## Abstract

Soil emissions of nitrogen compounds, including NO and HONO, play a significant role in atmospheric nitrogen budget. However, HONO has been overlooked in previous research on soil reactive nitrogen (Nr) emissions and their impacts on air quality in China. This study estimates both soil NO<sub>x</sub> and HONO emissions (SNO<sub>x</sub> and SHONO) in North China during July 2018 with an updated soil Nr emissions scheme in a chemical transport model, the Unified Inputs for WRF-Chem (UI-WRF-Chem). The effects of soil Nr emissions on O<sub>3</sub> pollution, air quality and temperature rise are also studied, with a focus on two key regions, Beijing-Tianjin-Hebei (BTH) and Fenwei Plain (FWP), known for high soil Nr and anthropogenic emissions. We find that the flux of SNO<sub>x</sub> is nearly doubled those of SHONO; the monthly contributions of SNO<sub>x</sub> and SHONO account for 37.3% and 13.5% of anthropogenic NO<sub>x</sub> emissions in the BTH, and 29.2% and 19.2% in the FWP during July 2018, respectively. Soil Nr emissions have a significant impact on surface O<sub>3</sub> and nitrate, exceeding SNO<sub>x</sub> or SHONO effects alone. On average, soil Nr emissions increase MDA8 O<sub>3</sub> by 16.9% and nitrate concentrations by 42.4% in the BTH, 17.2% for MDA8 O<sub>3</sub> and 42.7% for nitrate in the FWP. Reducing anthropogenic NO<sub>x</sub> emissions leads to a more substantial suppressive effect of soil Nr emissions on O<sub>3</sub> mitigation, particularly in BTH. Soil Nr emissions, via their role as precursors for secondary inorganic aerosols, can result in a slower increase rate of surface air temperature-under future emission reduction scenarios. This study suggests that mitigating O<sub>3</sub> pollution and addressing climate change in China should consider the role of soil Nr emission, and their regional differences.

## 1. Introduction

Surface ozone ( $O_3$ ) is a major air pollutant harmful to human health, terrestrial vegetation, and crop growth (Feng et al., 2022b; Turner et al., 2016; Unger et al., 2020; Yue et al., 2017). China is confronting serious  $O_3$  pollution, with the surface  $O_3$  concentrations routinely exceeding air quality standards (Li et al., 2019). Although the Chinese Action Plan on Air Pollution Prevention and Control implemented in 2013 has significantly reduced the nationwide anthropogenic emissions of primary pollutants including particulate matter (PM) and nitrogen oxides ( $NO_x = NO + NO_2$ ), the summertime  $O_3$  concentrations observed by national ground sites and satellite observations both show an increasing trend of 1-3 ppbv  $a^{-1}$  in megacity clusters of eastern China from 2013 to 2019 (Wang et al., 2022b; Wei et al., 2022). Many studies have explored the causes of  $O_3$  pollution from the perspective of changes in meteorology and anthropogenic emissions, and attributed the  $O_3$  increase to decreased PM levels and anthropogenic  $NO_x$  emissions, and adverse meteorological conditions (Li et al., 2021b; Li et al., 2019; Li et al., 2020; Li et al., 2021b; Liu and Wang, 2020a, b; Lu et al., 2019).

Soil emissions are an important natural source of reactive nitrogen species, including  $N_2O$ ,  $NO_x$ , HONO and  $NH_3$ , and can strongly affect the atmospheric chemistry, air pollution and climate change (Elshorbany et al., 2012; Pinder et al., 2012). It has been acknowledged that the soils emissions account for 12-20% of total emissions of  $NO_x$  ~~in~~<sup>on</sup> global average (Vinken et al., 2014; Yan et al., 2005), and 40-51% in agricultural regions during periods in which fertilizers are applied to soils, resulting in

a significant increase in O<sub>3</sub> and NO<sub>2</sub> concentrations in US (Almaraz, [et al.](#), 2018; Romer et al., 2018; Sha et al., 2021; Wang et al., 2021a), Europe (Skiba et al., 2020) and sub-Saharan Africa (Huang et al., 2018).

China has a large area of cultivated land ( $\sim 1.276 \times 10^6$  km<sup>2</sup>, [http://gi.mnr.gov.cn/202304/t20230414\\_2781724.html](http://gi.mnr.gov.cn/202304/t20230414_2781724.html), last access: 18<sup>th</sup> December 2023), which contributes to one-third of the global nitrogen fertilizer use and has extensive nitrogen deposition (Liu et al., 2013; Lu and Tian, 2017; Reay, 2008). So far, only a limited studies focused on the impact of soil NO<sub>x</sub> emissions (denoted as SNO<sub>x</sub>) on O<sub>3</sub> pollution in China (Huang et al., 2023; Lu et al., 2021; Shen et al., 2023; Wang et al., 2008; Wang et al., [2022a](#); [Wang et al.](#), 2023a; ~~Wang et al., 2022a~~). Lu et al. (2021) demonstrated that the presence of SNO<sub>x</sub> in the North China Plain significantly reduced the sensitivity of surface O<sub>3</sub> to anthropogenic emissions. Huang et al. (2023) suggested that substantial SNO<sub>x</sub> could increase the maximum daily 8 h (MDA8) O<sub>3</sub> concentrations by 8.0–12.5 µg m<sup>-3</sup> on average for June 2018 in China. These studies focused only on NO<sub>x</sub> emitted from soils, and neglected that similar soil microbial activities also emit nitrous acid (HONO). The measurements in laboratory showed that the emission rates of soil HONO were comparable to those of NO (Oswald et al., 2013; Weber B, 2015). The photolysis of HONO has been identified to be an important source of atmospheric hydroxyl radical ( $\cdot\text{OH}$ ), which enhances concentrations of hydroperoxyl (HO<sub>2</sub>) and organic peroxy radicals (RO<sub>2</sub>), accelerating the conversion of NO to NO<sub>2</sub>, resulting in more concentrations of O<sub>3</sub> and secondary pollutants. Although the sources and formation mechanisms of HONO are still not fully understood, recent model studies

suggested that HONO emission from soils in the agriculture-intensive North China Plain could increase the regionally averaged daytime  $\cdot\text{OH}$ ,  $\text{O}_3$ , and daily fine particulate nitrate concentrations (Feng et al., 2022a; Wang et al., 2021b).

Only a few studies simultaneously considered the impact of soil HONO emissions (denoted as SHONO) along with  $\text{SNO}_x$  on  $\text{O}_3$  and other secondary pollutants (Tan et al., 2023; Wang et al., 2023b, 2023c). Wang et al. (2023b) Wang et al. (2023c) found that the  $\text{NO}_x$  and HONO emissions from natural soils (i.e., soil background emissions) increased daily average  $\text{O}_3$  concentrations by 2.0% in the Northeast Plain during August 2016 without considering the contribution from fertilized croplands. Tan et al. (2023) believed that the contribution of soil  $\text{NO}_x$  and HONO to  $\text{O}_3$  pollution has been in an increasing trend from 2013 (5.0 pptv) to 2019 (8.0 pptv) in the summer season over the North China Plain by using the GEOS-Chem model; however the coarse resolution of GEOS-Chem simulation may not be sufficient to resolve the spatial heterogeneity in soil emission distribution (Lu et al., 2021). Associated with the decreasing anthropogenic emissions is the increasing contribution of soil emissions to the atmospheric nitrogen budget in China. Therefore, it is critical to quantify the impact of soil reactive nitrogen (Nr:  $\text{NO}_x$  and HONO) emissions on  $\text{O}_3$  and secondary pollutants.

