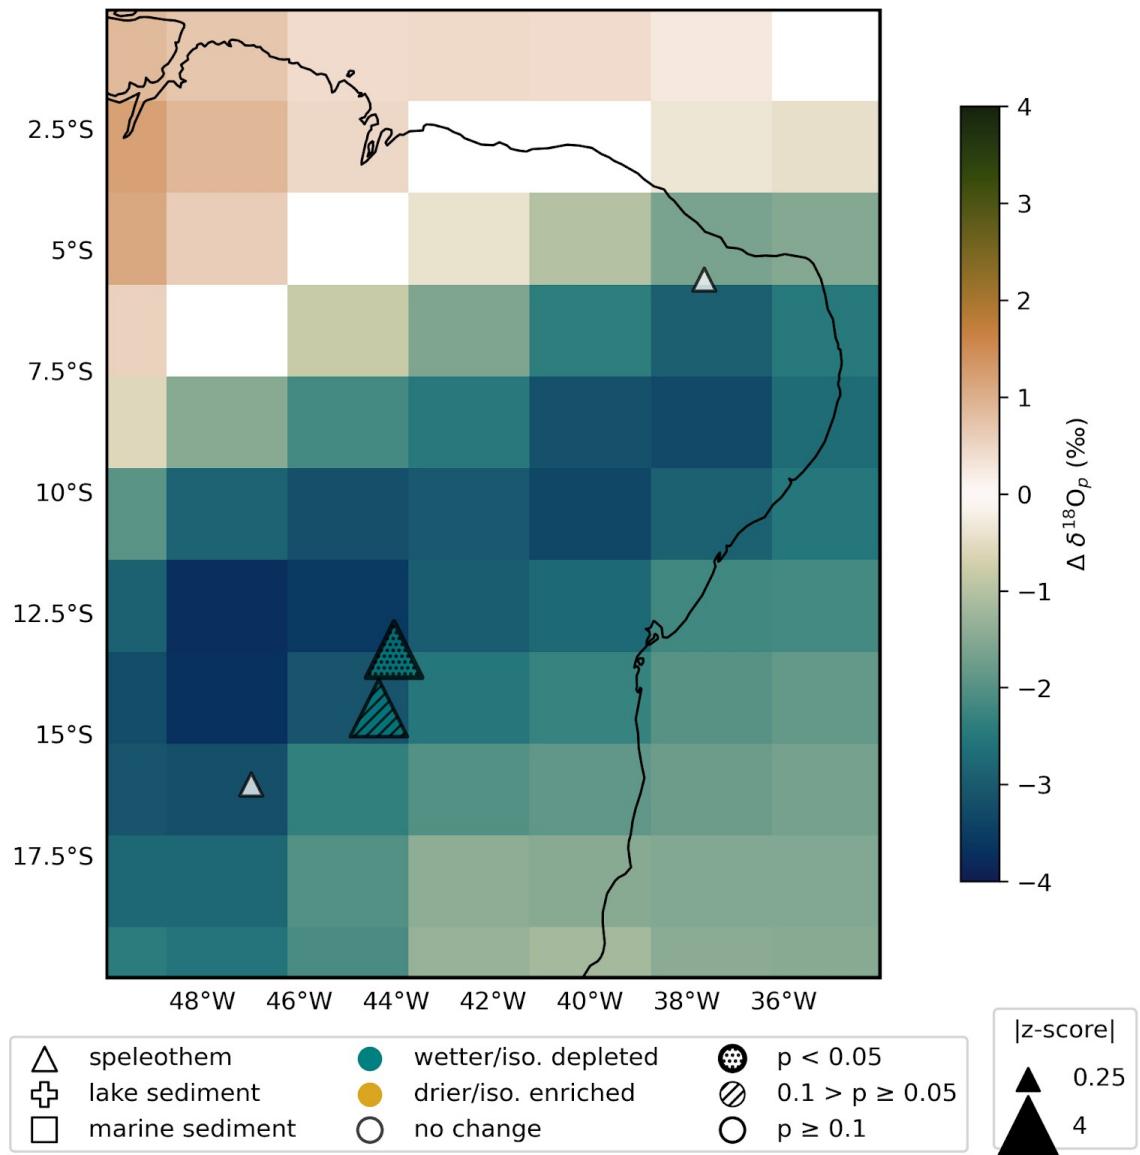

1480 **Figure 3.** (a) Map of the detected 8.2 ka hydroclimate events using the modified Morrill et al. (2013) method (MM). Blue symbols  
 represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions.  
 Grey symbols indicate the locations of proxy data where no significant change was detected. Archive type is indicated by the symbol  
 shape, and symbol size is scaled by  $250\ln(1+|z\text{-score}|)$ , calculated from the per-record mean and standard deviation over the 7 ka-10 ka  
 interval. Stippling indicates an event detected over the 7.9 ka-8.5 ka detection window. (b) Same as for (a) but using the actR event  
 detection method. Here, stippling indicates that a "significant" event was detected in each record by actR with event "start" and "end"  
 1485 times within the 7.9 ka-8.3 ka interval at the  $p < 0.05$  significance level. Slashed hatching indicates the presence of a "tentative"  
 hydroclimate anomaly, defined by two consecutive changepoints with  $p < 0.1$  over an extended 7.7 ka-8.5 ka window (see Methods).

1490 **Figure 4.** As in Fig. 3b, but with the proxy symbols overlaid on contour maps of the simulated anomalous (a) amount-weighted  $\delta^{18}\text{O}_p$ , (b) precipitation amount, and (c) effective moisture (P-E), calculated from the difference between the last 50 years of the iCESM “hose” and “ctrl” experiments, where only anomalies that exceed the 95% confidence level ( $p < 0.05$ ) are plotted.

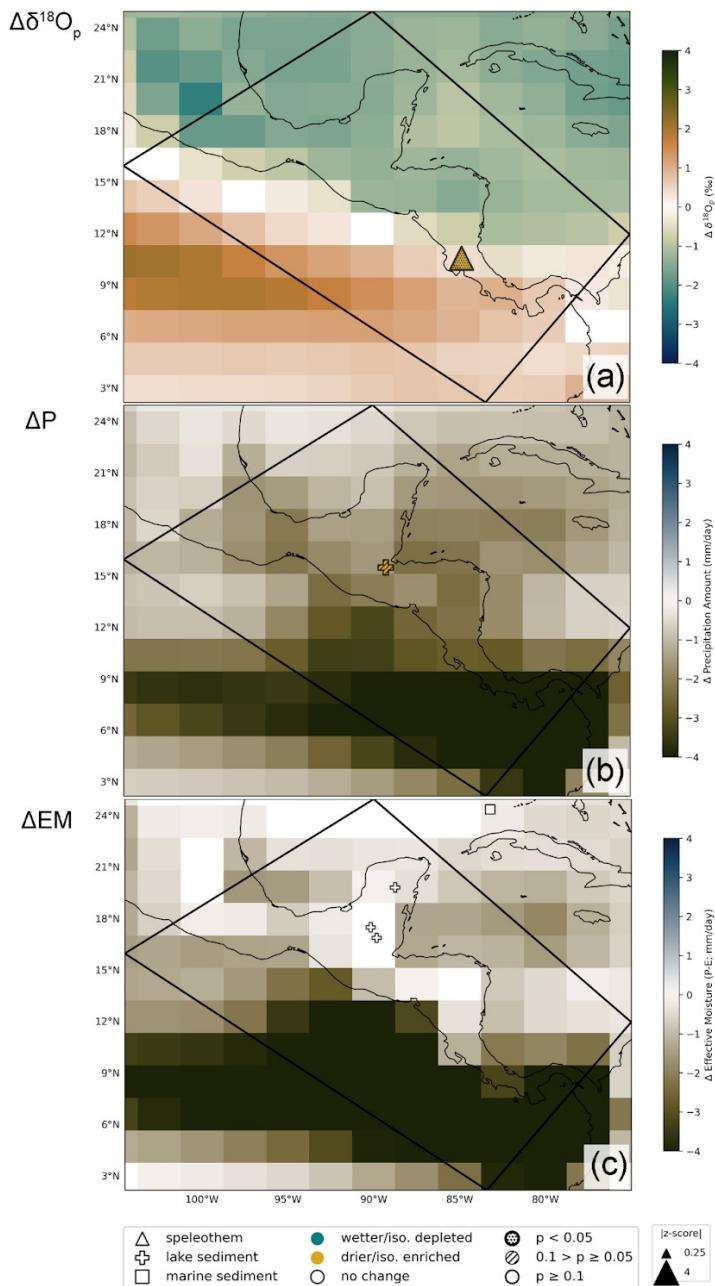

**Figure 5.** Data-model comparison of IPCC region 35: East Asia (box). Model shading represents (a) the precipitation amount-weighted  $\delta^{18}\text{O}$  anomaly, and (b) the precipitation amount anomaly between the last 50 years of the “hose” and “ctrl” simulations that exceed the 95% confidence level ( $p < 0.05$ ) using an unpaired two sample Student’s t-test. Symbols represent paleoclimate proxy archives within the region corresponding to each respective climate variable, where the brown shaded triangles indicate speleothem records with recorded dry hydroclimate/enriched isotopic anomalies during the 8.2 ka Event and grey symbols indicate records with no hydroclimate anomalies (“no change”) over the 7.9 ka-8.3 ka interval. For symbols showing an anomaly associated with the 8.2 ka Event, size is scaled by  $400\ln(1+|z\text{-score}|)$  relative to each record’s mean and standard deviation.

**Figure 6.** As in Fig. 5, but for IPCC region 11: northeastern South America (box). Model shading represents the precipitation-weighted  $\delta^{18}\text{O}$  anomaly between the last 50 years of the “hose” and “ctrl” simulations.