In this study, we improve the soil Nr emissions scheme in the Unified Inputs (initial and boundary conditions) for Weather Research and Forecasting model coupled with Chemistry (UI-WRF-Chem) by considering all potential sources of HONO published in the literature. ~~Since serious~~ July 2018 was chosen as the study period because of severe  $\text{O}_3$  pollution during this month, as well as higher air temperatures and

117 ~~high~~more frequent precipitation compared to June and August (Figure S1 and S2),  
118 ~~which could contribute to enhanced the~~ soil Nr emissions ~~always occurred in~~  
119 ~~summer,~~(Figure S3). We conduct a series of sensitivity experiments ~~are conducted~~ to  
120 quantify the coupled and separate impact of SNO<sub>x</sub> and SHONO on O<sub>3</sub> and secondary  
121 pollutants during July 2018 over the North China, focusing on two city clusters, the  
122 Beijing-Tianjin-Hebei (BTH) region and Fenwei Plain (FWP) region, both of which  
123 have the vast areas of croplands and dense populations and experiencing severe O<sub>3</sub> and  
124 PM<sub>2.5</sub> pollutions. In addition, by quantitatively analyzing the difference in the response  
125 of surface O<sub>3</sub> concentrations and surface air temperature to the anthropogenic ~~NO<sub>x</sub>~~  
126 emissions reductions in the presence vs. absence of soil Nr emissions, the roles of soil  
127 Nr emissions on O<sub>3</sub> mitigation strategies and climate change are also studied. Our study  
128 is designed to address the underestimated role of soil Nr emission in O<sub>3</sub> pollution,  
129 thereby providing the scientific basis for O<sub>3</sub> mitigation strategies and climate change.

## 130 **2. Methodology**

### 131 **2.1 Model description**

#### 132 **2.1.1 Model configurations, input data, and non-soil HONO emission**

133 The UI-WRF-Chem model, developed upon the standard version of WRF-Chem  
134 3.8.1 (Grell et al., 2005), was used in this study. The 0.625°×0.5° Modern-Era  
135 Retrospective analysis for Research and Applications, Version 2 (MERRA-2) reanalysis  
136 data provide both the meteorological and chemical boundary and initial conditions  
137 (Gelaro et al., 2017). The 0.25° × 0.25° Global Land Data Assimilation System  
138 (GLDAS) data provides the initial and boundary conditions of soil properties, i.e., soil

moisture and temperature (~~Rodell, 2004~~)([Rodell et al., 2004](#)). Details of Unified Inputs of meteorological and chemical position data for UI-WRF-Chem, can be found in recent publications (Li et al., 2024; Wang et al., ~~2023e~~[2023d](#)). Anthropogenic emissions are imported from the Multi-resolution Emission Inventory for China (MEIC: <http://www.meicmodel.org/>) with a spatial resolution of  $0.25^{\circ} \times 0.25^{\circ}$  for the year 2017. Due to the differences in spatial resolution and map projection between the MEIC inventory and model grid, we applied a spatial interpolation method to convert the MEIC inventory to the model-ready formats. The descriptions are detailed in Text S1. Biomass burning emissions are from the Fire Inventory from NCAR version (FINN, version 1.5, <https://www.acom.ucar.edu/Data/fire/>). Biogenic emissions are calculated using the Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1 (Guenther et al., 2012).

The physical and chemical schemes include the Morrison 2-moment microphysical scheme (Morrison et al., 2009), Grell 3-D cumulus scheme (Grell and Dévényi, 2002), RRTMG for both longwave and shortwave radiation scheme (Iacono et al., 2008), Yonsei University planetary boundary layer scheme (~~Hong, 2006~~)([Hong et al., 2006](#)), Noah land surface model (~~Tewari, 2004~~)([Tewari et al., 2004](#)), and the Carbon Bond Mechanism (CBMZ) for gas-phase chemistry and the Model for Simulating Aerosol Interactions and Chemistry (MOSAIC) aerosol module with four sectional aerosol bins and aqueous reactions (~~Zaveri et al., 2008; Zaveri and Peters, 1999~~)([Zaveri and Peters, 1999; Zaveri et al., 2008](#)) are adopted in the UI-WRF-Chem model. Two nested domains are used, domain one covers China with a horizontal

resolution of 27 km and contains 112×112 grid cells, and domain two covers central and eastern China and its surrounding area with a horizontal resolution of 9 km, containing 196×166 grid cells (study region are shown in Figure [S1S4](#)), both domains have 74 vertical levels from surface to 50 hPa and 4 levels of soil. The simulations are conducted from 29<sup>th</sup> June to 31<sup>th</sup> July in 2018 with the first 2 days as the spin-up period. The model outputs from 1<sup>th</sup> to 31<sup>th</sup> July in 2018 are analyzed.

The default WRF-Chem model only considers the gas-phase formation of HONO ( $\text{NO} + \text{OH} \rightarrow \text{HONO}$ ), thus underestimating the HONO concentrations. In this study, in addition to considering SHONO (details in Section 2.1.2), potential sources of HONO recognized in recent studies are also taken into account in the current model (~~Fu et al., 2019; Li et al., 2010; Ye et al., 2016; Ye et al., 2017; Zhang et al., 2022b; Zhang et al., 2022a; Zhang et al., 2016; Zhang et al., 2021; Zhang et al., 2020~~)(~~Fu et al., 2019; Li et al., 2010; Ye et al., 2016; Ye et al., 2017; Zhang et al., 2016; Zhang et al., 2020; Zhang et al., 2021; Zhang et al., 2022a, b~~), including traffic emissions, NO<sub>2</sub> heterogeneous reactions on ground and aerosol surfaces, and inorganic nitrate photolysis in the atmosphere. Through a series of tests and comparisons with observed surface HONO concentrations, the specific parameterization schemes of HONO sources adopted in this study are shown in Text [S1S2](#).

### 2.1.2 Parameterization of soil Nr emissions

The soil Nr emissions schemes in the UI-WRF-Chem model are updated in this study. The default SNO<sub>x</sub> scheme in UI-WRF-Chem, MEGAN v2.1, is replaced by the Berkeley–Dalhousie–Iowa Soil NO Parameterization (BDISNP), and the

implementation of BDISNP can be found in Sha et al. (2021). Considering that the baseline year of N fertilizer data is 2006, and the amount of N fertilizer application in China has changed in the past ten years, we update the N fertilizer data to the year 2018 based on the N fertilizer application data at the province level from the statistical yearbook (Table S1).

The process of soil HONO emission is similar to that of  $\text{NO}_x$ , as both are influenced by the physical and chemical characteristics of soils. Consequently, soil emissions of HONO with consideration of their dependence on land type, soil humidity, and temperature are also parameterized into the UI-WRF-Chem model. We first map the soil types measured in Oswald et al. (2013) (collected from 17 ecosystems in Table S2) into the most closely matching MODIS land cover types in the model following Feng et al. (2022a), described in Table S3. The optimal emission flux for each MODIS land cover type is calculated as the average of the measured fluxes from the category/categories in Oswald et al. (2013) that is/are been mapped into a specific MODIS classification. We also collect the SHONO data from various ecosystems in China published in different studies to correct the optimal SHONO fluxes in the model (Table S4). These ecosystems include semi-arid, fertilized and irrigated farmland in China. Consequently, the parameterization scheme takes into account the effect of fertilizer application on the SHONO. After that, the optimal fluxes over the domains are digested into the model and further scaled online according to the soil temperature and water content in each model grid at each time step throughout the simulation period by the following of equation from (Zhang et al., 2016):

$$F_N(\text{HONO}) = F_{N,opt}(\text{HONO}) \cdot f(T) \cdot f(\text{SWC})$$

where  $F_{N,opt}(\text{HONO})$  is the optimum flux of SHONO in terms of nitrogen.  $f(T)$  and  $f(\text{SWC})$  are the scaling factors of soil temperature ( $T$ ) and water content ( $\text{SWC}$ ).

$$f(T) = e^{\frac{E_a}{R}(\frac{T}{T_{opt}} - \frac{1}{T})}$$

$E_a$  is the activation energy of HONO (80 kJ mol<sup>-1</sup>),  $R$  is the gas constant,  $T_{opt}$  is the temperature at which optimum flux is emitted (298.15 K),  $T$  is the soil temperature calculated online by the model,  $f(\text{SWC})$  is fitted based on the data curves in Figures 1 and 3 in (Oswald et al., 2013) and the equation is as follows:

$$f(\text{SWC}) = 1.04 \times \exp\left(-e^{\frac{\text{SWC}-11.32586}{5.27335} - \frac{\text{SWC}-11.32586}{5.27335} + 1}\right)$$

## 2.2 Model experiment design

The descriptions of the sensitivity simulations are shown in Table S5.1. Default simulation uses MEGAN scheme to estimate SNO<sub>x</sub> and no SHONO is considered. Base simulation uses soil Nr emissions schemes with the improvement of using BDISNP scheme for SNO<sub>x</sub> and consideration of SHONO and other four HONO sources (as described above). Comparison of results from Default and Base simulations is used to show the improvement in the model performance after updating the soil Nr emissions schemes and incorporating HONO potential sources. To explore the impact of soil Nr emissions on O<sub>3</sub> and secondary pollutants, we conduct a series of sensitivity simulations with soil NO<sub>x</sub> and HONO emissions turned on/off separately and jointly (anthropogenic emissions for the year 2017), i.e., NoSoilNr, NoSHONO and NoSNO<sub>x</sub>. ~~To evaluate the role of soil Nr emissions on O<sub>3</sub> mitigation strategies~~ To investigate the relative importance and air temperature change under different interaction between

anthropogenic ~~emission reduction scenarios, we further~~ and natural emissions of  
nitrogen-containing pollutants, we conduct the Base\_redANO<sub>x</sub> and NoSoil\_redANO<sub>x</sub>  
simulations ~~with~~ to evaluate the role of soil Nr emissions on O<sub>3</sub> mitigation strategies, in  
which anthropogenic NO<sub>x</sub> emissions reduced by 20%, 40%, 60%, 80%~~0%~~, and 100%,  
respectively. Furthermore, considering the co-control of multiple air pollutants and  
greenhouse gas reductions in future emission reduction scenarios, the Base\_redAnt and  
NoSoil\_redAnt simulations are conducted to evaluate the role of soil Nr emissions on  
air temperature change, and the anthropogenic reduction scenarios simultaneously  
consider SO<sub>2</sub>, NO<sub>x</sub>, primary PM<sub>2.5</sub>, VOCs, and CO emissions reductions (reduced by  
20%, 40%, 60%, 80%, and 100%).

### 2.3 Observational data

The tropospheric column densities of NO<sub>2</sub> from TROPOMI (TROPOspheric  
Monitoring Instrument) level-2 in version 1 with the horizontal spatial resolution of 3.5  
× 7 km<sup>2</sup> are used- (Van Geffen et al., 2021). The quality controls, i.e., cloud-screened  
(cloud fraction below 30%) and quality-assured (qa\_value above 0.50), and averaging  
kernels (AK) are applied in the comparison of the TROPOMI and UI-WRF-Chem  
simulated tropospheric NO<sub>2</sub> vertical column densities (defined as NO<sub>2</sub> VCD).

To evaluate the model performance on simulating surface air pollutants, we use  
the hourly surface O<sub>3</sub> concentrations at 888 monitoring sites from the China National  
Environmental Monitoring Center (CNEMC), and hourly surface HONO  
concentrations measured by the In-situ Gas and Aerosol Compositions monitor (IGAC)  
(~~Zhan et al., 2021~~)(Zhan et al., 2021) at Nanjing University of Information Science &

Technology (NUIST) (32.2° N, 118.7° E; 22m above sea level) (Xu et al., 2019).

### 3. Results and discussions

#### 3.1 Soil nitrogen emissions and air pollution evaluation

~~Figure 1 shows the spatial distribution of simulated monthly mean SNO<sub>x</sub> and SHONO fluxes in July 2018 across North China. In most regions, SNO<sub>x</sub> flux is nearly doubled that of SHONO.~~ The soil Nr emissions in July are much higher than the other seasons due to higher air temperatures and frequent precipitation, accounting for 39.5% of anthropogenic NO<sub>x</sub> emissions over the study region, and 50.2% in the BTH, 47.4% in FWP, which is consistent with the previous studies (Huang et al., 2023; Shen et al., 2023; Wang et al., 2023c). And the proportions can increase to 58.9%, 57.0%, and 65.0%, respectively, when only statistics over the cropland in these regions (Figure S3). Given the substantial contribution of soil emissions to the atmospheric nitrogen budget in July, we thus choose this month to assess the impact of soil Nr emissions on air quality and climate change. From the spatial distribution of simulated monthly mean SNO<sub>x</sub> and SHONO fluxes across North China in July 2018 (Figure 1), it is shown that SNO<sub>x</sub> flux is nearly doubled that of SHONO in most regions, and higher SNO<sub>x</sub> and SHONO are concentrated in areas dominated by cropland. The monthly total soil emissions over the whole study domain (cropland) are 104.5 (82.4) Gg N mon<sup>-1</sup> for NO<sub>x</sub> and 52.7 (45.9) Gg N mon<sup>-1</sup> for HONO. In the densely populated BTH region, the monthly total SNO<sub>x</sub> are 18.7 Gg N mon<sup>-1</sup> in July, which is equivalent to 37.3% of anthropogenic NO<sub>x</sub> emissions for the year 2017. For the FEW region, where also experiences severe O<sub>3</sub> and PM<sub>2.5</sub> ~~pollution~~pollutions, the monthly total SNO<sub>x</sub> (7.0 Gg

N mon<sup>-1</sup>) account for 29.2% of anthropogenic NO<sub>x</sub> emissions. The monthly total SHONO in both study regions are much lower than their SNO<sub>x</sub> counterparts, with the emissions of 6.9 and 4.6 Gg N mon<sup>-1</sup>, accounting for 13.5% and 19.2% of anthropogenic NO<sub>x</sub> emissions in BTH and FWP regions, respectively.