**Figure 1.** The distribution of proxy records comprising each interpretation group included in this study.

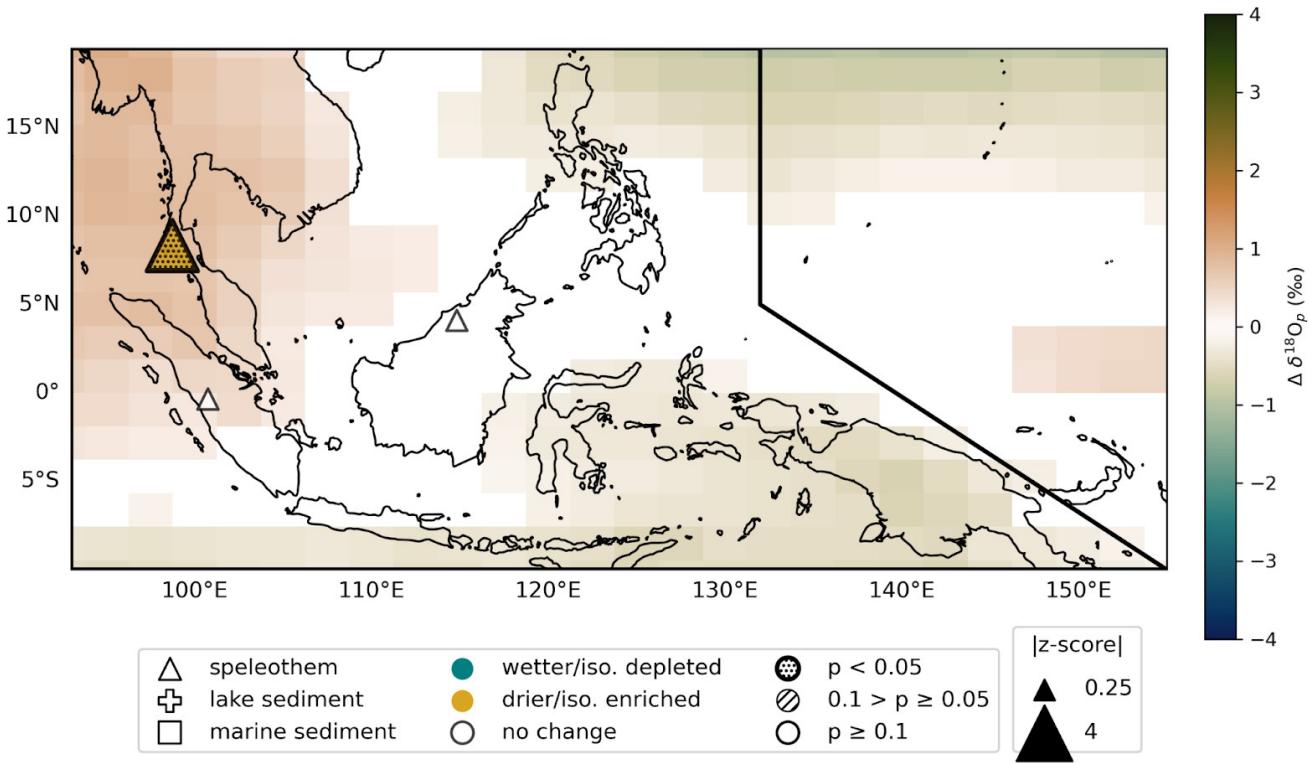

**Figure 7.** As in Fig. 5, but for IPCC region 7: southern Central America (box), with the addition of (c) the effective moisture (precipitation minus evaporation) anomaly between the last 50 years of the “hose” and “ctrl” simulations.

1515 **Figure 2.** (a) Tropical hydroclimate anomalies detected in proxy archives over the 7.9–8.5ka interval using the method described in Morrill et al. (2013). Blue symbols represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions relative to each record's mean climatology over the 7.4–7.9ka and 8.5–9.0ka windows described in the text. Grey symbols indicate the locations of proxy data where no significant 8.2ka hydroclimate event was detected. Symbol size is scaled by  $100 \times |z\text{-score}|$ , calculated from the per record mean and standard deviation over the 7ka–10ka interval. (b) Tropical hydroclimate anomalies detected in proxy archives over the 7.9–8.3ka (“significant”) and 7.7–8.5ka (“tentative”) intervals. Blue symbols represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions relative to each record's mean climatology over 7ka–10ka. Grey symbols indicate the locations of proxy data where no significant 8.2ka hydroclimate event was detected. Symbol size is scaled by  $100 \times |z\text{-score}|$ , calculated from the per record mean and standard deviation over the 7ka–10ka interval.

1520 **Figure 2.** (a) Tropical hydroclimate anomalies detected in proxy archives over the 7.9–8.5ka interval using the method described in Morrill et al. (2013). Blue symbols represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions relative to each record's mean climatology over the 7.4–7.9ka and 8.5–9.0ka windows described in the text. Grey symbols indicate the locations of proxy data where no significant 8.2ka hydroclimate event was detected. Symbol size is scaled by  $100 \times |z\text{-score}|$ , calculated from the per record mean and standard deviation over the 7ka–10ka interval. (b) Tropical hydroclimate anomalies detected in proxy archives over the 7.9–8.3ka (“significant”) and 7.7–8.5ka (“tentative”) intervals. Blue symbols represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions relative to each record's mean climatology over 7ka–10ka. Grey symbols indicate the locations of proxy data where no significant 8.2ka hydroclimate event was detected. Symbol size is scaled by  $100 \times |z\text{-score}|$ , calculated from the per record mean and standard deviation over the 7ka–10ka interval.

1535

**Figure 8.** As in Fig. 5, but for IPCC region 38: Southeast Asia (box). Model shading represents the precipitation amount-weighted  $\delta^{18}\text{O}$  anomaly between the last 50 years of the “hose” and “ctrl” simulations.

**Figure 3.** Summary of the 8.2 ka events detected using our modified Morrill et al. (2013) method (MM; left) and aetR (right) for the paleoclimate records included in this study. Records with drier and/or isotopically enriched events are shown in brown, records with wetter and/or isotopically depleted events are shown in green, and records in which no event was detected are shown in grey. Stippling indicates that a “significant” event was detected in a given record by aetR with event “start” and “end” times within the 7.9–8.3 ka interval at the  $p < 0.05$  significance level. Slashed hatching indicates the presence of a “tentative” hydroclimate anomaly, with either a “significant” event detected outside of the 7.9–8.3 ka window (between 7.7–8.5 ka) or an event within that window where  $0.1 > p \geq 0.05$ . The archive type is indicated by the symbol (triangle = speleothem, plus = lake sediment, square = marine sediment). Symbol size is scaled by  $100 \times |z\text{-score}|$ , calculated from the per-record mean and standard deviation over the 7 ka–10 ka interval. Symbols are shown mapped over the simulated anomalous (a, d) amount-weighted oxygen isotopic composition of precipitation, (b, e) precipitation amount, (c, f) and effective moisture from the last 50 years of the iCESM “hose” and “ctrl” experiments.

1560 **Figure 4.** Data-model comparison of IPCC region 35: East Asia (box). Model shading represents (a) the  
 1565 precipitation amount-weighted  $\delta^{18}\text{O}$  anomaly, (b) the precipitation amount anomaly, and (c) the effective  
 moisture (precipitation minus evaporation) between the last 50 years of the “hose” and “etrl” simulations.  
 Symbols represent paleoclimate proxy archives within the region corresponding to each respective climate  
 variable, where the brown shaded triangles indicate speleothem records with recorded dry  
 hydroclimate/enriched isotopic anomalies during the 8.2ka Event and grey symbols indicate records with no  
 hydroclimate anomalies (“no change”) over the 8.3–7.9ka interval. For symbols showing an anomaly  
 associated with the 8.2ka Event, size is scaled by  $200 \times |z\text{-score}|$  relative to each record’s mean and standard

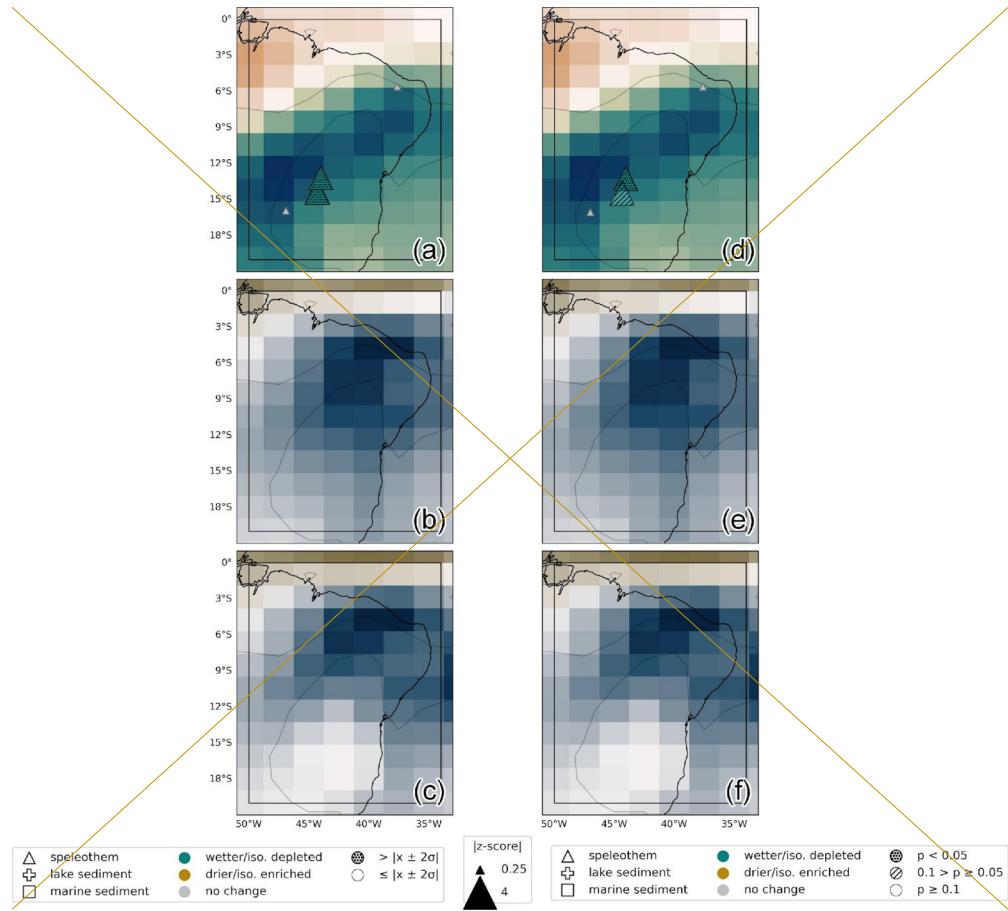

deviation.

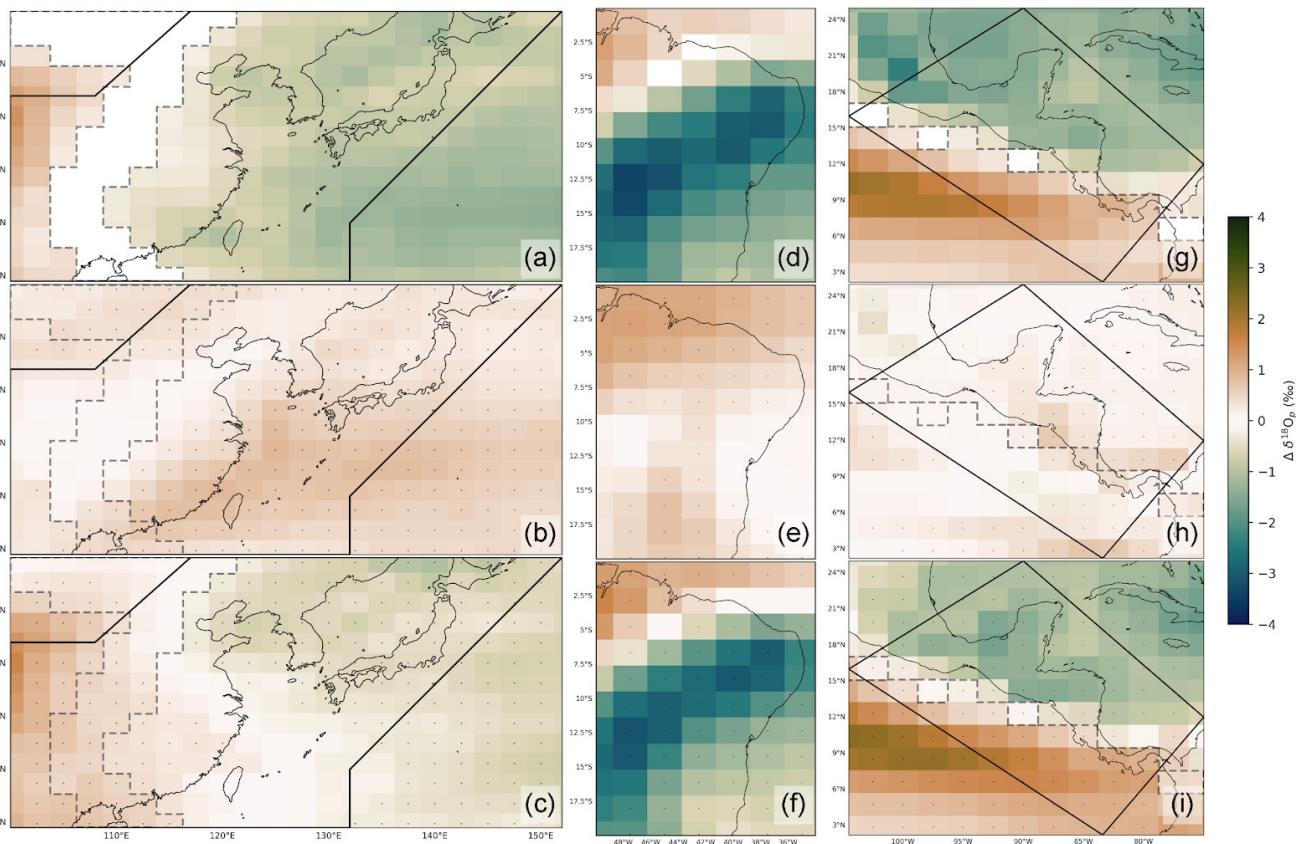

**Figure 9.** The contribution of (a) the changes in the amount of monthly precipitation and (b) the monthly changes in  $\delta^{18}\text{O}_p$  to the total change in mean annual amount-weighted  $\delta^{18}\text{O}_p$  between the last 50 years of the “hose” and “ctrl” simulations. Stippling represents data plotted at the 95% confidence level ( $p < 0.05$ ).

**Figure 5.** As in Fig. 4, but for IPCC region 11: northeastern South America (box).

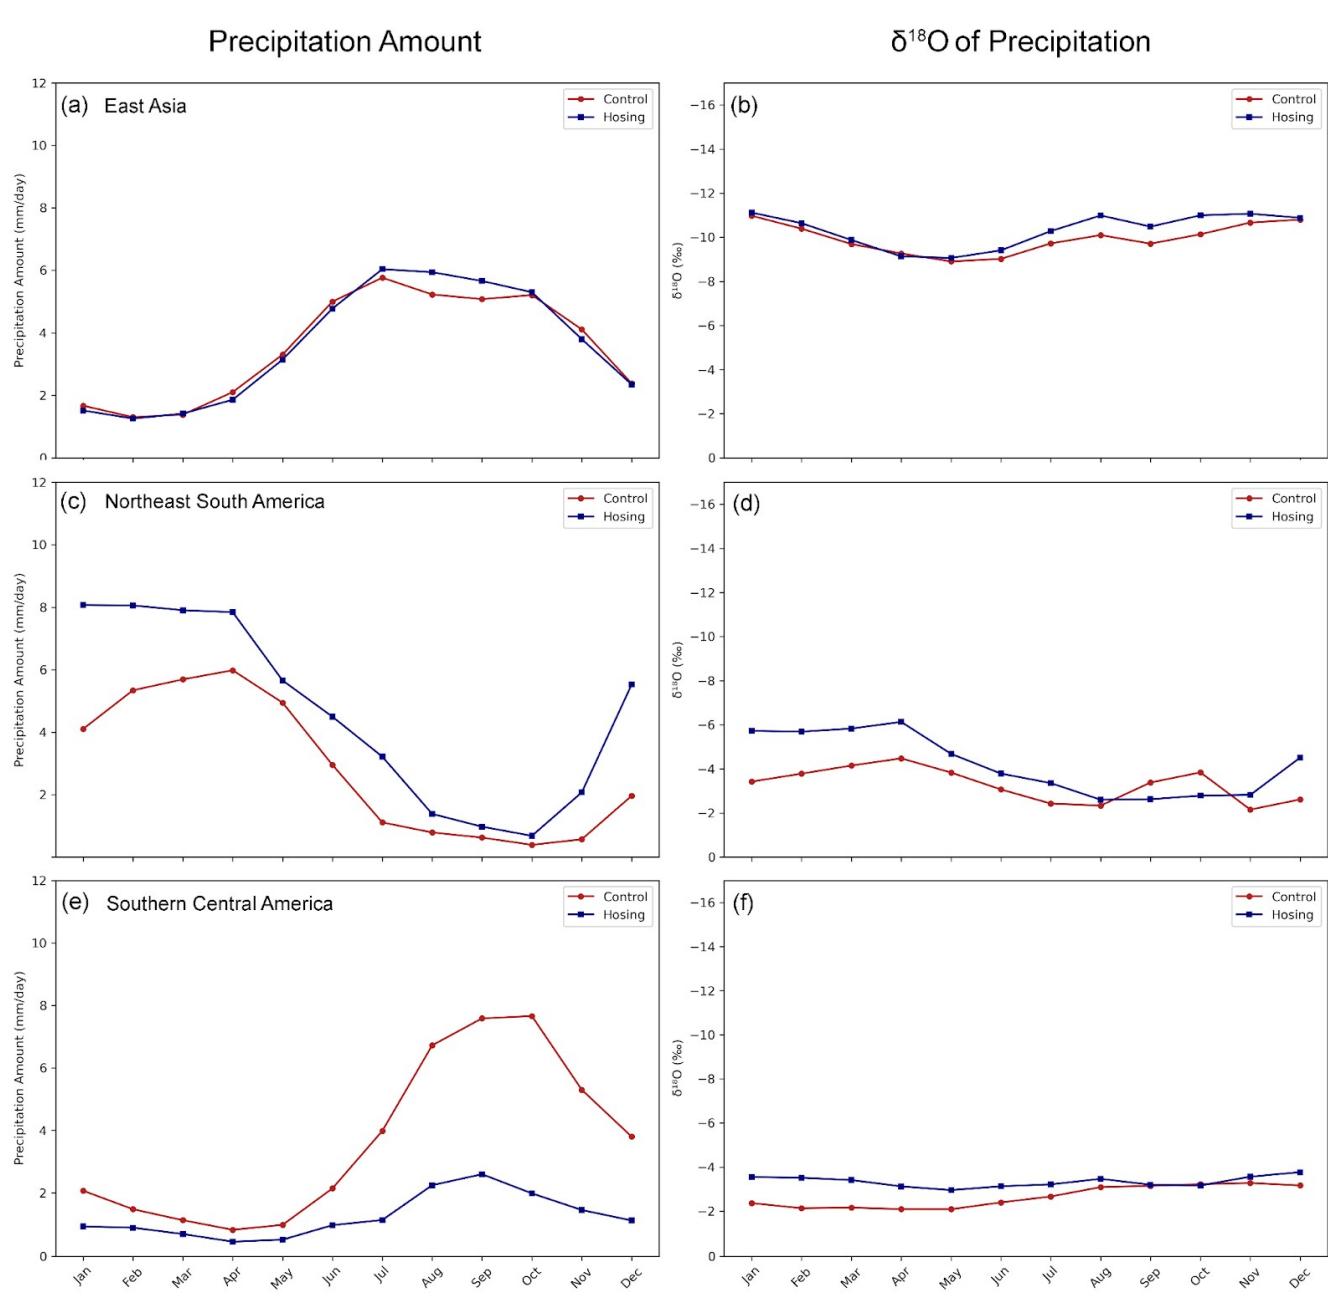

**Figure 6.** As in Fig. 4, but for IPCC region 7: southern Central America (box).

1620

**Figure 10.** As in Fig. 9, but for East Asia (left column; a,b,c), northeast South America (middle column; d,e,f), and southern Central America (right column; g,h,i). The panels in the upper row show the annual amount-weighted  $\delta^{18}\text{O}_p$  anomaly of each region, as plotted in Fig. 4a. The panels in the middle and bottom rows depict the same data as in Fig. 9a and b, respectively, at the regional level. The unfilled black polygons (exterior) represent the boundaries of each region defined by the IPCC. The grey dotted lines subdivide East Asia and southern Central America into E-W and N-S subregions defined by the distinct  $\Delta\delta^{18}\text{O}_p$  dipoles shown in panels (a) and (g), respectively.