To evaluate the model performance, Figure 2 shows the tropospheric NO<sub>2</sub> VCD from TROPOMI satellite products and UI-WRF-Chem simulations (Default and Base) in North China during July 2018 ~~in North China~~. Default and Base can both reproduce the hot spots of NO<sub>2</sub> VCD in urban areas shown in the TROPOMI observations. However, the Default significantly underestimates the NO<sub>2</sub> VCD, especially in regions surrounding urban areas. It is found that Default underestimates NO<sub>2</sub> VCD by 48% over the regions where soil emissions dominate (i.e., soil Nr emissions contribute more than half to the atmospheric nitrogen emissions), while the Base reduced the bias to 13% (Figure ~~S2S5~~). Overall, Base shows the improved performance in simulating NO<sub>2</sub> VCD in comparison to Default with a decreasing bias from -30% (-21%) to +4% (+17%) and an increasing spatial correlation coefficient (R) from 0.62 (0.50) to 0.65 (0.54) in the study region (cropland). ~~The overestimated~~ However, there is still a discrepancy between the Base simulation and TROPOMI NO<sub>2</sub> VCD. This discrepancy could be driven by the combined effects from uncertainties in Base is most likely attributed to simulations and observations, associated with the time lag in anthropogenic emissions inventory used in the studymodel (Chen et al., 2021), ~~uncertainties in the stratospheric portion of NO<sub>2</sub> VCD and AK caused the retrieval errors (Van Geffen et al., 2020).~~ instantaneous uncertainties in TROPOMI tropospheric NO<sub>2</sub> VCD at the pixel

level (up to 25-50% or  $0.5\sim0.6\times10^{15}$  molecules  $\text{cm}^{-2}$ ), as well as uncertainties of  
 stratospheric portion of  $\text{NO}_2$  VCD and AK caused the retrieval errors (Van Geffen et al.,  
 2020; Van Geffen et al., 2021). Additionally, the estimated  $\text{SNO}_x$  are also subjected to  
 certain limitations and uncertainties. The first uncertainty comes from the amount of N  
 fertilizer application, which has been identified as the dominant contributor to  $\text{SNO}_x$ .  
 In this study, we use the amount of agricultural N fertilizer application at the province  
 level from the statistical yearbook to update the default N fertilizer application data in  
 the model (the baseline year for 2006), but a recent study showed that compound  
 fertilizer, usually with nitrogen (N), phosphorus (P), and potassium (K), were more  
 commonly used in China; if only N fertilizer is considered to nudge the N fertilizer  
 application data in the model, the estimated  $\text{SNO}_x$  may be underestimated by 11.1%–  
 41.5% (Huang et al., 2023). Furthermore, although we use the modeled green  
 vegetation fraction (GVF) to determine the distribution of arid ( $\text{GVF} \leq 30\%$ ) and non-  
 arid ( $\text{GVF} > 30\%$ ) regions. Huber et al. (2023) showed that the estimated  $\text{SNO}_x$  based  
 on the static classification of arid vs. non-arid is very sensitive to the soil moisture, and  
 thus could not produce self-consistent results when using different input soil moisture  
 products unless a normalized soil moisture index to represent. Therefore, more direct  
 measurements of soil  $\text{Nr}$  fluxes are crucial to better constrain soil emissions and  
 improve the parametrization in the model. Nevertheless, the improved simulation  
performance of  $\text{NO}_2$  VCD with a reduced bias and increased spatial correlation  
coefficient in Base is credible, and soil  $\text{Nr}$  emission scheme has the fidelity needed to  
study the implication of soil  $\text{Nr}$  emissions to air quality in North China.

We evaluate the simulation with the surface O<sub>3</sub> observations from the China National Environmental Monitoring Centre (CNEMC) network (<http://www.cnemc.cn/en/>) (Figure 3). Over the whole study region, the Base can better capture the spatial distribution of observed surface MDA8 O<sub>3</sub> with a relatively higher spatial correlation of  $R = 0.68$  than that in Default ( $R = 0.46$ ). The simulated monthly averaged MDA8 O<sub>3</sub> concentrations across the 888 sites in the study region are 123.0  $\mu\text{g m}^{-3}$  in Default and 132.5  $\mu\text{g m}^{-3}$  in Base, respectively, which are both slightly higher than the observed concentrations (120.7  $\mu\text{g m}^{-3}$ ). Overprediction is also observed for the FWP and BTH regions in the Base simulation, with the normalized mean bias (NMB) of 6.1% and 4.9%, respectively (Figure S3). ~~These positive biases are mainly due to overestimated transport of boundary O<sub>3</sub> in both horizontal and vertical directions (Huang et al., 2023) and underestimated precipitation and cloud cover in the current model (Sun et al., 2019).~~ S6). Previous studies showed that the NMB of simulated O<sub>3</sub> concentrations were within  $\pm 30\%$  for nearly 80% of the cases collected from air quality model studies (Yang and Zhao, 2023). These discrepancies may arise from simplifications of complex chemical mechanisms and physical processes, such as dry deposition and vertical mixing (Akimoto et al., 2019; Travis and Jacob, 2019). The uncertainties of input data, including emission inventories, meteorological fields, and other parameters, may also contribute to these discrepancies (Sun et al., 2019; Ye et al., 2022), suggesting a potential systematic O<sub>3</sub> bias in air quality models. Therefore, the increased spatial correlation and reasonable bias found in the Base indicate that the application of the soil Nr emission schemes can effectively improve the simulation

performance of MDA8 O<sub>3</sub>.

We also compare the simulated surface HONO and nitrate concentrations to the observations at a rural station in Nanjing during July 2018. Figure 4 shows that the simulated HONO concentrations in Default are 98.3% lower than the observations. In comparison, the Base with considering SHONO and other HONO potential sources significantly improves the simulation performance and reduces the bias to 47.8%, and also reproduces the diurnal variation of HONO with the temporal correlation of  $R = 0.76$ . It is worth noting that the simulated concentrations of HONO from 08 am to 18 pm are lower than the observations, this discrepancy may be attributed to the underestimated contribution from the predominant sources of HONO during the daytime, such as NO<sub>2</sub> heterogeneous reactions on ground and aerosol surfaces. Moreover, the contributions of different sources to ambient HONO concentrations at this rural station are also evaluated, the soil emissions could contribute almost 25.8% to the surface HONO concentrations, which may be partially attributed to the high emissions of HONO from croplands around the city of Nanjing (Figure S4S7). The results that soil emissions contribute less to the daytime positive flux than the other source is consistent with previous studies (Skiba et al., 2020; Wang et al., 2023b2023c). For nitrate concentration, the Base simulation shows a lower bias (5.6%) and an improved diurnal variation (temporal correlation of  $R = 0.92$ ) compared to the Default simulation (bias = 27.8%,  $R = 0.85$ ). We acknowledge that there are certain uncertainties in the current model. Nevertheless, the improved simulation performance of NO<sub>2</sub> VCD, surface HONO, MDA8 O<sub>3</sub>, and nitrate concentrations compared to the

Default illustrates the credibility of the results obtained from the Base simulation.

### 3.2 Impact on O<sub>3</sub> formation and air quality

To quantify the effects of SNO<sub>x</sub> and SHONO on atmospheric oxidation capacity, O<sub>3</sub> formation and air quality as well as their combined effect, the conventional brute-force method was used, i.e., the impact of a specific source is determined in atmospheric chemistry models as the differences between the standard/base simulation with all emissions turned on and a sensitivity simulation with this source turned off or perturbed (Table S51). As shown in Figure 5, the contribution of SNO<sub>x</sub> and SHONO to surface NO<sub>2</sub> and HONO has a different spatial pattern from that of the fluxes of SNO<sub>x</sub> and SHONO in July. Overall, the maximum contribution of SNO<sub>x</sub> to the monthly average surface NO<sub>2</sub> concentrations is 78.6%, with a domain-averaged value of 30.3%. Regionally, SNO<sub>x</sub> contribute 5.5 µg m<sup>-3</sup> (37.1%) and 2.5 µg m<sup>-3</sup> (31.8%) to the surface NO<sub>2</sub> in the BTH and FWP regions, respectively, which are both higher than the domain-averaged contribution. Although SHONO fluxes are lower than that of SNO<sub>x</sub> in this period, its effect on ambient HONO cannot be ignored. Over the study region, the contribution of SHONO to surface HONO concentration ranges from 0 to 49.0%, with a domain-averaged value of 35.6%. For the selected key regions, there are 1.8 µg/m<sup>3</sup> (36.7%) and 1.5 µg/m<sup>3</sup> (38.0%) of the monthly average HONO concentrations in the BTH and FWP regions, respectively, from soil emissions. It is noteworthy that, despite the surface NO<sub>2</sub> (HONO) concentrations in the study regions being impacted by less than 13% (17%) due to SHONO (SNO<sub>x</sub>), the combined effects of soil Nr emissions on surface NO<sub>2</sub> (HONO) are found to be greater than the individual effects, which are 38.4%

(40.3%) for BTH and 33.9% (40.1%) for FWP region, respectively (Table S6S5). These results highlight the importance of considering the cumulative impacts of multiple reactive nitrogen emissions from soils on air pollution.

Consequently, substantial soil Nr emissions in July have a non-negligible effect on atmospheric oxidation and the formation of secondary pollutants. For atmospheric oxidation, we assess the impact of soil Nr emission on the maximum 1 h (max-1h)  $\cdot\text{OH}$  levels and find that SHONO have a potential to increase the max-1h  $\cdot\text{OH}$  in most areas, with a domain-averaged increase of 10.0%. On the contrary, the inclusion of  $\text{SNO}_x$  results in a significant reduction of 31.3% in the max-1h  $\cdot\text{OH}$  across the entire study domain. Considering the combined effect of  $\text{SNO}_x$  and SHONO, there is an overall decrease of 24.3% in the max-1h  $\cdot\text{OH}$  over the study domain, with the BTH region experiencing a decrease of 22.6% and FWP region showing a relatively greater reduction of 32.2% (Table S7S6). These findings are different from the previous study, which showed that soil background emissions including  $\text{NO}_x$  and HONO led to a 7.5% increase in max-1h  $\cdot\text{OH}$  in China (Wang et al., 2023b). ~~We~~(Wang et al., 2023c). The discrepancy between our findings and those of other studies regarding the impact of  $\text{SNO}_x$  on  $\cdot\text{OH}$  levels could be attributed to the abundance of ambient  $\text{NH}_3$  in China during summer, where soil emissions may lead to a significant increase in nitrate, and the increased aerosols can affect the concentrations of  $\cdot\text{OH}$  through photochemical reactions (Wang et al., 2011; Xu et al., 2022). Additionally, after taking into account the  $\text{SNO}_x$  in the model, the environment may shift to a relatively  $\text{NO}_x$ -saturated regime, thus the termination reaction for  $\text{O}_3$  production could be  $\text{NO}_2$  and  $\cdot\text{OH}$  to generate

HNO<sub>3</sub> (Chen et al., 2022; Wang et al., 2023b). We also stress the crucial role of SNO<sub>x</sub> in influencing ·OH concentrations and highlight the varying impacts across different regions. For secondary pollutants, substantial O<sub>3</sub> enhancement is found in Henan and Hubei provinces, while the increase in nitrate is consistent with the spatial pattern of surface NO<sub>2</sub> from soil emissions. Specifically, soil Nr emissions increase the monthly average MDA8 O<sub>3</sub> and nitrate concentrations by 18.2% and 31.8%, respectively, across the study domain, with the increase of 16.9% and 42.4% in the BTH region and 17.2% and 42.7% in the FWP region. Moreover, ~~soil emissions of NO<sub>x</sub>~~ SNO<sub>x</sub> have a stronger effect on O<sub>3</sub> and nitrate in North China in July than those of SHONO.

The ratio of surface H<sub>2</sub>O<sub>2</sub> to HNO<sub>3</sub> concentrations (hereafter H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub>) was used as an indicator of the O<sub>3</sub> formation regime to study the changes in sensitivity of summer O<sub>3</sub> to its precursors after considering the soil Nr emissions. The threshold of H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> for determining O<sub>3</sub> formation regime varies regionally ~~(Sillman, 1995)~~ (Sillman, 1995), thus in this study, we identify the regions with H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> values greater than 0.65 as NO<sub>x</sub>-sensitive regime, H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> values lower than 0.35 as VOCs-sensitive regime, and H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> values between 0.35 and 0.65 as VOCs-NO<sub>x</sub> mixed sensitive regime (Shen et al., 2023). Figure 6 illustrates that the majority of BTH region has H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> values lower than 0.35 in Base simulation, indicating a VOCs-sensitive regime or NO<sub>x</sub>-saturated regime, ~~which is consistent with the previous studies based on satellite observations and model simulations (Wang et al., 2019; Wang et al., 2017).~~ The in July. In contrast, the distribution of sensitivity of O<sub>3</sub> to precursor emission in FWP regions ~~are~~ is more complex with a mix of three O<sub>3</sub> formation regimes;

~~which is attributed to the large population, regional urbanization and industrialization.~~

The spatial patterns of O<sub>3</sub> formation regimes presented in this study are consistent with the previous studies based on satellite observations and model simulations during summer seasons, despite using a different method (Wang et al., 2019; Wang et al., 2023b). This agreement across multiple approaches strengthens the confidence in the spatial patterns of O<sub>3</sub> formation regimes in the key regions of China. However, when

soil nitrogen emissions are excluded, the H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> values mostly increase within 40% and the O<sub>3</sub> formation regime shifts to VOCs-NO<sub>x</sub> mixed sensitive regime and NO<sub>x</sub>-sensitive regime in both BTH and FWP regions. Although soil Nr emissions are lower than anthropogenic emissions, they still could affect the sensitivity of O<sub>3</sub> to its precursors and thus have an impact on the effectiveness of emission reduction policies. Therefore, soil emissions must be considered in formulating policies for the prevention and management of O<sub>3</sub> pollution.

### **3.3 Implication on O<sub>3</sub> mitigation strategies and temperature rise**

Due to the influence of soil Nr emissions, the sensitivity of O<sub>3</sub> pollution to its precursors varies spatially, depending on the local levels of anthropogenic emissions. It is thus important to quantify the role of soil Nr emissions in O<sub>3</sub> pollution regulation for improving the effectiveness of air control measures. We conduct a series of sensitivity experiments with anthropogenic NO<sub>x</sub> emissions reduced by 20%, 40%, 60%, 80% and 100%, respectively, relative to the Base simulation (Table S51), and analyze the difference in the response of surface O<sub>3</sub> concentrations to the anthropogenic NO<sub>x</sub> emissions reductions in the presence and absence of soil Nr emissions. Figure 7 shows

that with the reduction of anthropogenic NO<sub>x</sub> emissions, MDA8 O<sub>3</sub> concentrations show an accelerated decreasing trend, suggesting increasing efficiency of anthropogenic NO<sub>x</sub> control measures. And MDA8 O<sub>3</sub> response to anthropogenic NO<sub>x</sub> emissions in the BTH region is more curved (nonlinear) than that in the FWP region, which is consistent with the fact that the BTH tends to have more NO<sub>x</sub>-saturated ~~O<sub>3</sub>-production regime~~ (Figure 6).