**Table 2.** Archive and interpretation metadata for the paleoclimate proxy datasets used in this study. Tier 1 data meet all strict inclusion criteria, while Tier 2 data are deficient in either dating or data resolution over the 7ka-10ka interval. Tier 3 data meet none of the strict inclusion criteria and are not included in quantitative analyses. All foraminifera used in the compilation are *G. ruber* (white). BSi MAR is the biogenic silica mass accumulation rate, in  $\text{mg SiO}_2 \text{cm}^{-2} \text{yr}^{-1}$ .

**Table 2.** Archive and interpretation metadata for the paleoclimate proxy datasets used in this study. Tier 1 data meet all strict inclusion criteria, while Tier 2 data are deficient in either dating or data resolution over the 7ka–10ka interval. Tier 3 data meet none of the strict inclusion criteria and are not included in quantitative

analyses. All foraminifera used in the compilation are *G. ruber* (white). BSi MAR is the biogenic silica mass accumulation rate, in mg SiO<sub>2</sub>/cm<sup>2</sup>yr.

## Appendix B

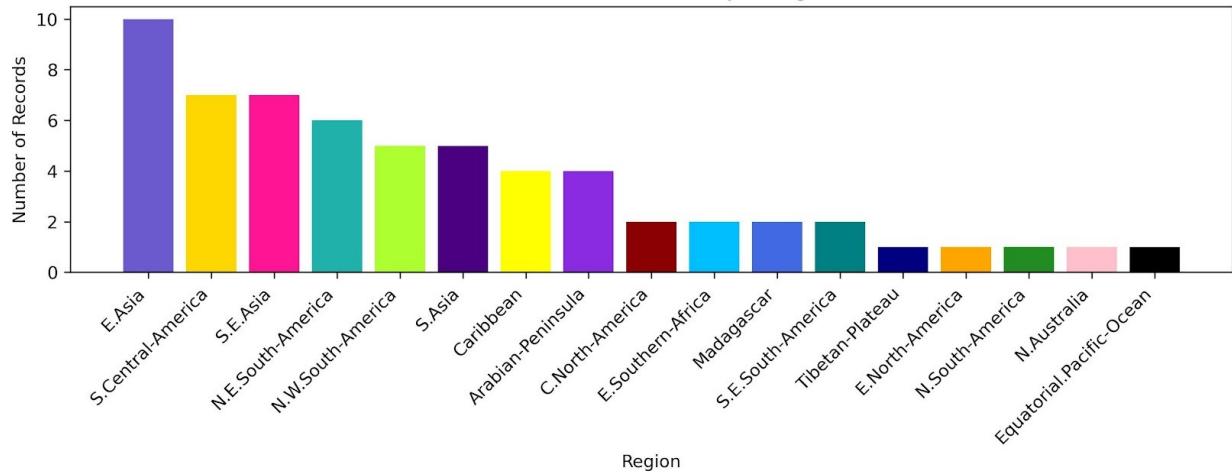

**Figure B1.** A schematic illustrating the application of our modified Morrill method to (a) the speleothem record of Lachniet et al., 2004 (V1) and (b) the record of Zhang et al., 2013 (LH2). The green and purple shading represents  $\bar{x} \pm 2\sigma$  in each reference window (7.4 ka-7.9 ka and 8.5 ka-9.0 ka, respectively). The top panel highlights an anomalous isotopic enrichment event which is composed of three separate “events” (separated by < 20 years). As per the event detection methods, these events have been consolidated into a single 8.2 ka Event (8.058 ka-8.124 ka) with the event magnitude given by the maximum absolute z-score over this period (+3.4 $\sigma$ ). The bottom panel shows multiple events of opposing signs within the detection window: an anomalous isotopic depletion (-1.4 $\sigma$ , 8.208 ka-8.221 ka) and an anomalous enrichment (+2.1 $\sigma$ , 8.129 ka-8.138 ka). As per the event detection methods, the event with the larger absolute z-score is taken to represent the 8.2 ka Event.