It is noted that the reduction of anthropogenic NO<sub>x</sub> emissions in the presence of soil Nr emissions leads to a slower decrease in MDA8 O<sub>3</sub> compared to when soil Nr emissions are excluded. We further analyze the details of the domain-averaged MDA8 O<sub>3</sub> changes under different anthropogenic reduction scenarios for the two key regions. Specifically, in the BTH region, MDA8 O<sub>3</sub> decrease by 1.3% (1.8 μg m<sup>-3</sup>), ~~3.4% (4.6 μg m<sup>-3</sup>)~~, 6.3% (8.7 μg m<sup>-3</sup>), ~~10.7% (14.7 μg m<sup>-3</sup>)~~, and 17.4% (24.0 μg m<sup>-3</sup>) with anthropogenic NO<sub>x</sub> emission reductions by 20%, ~~40%, 60%, 80%~~, and 100%, respectively, in the presence of soil Nr emissions. Comparatively, in the absence of soil Nr emissions, the reductions in MDA8 O<sub>3</sub> are more pronounced and decrease by 2.3% (2.7 μg m<sup>-3</sup>), ~~5.6% (6.6 μg m<sup>-3</sup>)~~, 10.7% (12.8 μg m<sup>-3</sup>), ~~19.4% (23.2 μg m<sup>-3</sup>)~~, and 42.3% (50.6 μg m<sup>-3</sup>), respectively. In the FWP region, with a 20% reduction in anthropogenic NO<sub>x</sub> emissions, MDA8 O<sub>3</sub> levels only exhibit a slight decrease of 1.7% (2.3 μg m<sup>-3</sup>) in the presence of soil Nr emissions, whereas a decrease of 2.3% (2.6 μg m<sup>-3</sup>) is found in the absence of soil Nr emissions. When anthropogenic NO<sub>x</sub> emissions are removed entirely, MDA8 O<sub>3</sub> decreases by 13.6% (17.7 μg m<sup>-3</sup>) in the presence of soil Nr emissions, and more significant decreases are found in the absent of soil Nr emissions

with a reduction of 27.4% ( $34.0 \mu\text{g m}^{-3}$ ) (as shown in Figure 7b-c, e-f). We conclude that the existence of soil Nr emissions could contribute to an additional part of  $\text{O}_3$  production, amounting to a range of 0-24.9% in the BTH and 0-13.8% in the FWP region in July, and these suppressions could be enlarged over the rural areas where have more substantial soil Nr emissions ~~(, i.e., 0-32.3% in cropland over the BTH and 0-15.0% in croplands over the FWP region).~~ These findings suggest that soil Nr emissions have the potential to suppress the effectiveness of measures implemented to mitigate  $\text{O}_3$  pollution, and this effect becomes more significant as anthropogenic  $\text{NO}_x$  emissions ~~increased~~decrease.

We also quantify the  $\text{O}_3$  generated from soil Nr emission source (denoted as the soil  $\text{O}_3$ ) in July under the different anthropogenic  $\text{NO}_x$  emission reduction scenarios. Overall, soil  $\text{O}_3$  concentrations in croplands are higher than in non-croplands. Regionally, in the BTH region, the soil  $\text{O}_3$  concentrations are  $19.8 \mu\text{g m}^{-3}$  under high anthropogenic emissions level (referred to as the Base simulation), while the soil  $\text{O}_3$  concentrations significantly increase to  $46.4 \mu\text{g m}^{-3}$  when all anthropogenic  $\text{NO}_x$  emissions are cut down (shown as red bar in Figure 7b). A similar trend is also found in the FWP region, although soil  ~~$\text{O}_3$  concentrations~~Nr emissions are relatively lower than that in the BTH region, the soil  $\text{O}_3$  concentrations are  $19.0 \mu\text{g m}^{-3}$  in the Base simulation, and do not change significantly with the reduction of anthropogenic emissions, but increase to  $31.9 \mu\text{g m}^{-3}$  when anthropogenic  $\text{NO}_x$  emissions are excluded (shown as red bar in Figure 7c). The reduction in anthropogenic  $\text{NO}_x$  emissions results in a shift of the  $\text{O}_3$  formation regime towards a more  $\text{NO}_x$ -sensitive ~~chemical~~ regime,

leading to a higher contribution of O<sub>3</sub> from soil emission sources. We conclude that with stricter anthropogenic emission reduction measures, the contributions of soil Nr emissions to O<sub>3</sub> production in both absolute and relative value would increase and further hamper the effectiveness of anthropogenic emission reductions. To effectively mitigate ~~the desired level of~~ O<sub>3</sub> ~~concentrations~~pollutions, it is necessary to implement much stricter control measures for anthropogenic emissions including coal burning and transportation due to the synergistic effects of SNO<sub>x</sub> and SHONO.

Here we show that the substantial soil Nr emissions present an additional challenge for O<sub>3</sub> pollution regulation in the North China. We further assess the impact of soil Nr emissions on air temperature change under different anthropogenic emission reduction scenarios. Under the background of climate change, future emission reduction scenarios should focus on the co-control of multiple air pollutants and greenhouse gas reductions. Therefore, we conduct multi-pollutant co-control reduction scenarios, taking into account the SO<sub>2</sub>, NO<sub>x</sub>, primary PM<sub>2.5</sub>, VOCs, and CO emissions reduced by 20%, 40%, 60%, 80%, and 100%, respectively, to investigate the impact of soil Nr emissions on air temperature change under different anthropogenic reduction scenarios (Table 1). By comparing changes in air temperature at 2m (T2) with and without soil Nr emissions under different ~~anthropogenic emission~~ reduction scenarios, Figure 8 shows that incorporating soil Nr emissions results in a slower rate of T2 increase compared to scenarios without soil Nr emissions, especially when multi-pollutant emissions are reduced to more than a half, and this phenomenon is consistent across all study regions. In the FWP region, when anthropogenic ~~NO<sub>x</sub>~~ emissions are eliminated, T2 increases by

0.056073 °C in the presence of soil Nr emissions, compared to 0.092095 °C in the absence of soil Nr emissions. In the BTH region, which has relatively high anthropogenic emissions, reducing anthropogenic NO<sub>x</sub> multi-pollutant emissions by the same proportion could result in relatively greater warming, and T2 increases by 0.084098 °C in the presence of soil Nr emissions, compared to 0.1514 °C in the absence of soil Nr emissions when anthropogenic NO<sub>x</sub> emissions are excluded. This is attributed to aerosols (such as sulfate and nitrate) and NO<sub>x</sub> emissions and their the effective radiative forcing (ERF) associated with the cooling effects of primary pollutants (e.g. SO<sub>2</sub>, NO<sub>x</sub>) and secondary inorganic aerosols (SIA), and positive ERF associated with the warming effects of CO and VOCs (high confidence) (Liao and Xie, 2021; Bellouin et al., 2020). (Bellouin et al., 2020; Liao and Xie, 2021). Decreases in aerosol primary pollutants emissions and SIA concentrations and NO<sub>x</sub> emissions could weaken the cooling effect and potentially accelerate warming to some extent, while the decrease in CO and VOCs emissions may still lead to temperature rise in a short-term. However, the soil Nr emissions can offset could contribute to a certain background concentration of aerosol, partially offsetting the temperature rise caused by declining anthropogenic NO<sub>x</sub> emissions of primary pollutants and greenhouse gas (Figure S5S8).

Therefore, although soil Nr emissions are relatively low compared to anthropogenic emissions, the combined effects of NO<sub>x</sub> and HONO emissions from natural soil and agricultural land should be considered when assessing climate change and implementing strategies to mitigate O<sub>3</sub> pollution.

#### 4. Conclusions

In this study, the updated soil Nr emission scheme was implemented in the UI-WRF-Chem model and used to estimate the combined and individual impact of SNO<sub>x</sub> and SHONO on subsequent changes in air quality and air temperature rise in North China, with a focus on two key regions (the BTH and FWP regions) because of high levels of soil Nr and anthropogenic emissions. We show that the SNO<sub>x</sub> ~~flux is nearly doubled that of~~ fluxes are almost twice as high as SHONO during July 2018, with higher soil emissions in areas with extensive cropland. The contribution of soil Nr emissions ~~in July to monthly~~ average ~~surface~~ NO<sub>2</sub> and HONO are 38.4% and 40.3% in the BTH, and 33.9% and 40.1% in the FWP region, respectively, and the substantial soil Nr emissions lead to a considerable increase in the monthly average MDA8 O<sub>3</sub> and nitrate concentrations, with the values of 16.9% and 42.4% in the BTH region and 17.2% and 42.7% in the FWP region, which both exceed the individual SNO<sub>x</sub> or SHONO effect. The presence of soil Nr emissions, acting as precursors of O<sub>3</sub> and ~~secondary inorganic aerosols~~ SIA, has a suppressing effect on efforts to mitigate summer O<sub>3</sub> pollution, particularly in the BTH region, and also leads to a slower increase rate of T2 (0.098 °C) in July compared to scenarios without soil Nr emissions (0.14 °C) when anthropogenic emissions are excluded. We note that the effect of soil Nr emissions shows spatial heterogeneity under different anthropogenic ~~NO<sub>x</sub>~~ emissions reduction scenarios.

However, we admit that uncertainties exist in both soil Nr and anthropogenic emissions, as well as the parameterization scheme of HONO sources. The agricultural emissions of another important reactive nitrogen gas, NH<sub>3</sub>, may also be underestimated due to uncertainties in agricultural fertilizer application and livestock waste in MEIC

inventory (Li et al., 2021a). These uncertainties could impact the aerosol formation and local cooling effect. Also, the discrepancies between simulated and observed NO<sub>2</sub>, O<sub>3</sub>, and other air pollutants in the model may affect the assessment of the role of soil Nr emissions in O<sub>3</sub> mitigation strategies and their impact on climate change. Thus, more direct measurements of soil Nr fluxes are crucial to better constrain soil emissions and improve the parametrization in the model.

Our study highlights that despite soil Nr emissions being lower than anthropogenic emissions, they still have a substantial impact on the effectiveness of O<sub>3</sub> pollution mitigation measures, and this effect becomes more significant as anthropogenic emissions decrease. Therefore, reactive nitrogen from soil emission ~~sources~~sources must be considered in formatting measures for the prevention and management of O<sub>3</sub> pollution, as well as addressing climate change.

**Code and data availability.** Some of the data repositories have been listed in Section 2.

The other data, model outputs and codes can be accessed by contacting Tong Sha via  
tong-sha@sust.edu.cn.

**Author contributions.** TS performed the model simulation, data analysis and  
manuscript writing. TS and JW proposed the idea. SY, QC and LL supervised this work  
and revised the manuscript. XM, ZF and KB helped the revision of the manuscript. YZ  
provided and analyzed the observation data.

882 <sup>a-h</sup> The values represent the reduction ratios applied to the anthropogenic emissions in the sensitivity

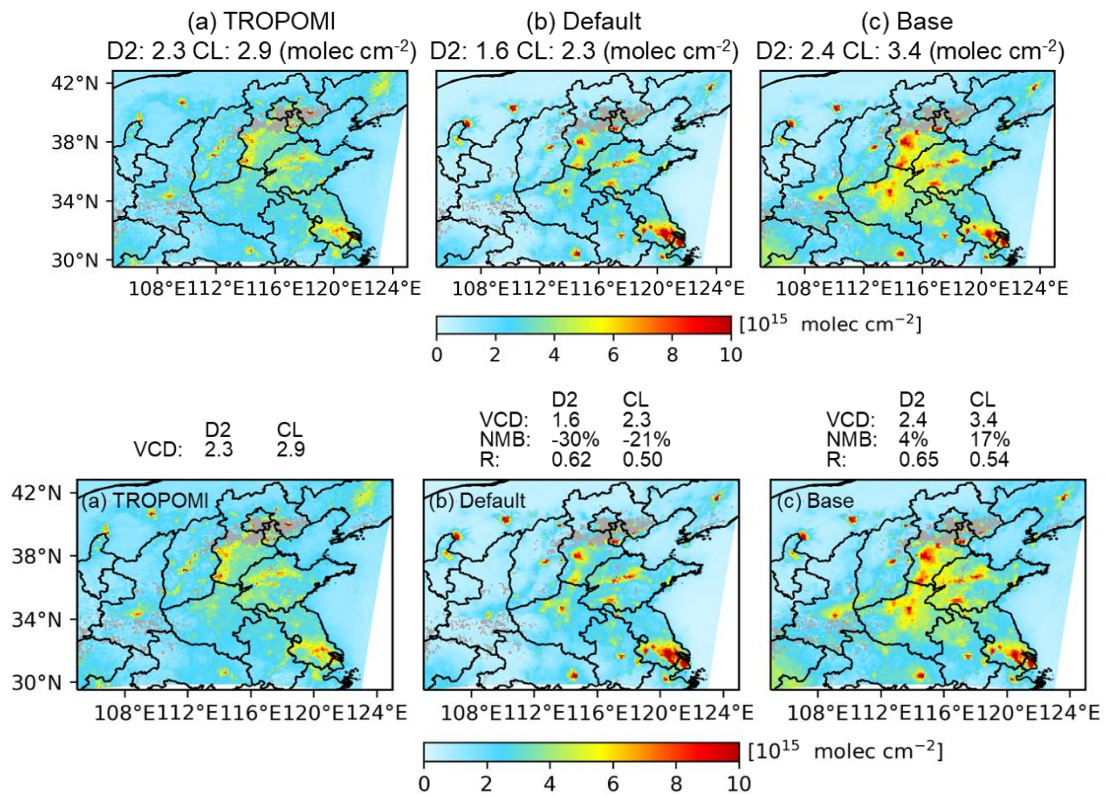

883 simulations compared to the Base.

884

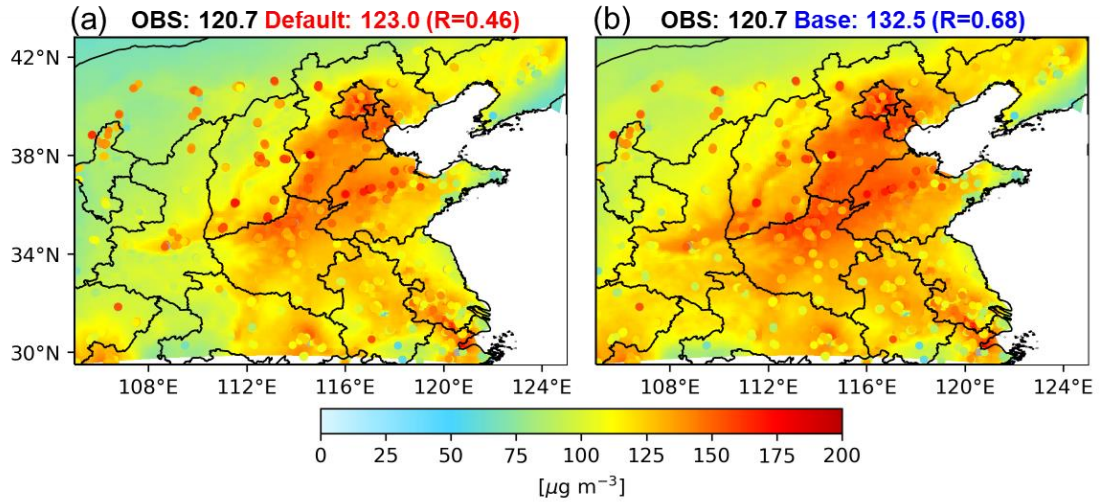

**Figure 1.** Distribution of the simulated monthly mean (a) soil  $\text{NO}_x$  emissions, (b) soil HONO emissions, and (c) anthropogenic  $\text{NO}_x$  emissions in North China in July 2018.