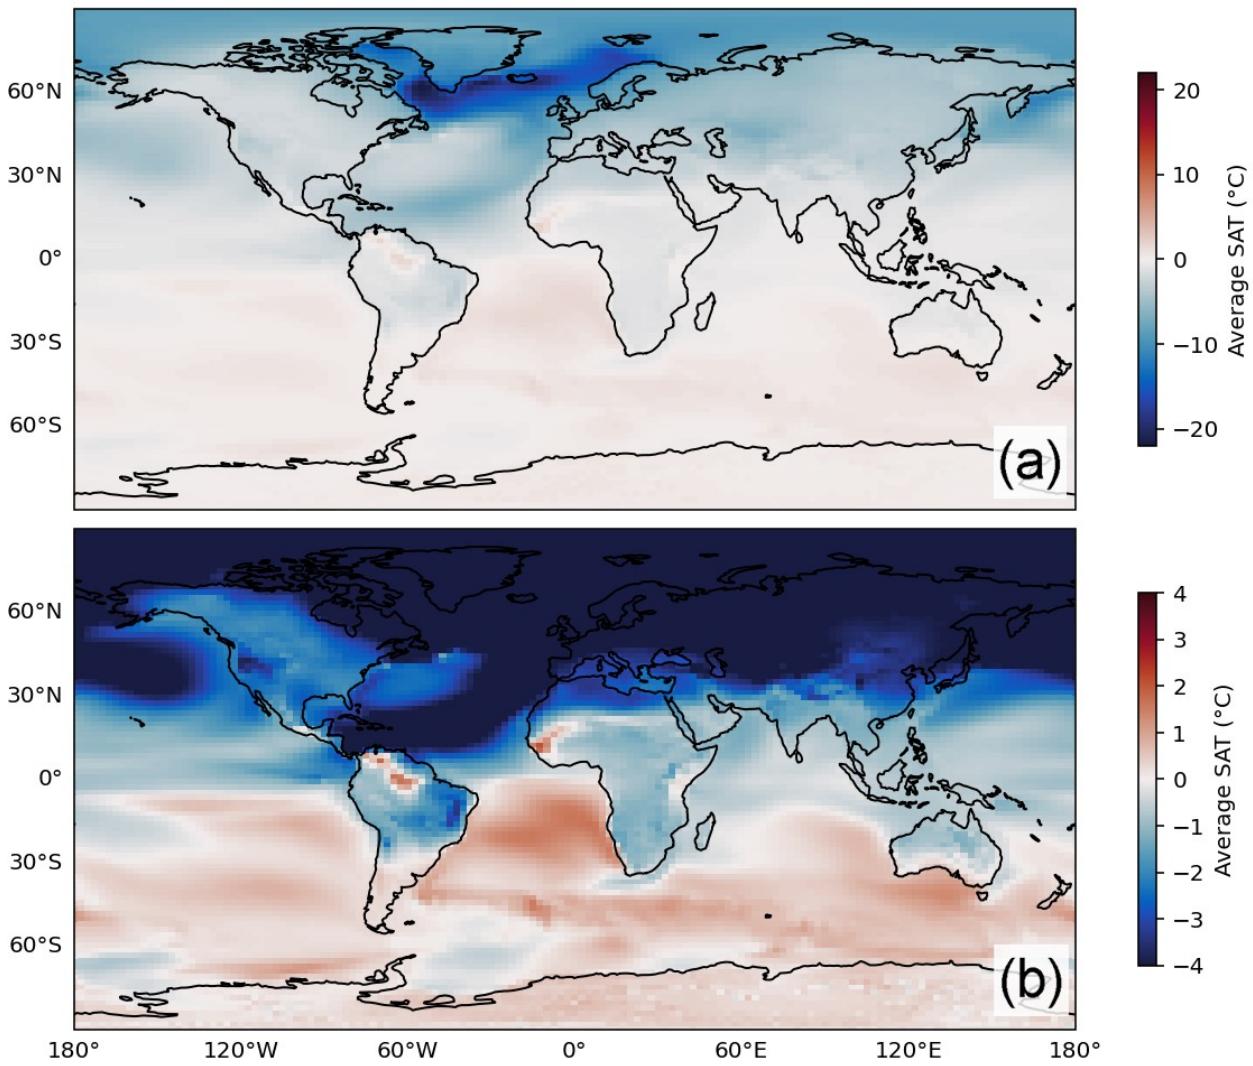

Global Map of Records within IPCC Regions

Total Number of Records per Region

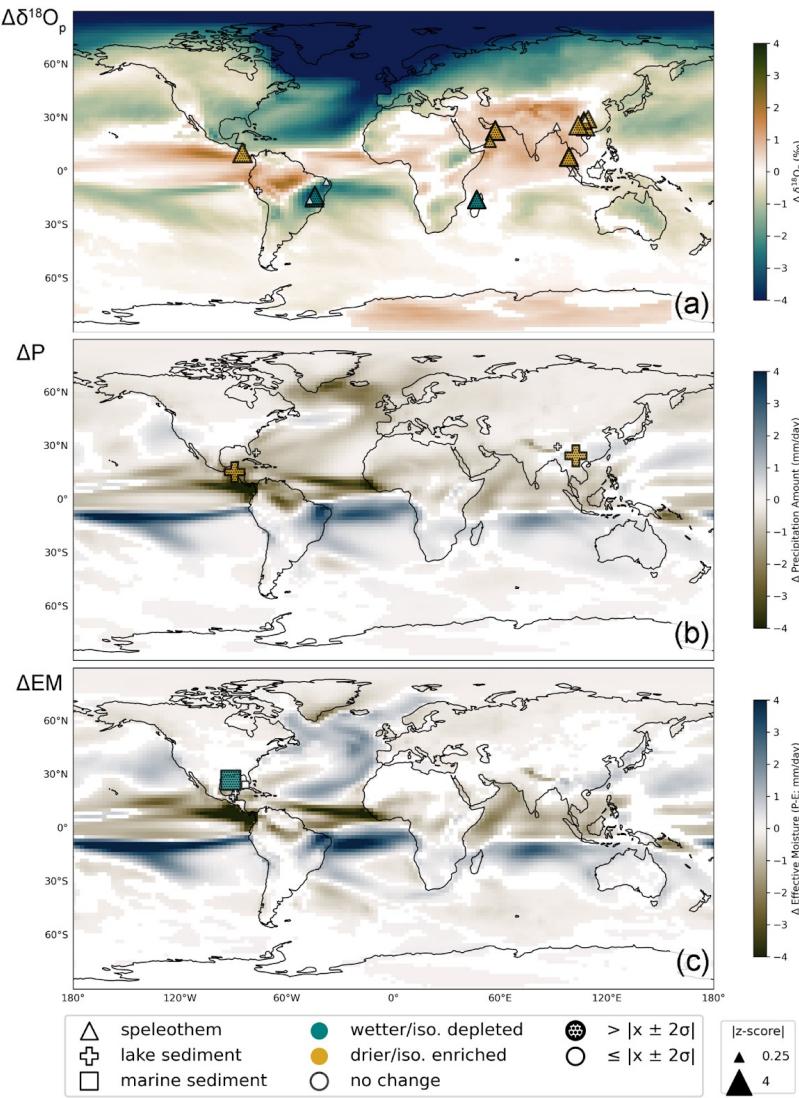

**Figure B2.** Locations of proxy records within climate reference regions defined in Iturbide et al. (2020).

1750

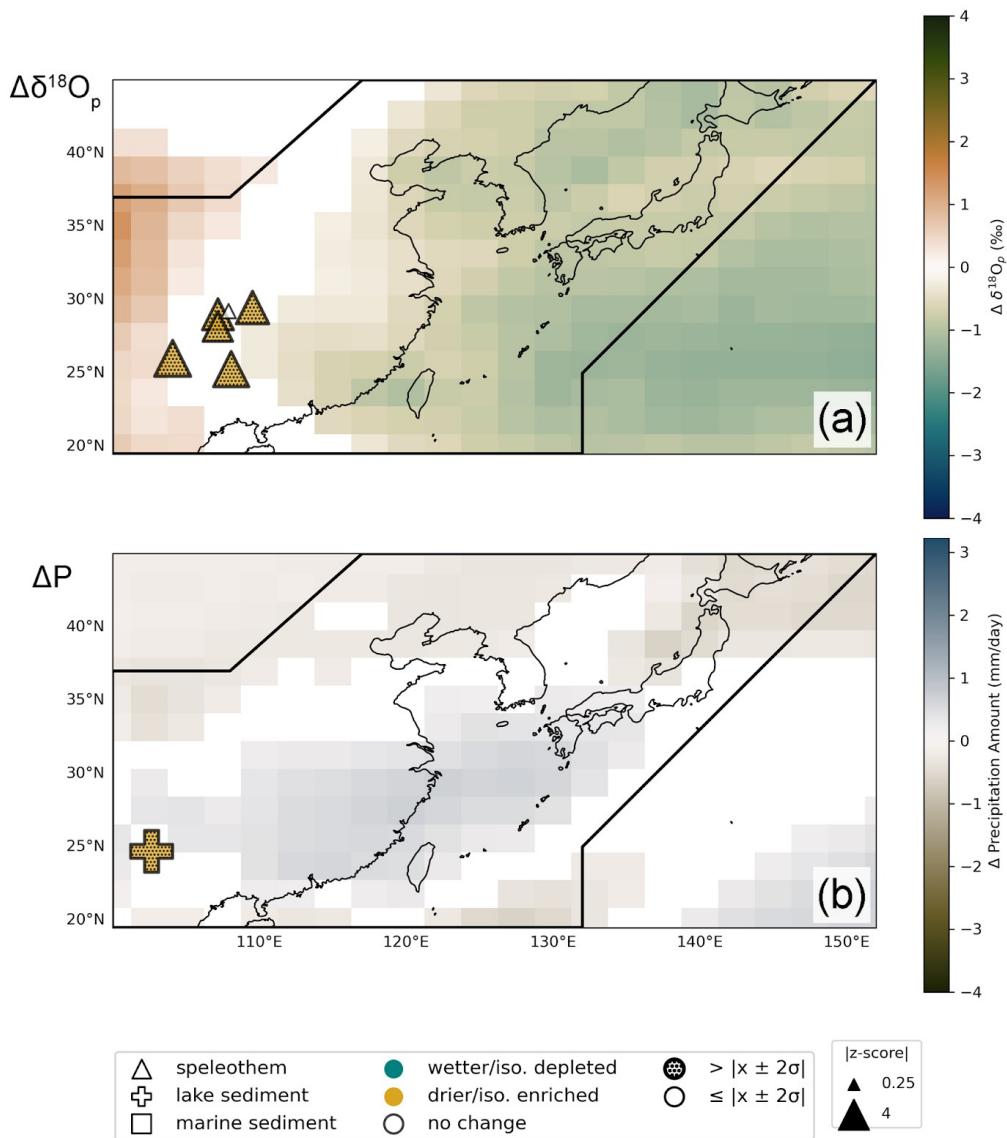

**Figure B3.** The difference in surface air temperatures between the last 50 years of the "hose" and "ctrl" simulations. Blue shaded areas represent anomalously cold regions, while anomalously warm regions are shaded in red on a global (a) and (b) tropical level.

1755

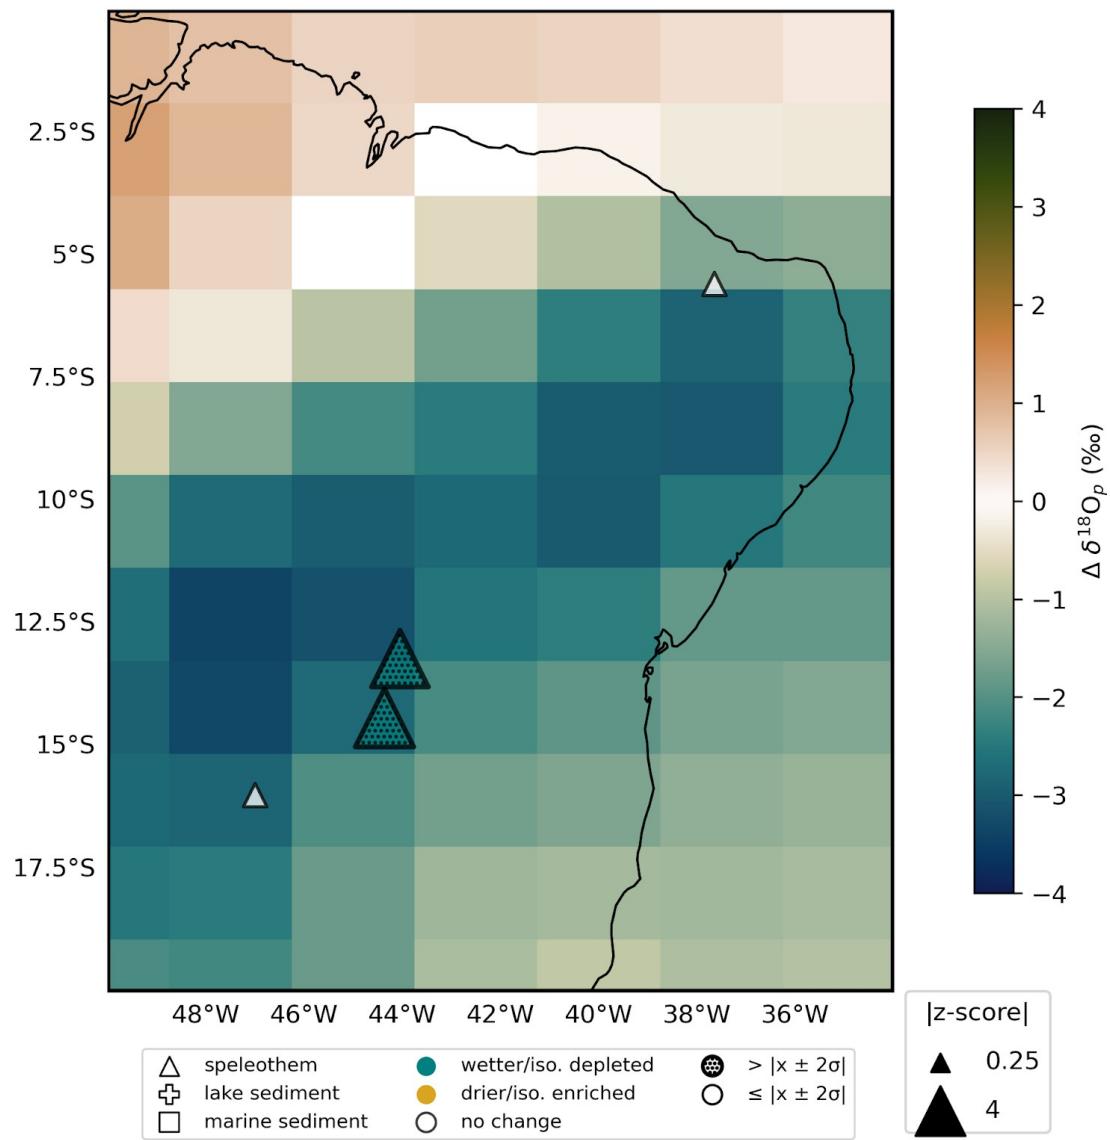

**Figure B4.** Summary of the 8.2 ka events detected using our modified Morril et al. (2013) method for the paleoclimate records showing agreement with actR (Fig. 4) in the direction of change. Blue symbols represent wetter (and/or isotopically depleted) conditions while brown symbols represent drier (and/or isotopically enriched) conditions relative to each record's mean climatology over the 7.4 ka-7.9 ka and 8.5 ka-9.0 ka windows described in the text. For records in which no event was detected, symbols are shown in white. The archive type is indicated by the symbol shape, and the symbol size is scaled by  $250\ln(1+|z\text{-score}|)$ . The proxy symbols are overlaid on a contour map of the simulated anomalous (a) amount-weighted  $\delta^{18}\text{O}_p$ , (b) precipitation amount, and (c) effective moisture (P-E), calculated from the difference between the last 50 years of the iCESM "hose" and "ctrl" experiments, where only anomalies that exceed the 95% confidence level ( $p < 0.05$ ) are shown.

1760

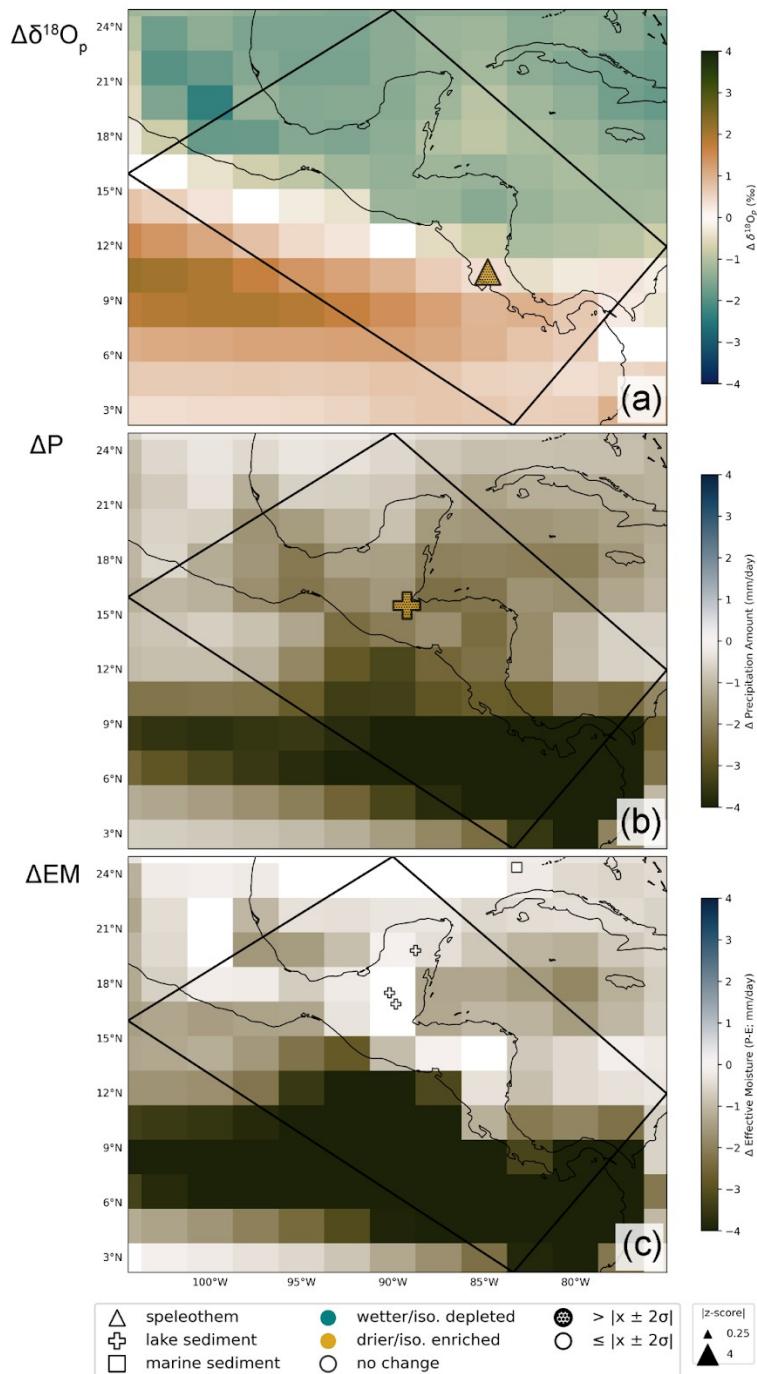

1765 **Figure B5.** Data-model comparison of IPCC region 35: East Asia (box). Model shading represents (a) the amount-weighted  $\delta^{18}\text{O}_p$  anomaly, and (b) the precipitation amount anomaly between the last 50 years of the "hose" and "ctrl" simulations that exceed the 95% confidence level ( $p < 0.05$ ). Symbols represent paleoclimate proxy archives within the region corresponding to each respective climate variable, where the brown shaded triangles indicate speleothem records with recorded dry hydroclimate/enriched isotopic anomalies during the 8.2 ka Event and grey symbols indicate records with no hydroclimate anomalies ("no change") relative to each record's mean climatology over the 7.4 ka-7.9 ka and 8.5 ka-9.0 ka windows used in our modified Morrill et al. (2013) method. For symbols showing an anomaly associated with the 8.2 ka Event, size is scaled by  $400\ln(1+|z\text{-score}|)$  relative to each record's mean and standard deviation.

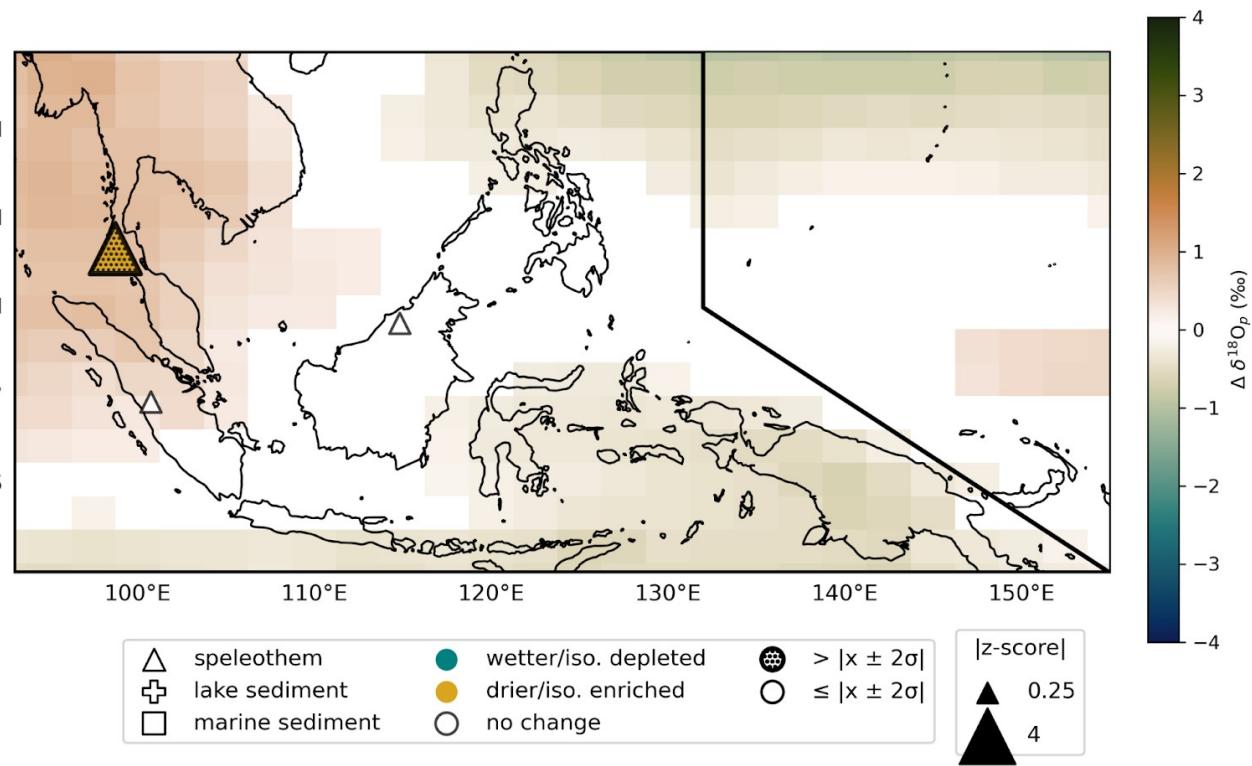

1770

**Figure B6.** As in Fig. B5, but for IPCC region 11: northeastern South America (box).

**Figure B7.** As in Fig. B5, but for IPCC region 7: southern Central America (box), with the addition of (c) the effective moisture (precipitation minus evaporation) anomaly between the last 50 years of the “hose” and “ctrl” simulations.

**Figure B8.** As in Fig. B5, but for IPCC region 38: Southeast Asia.

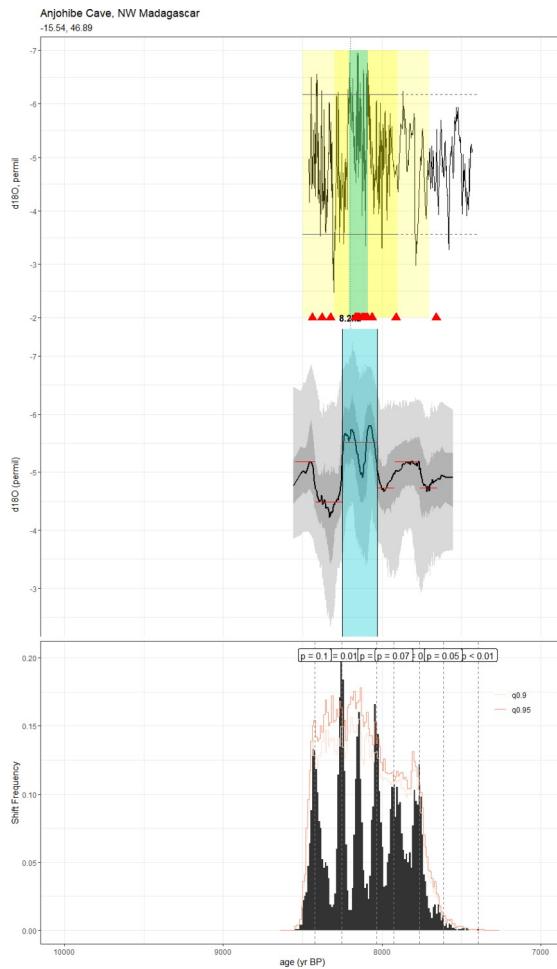

1780

1785

1790

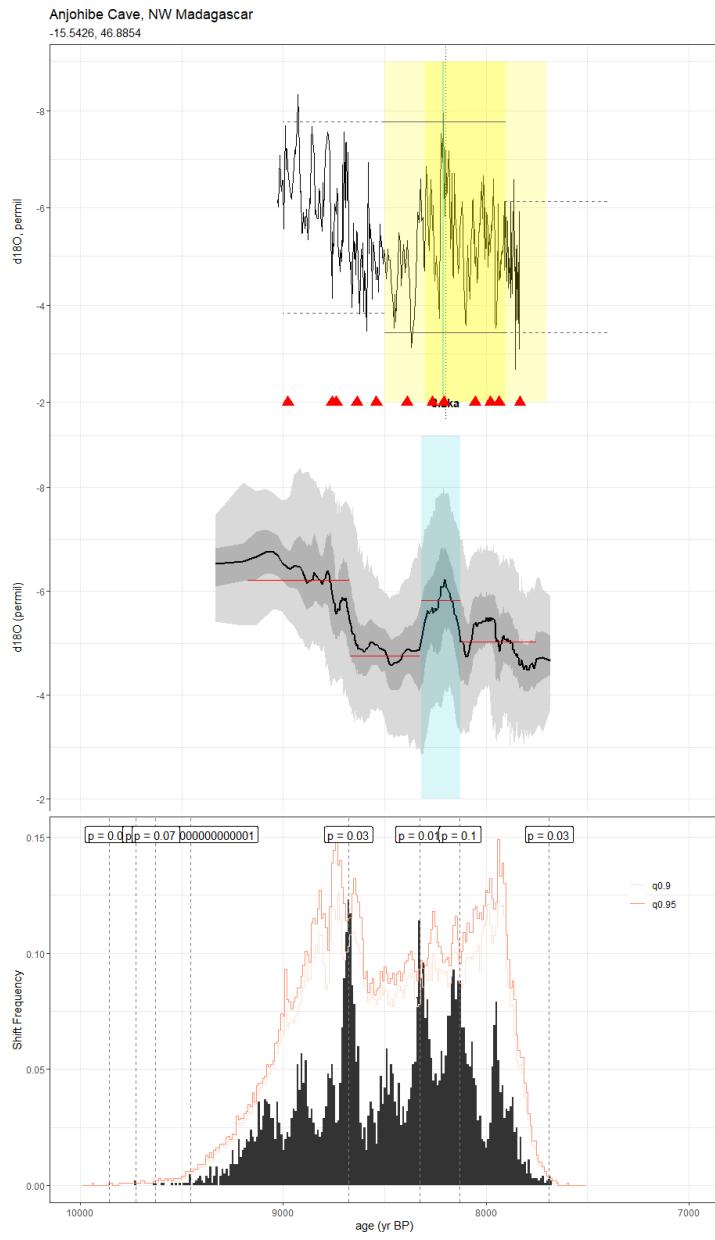

## Appendix C: actR-MM stackplots

### C1 Records with wet/depletion events in both actR and MM

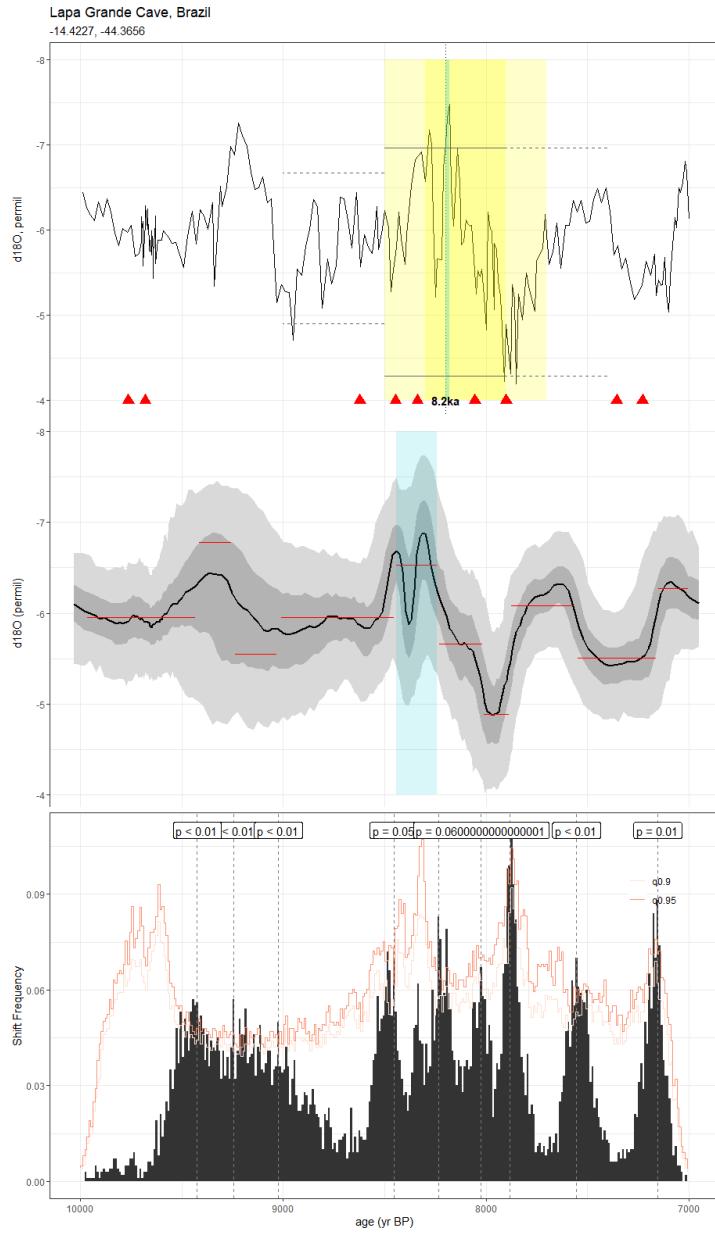

1795 **Figure C1.** A stackplot from the speleothem record of Duan et al., 2021 (ABC1). The top panel shows the raw oxygen isotope time series with 7.9 ka-8.3 ka highlighted in darker yellow and 7.7 ka-8.5 ka highlighted in lighter yellow (see schematic in Fig. B1 for more information). The middle panel shows the same time series with age and paleodata ensemble uncertainty quantile ribbons, where the outermost (lighter) bands represent extreme values and the innermost (darker) bands central values. The horizontal red lines represent mean values assigned to the data by actR, with discontinuities indicating significant changepoints. The lower panel depicts the frequency of shifts detected in the ensemble dataset (black) relative to 100 null hypothesis surrogate datasets (orange). Light and dark orange histogram lines represent confidence levels at 90% and 95%, respectively. Dashed vertical lines give the p-values of detected shifts in mean at the  $\alpha = 0.10$  level. The age model in the original publication was based on the MOD-AGE algorithm, while the age model used in this synthesis was constructed using the geoChronR package and BACON algorithm.

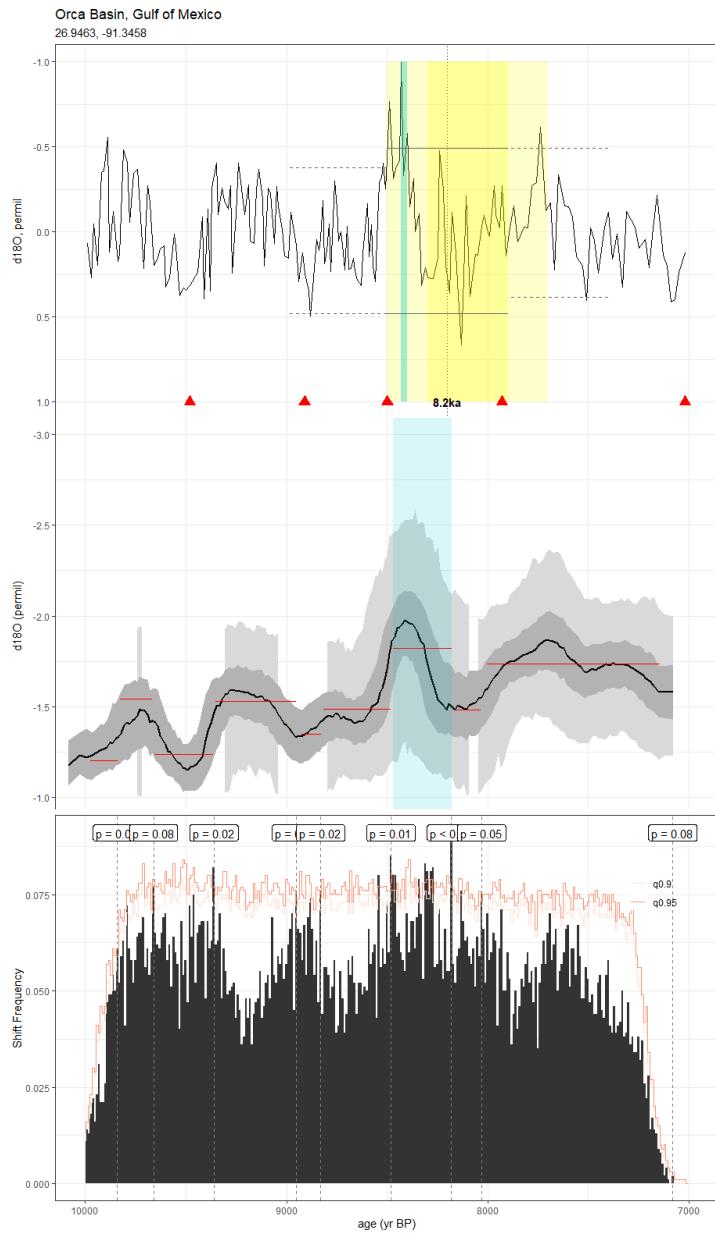

1800

1805

**Figure C2.** As in Fig. C1, but for the speleothem record of Voarintsoa et al., 2017 (ANJB2). The age model of the original publication was constructed using StalAge. Here, we used the BACON age ensemble from SISALv2.

**Figure C4.** As in Fig. C1, but for the foraminifera record of LoDico et al., 2006 (MD022550). The published age model was constructed using CALIB 5.0, with a 400-year reservoir age correction applied. Here, we used the BACON algorithm included in geoChronR to create the age ensemble.

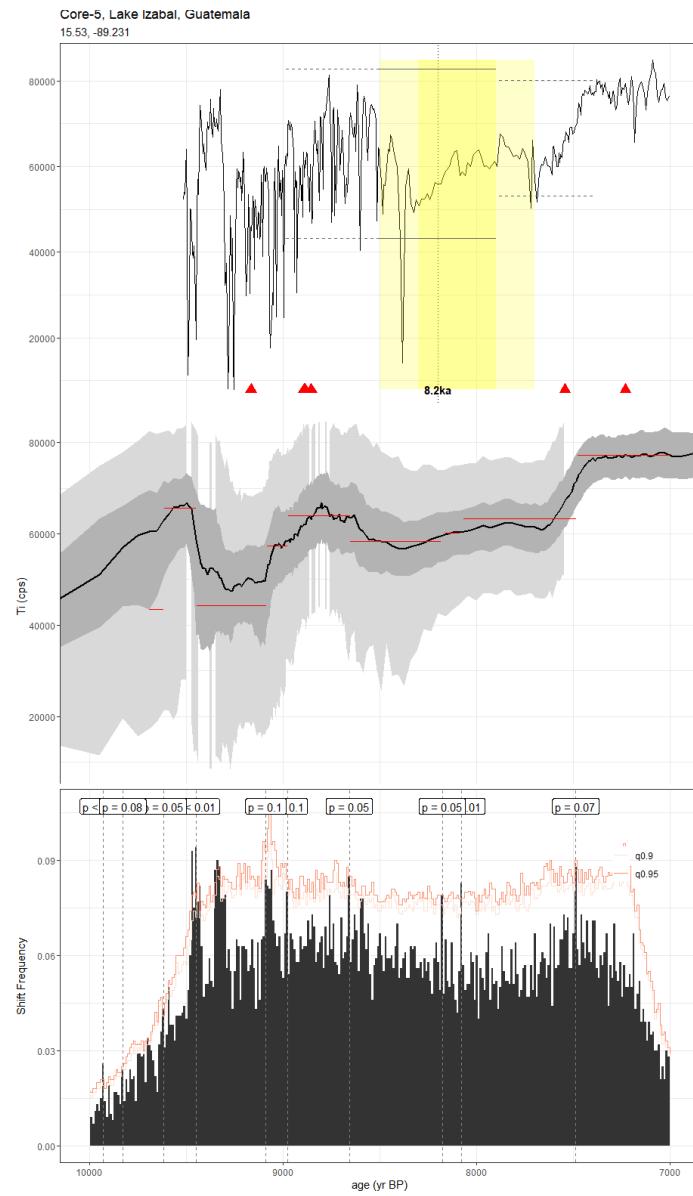

**Figure C5.** As in Fig. C1, but for the speleothem record of Cheng et al., 2009 (PAD07). The original age modeling method used in the construction of the published time series is unknown. Here, we present an age ensemble using the BACON algorithm provided by geoChronR.

1840

**Figure A1.** Locations of proxy records within climate reference regions defined in Iturbide et al. (2020).

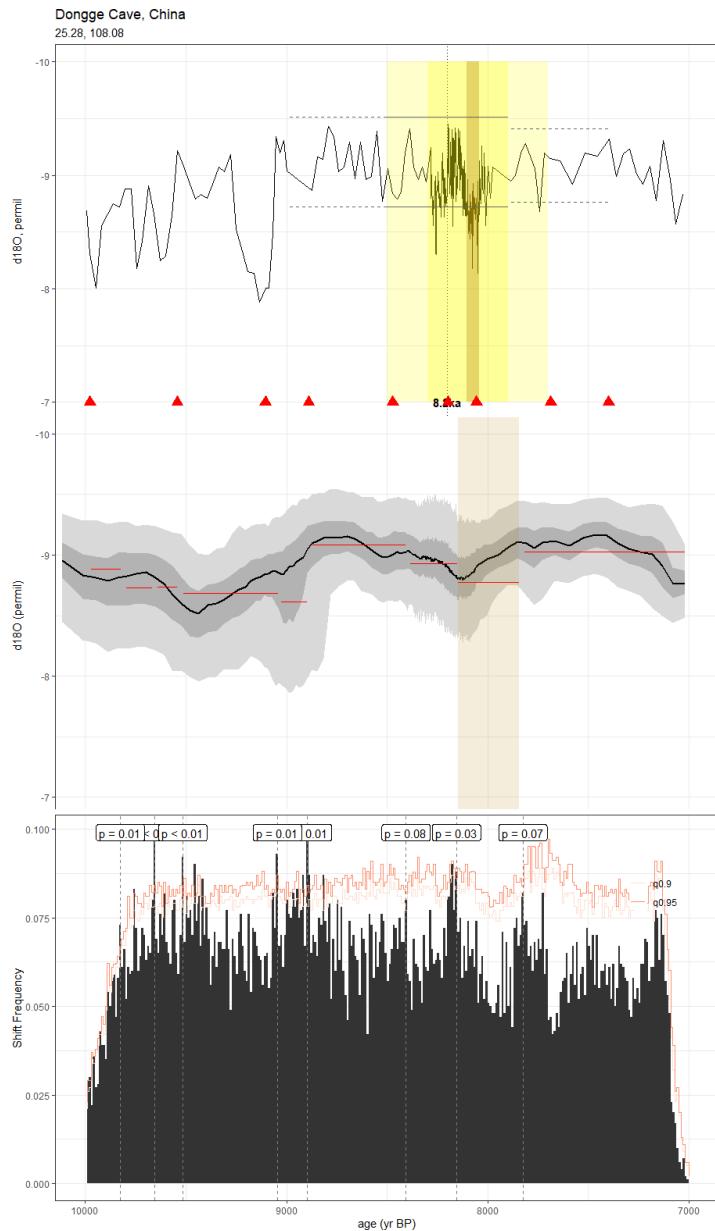

**Figure A1.** Locations of proxy records within climate reference regions defined in Iturbide et al. (2020).

**Figure C6.** As in Fig. C1, but for the lacustrine titanium content record of Duarte et al., 2021 (Core5LI). The published age model was constructed using BACON using the IntCal20 calibration curve, and here, we construct our age ensemble using the BACON algorithm included with geoChronR.

1855 **Figure A2.** The difference in surface air temperatures between the last 50 years of the “hose” and “ctrl” simulations, overlaid by contour intervals indicating the range of temperatures in the “ctrl” simulation over the full 100 years. Blue shaded areas represent anomalously cold regions, while anomalously warm regions are shaded in red on a global (a) and tropical (b) level.

1860 **Figure A2.** The difference in surface air temperatures between the last 50 years of the “hose” and “ctrl” simulations, overlaid by contour intervals indicating the range of temperatures in the “ctrl” simulation over the full 100 years. Blue shaded areas represent anomalously cold regions, while anomalously warm regions are shaded in red on a global (a) and tropical (b) level.

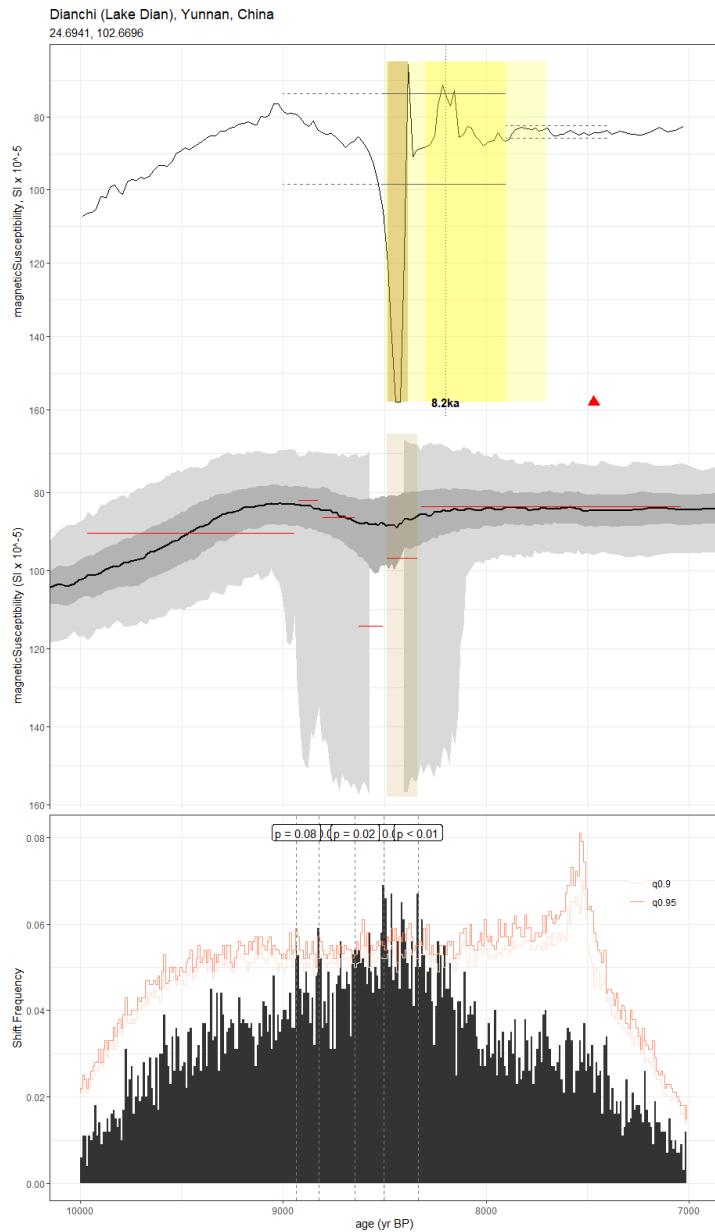

**Figure C7.** As in Fig. C1, but for the speleothem record of Dykoski et al., 2005 (D4Dykoski). The published age model was constructed by linearly interpolating between U/Th dates. Here, we reconstruct the age model using the BACON algorithm in geoChronR.

1865

**Figure A3.** A stackplot from the speleothem record of Duan et al., 2021 (ABC1). The top panel shows the raw oxygen isotope time series with 8.3–7.9 ka highlighted in darker yellow and 8.5–7.7 ka highlighted in lighter yellow. The middle

1870 panel shows the same time series with age and paleodata ensemble uncertainty ribbons. The horizontal red lines represent  
mean values assigned to the data by `actR`, with discontinuities indicating significant changepoints. The lower panel depicts  
the frequency of shifts detected in the ensemble dataset (black) relative to 100 null hypothesis surrogate datasets (orange).  
The age model in the original publication was based on the MOD-AGE algorithm, while the age model used in this  
synthesis was constructed using the `geoChronR` package and BACON algorithm.