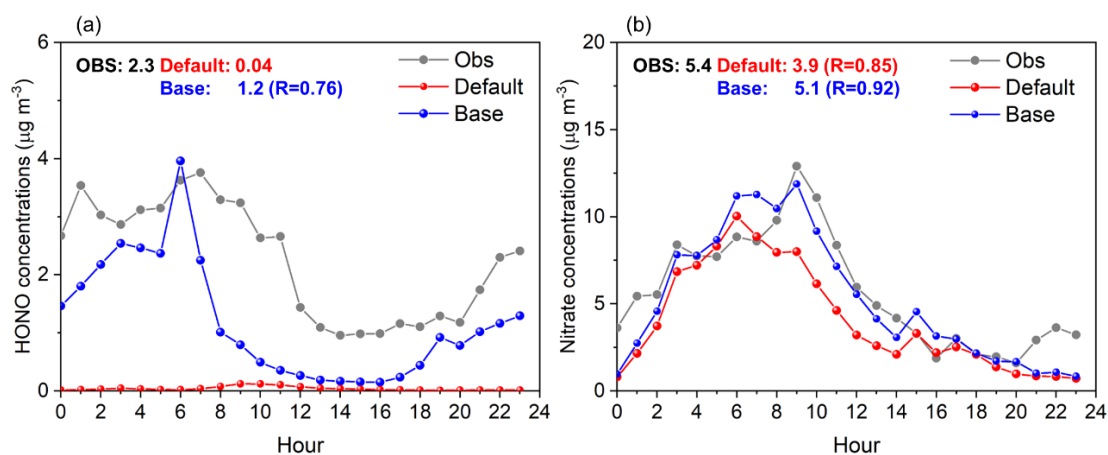

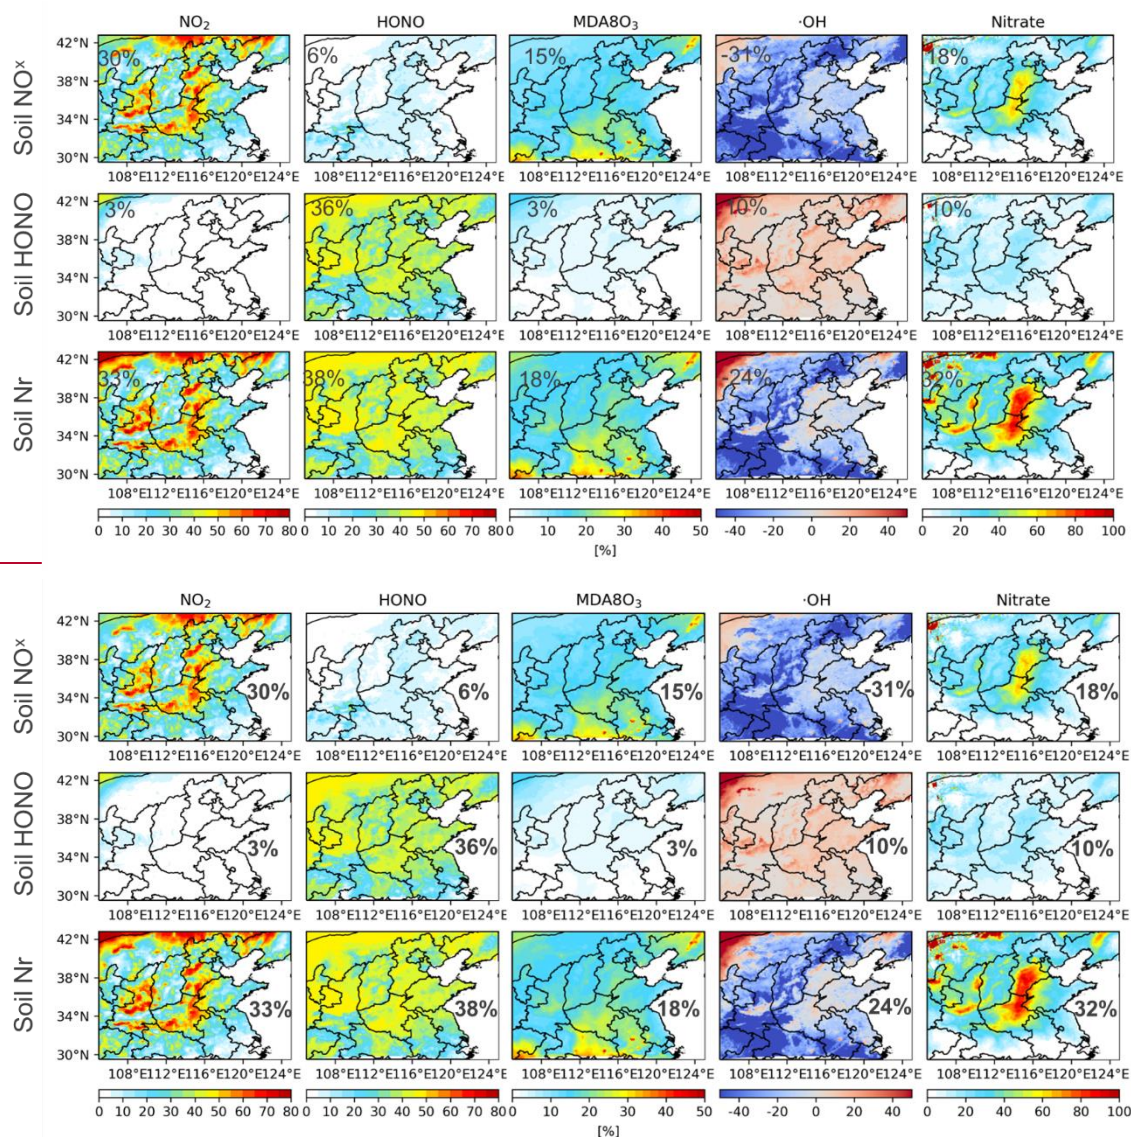

**Figure 2.** (a) Monthly mean tropospheric NO<sub>2</sub> VCD retrieved by TROPOMI measured at 12:00–14:00 LT and simulated by (b) Default and (c) Base averaged over the same periods in July 2018 in North China.

**Figure 3.** Distribution of observed (dots) and simulated (shaded) surface MDA8 O<sub>3</sub> from (a) Default and (b) Base in North China in July 2018. Statistics in the upper corner of panels are the monthly mean MDA8 O<sub>3</sub> concentrations averaged over the study region and the spatial correlation coefficient R between observations and simulations.

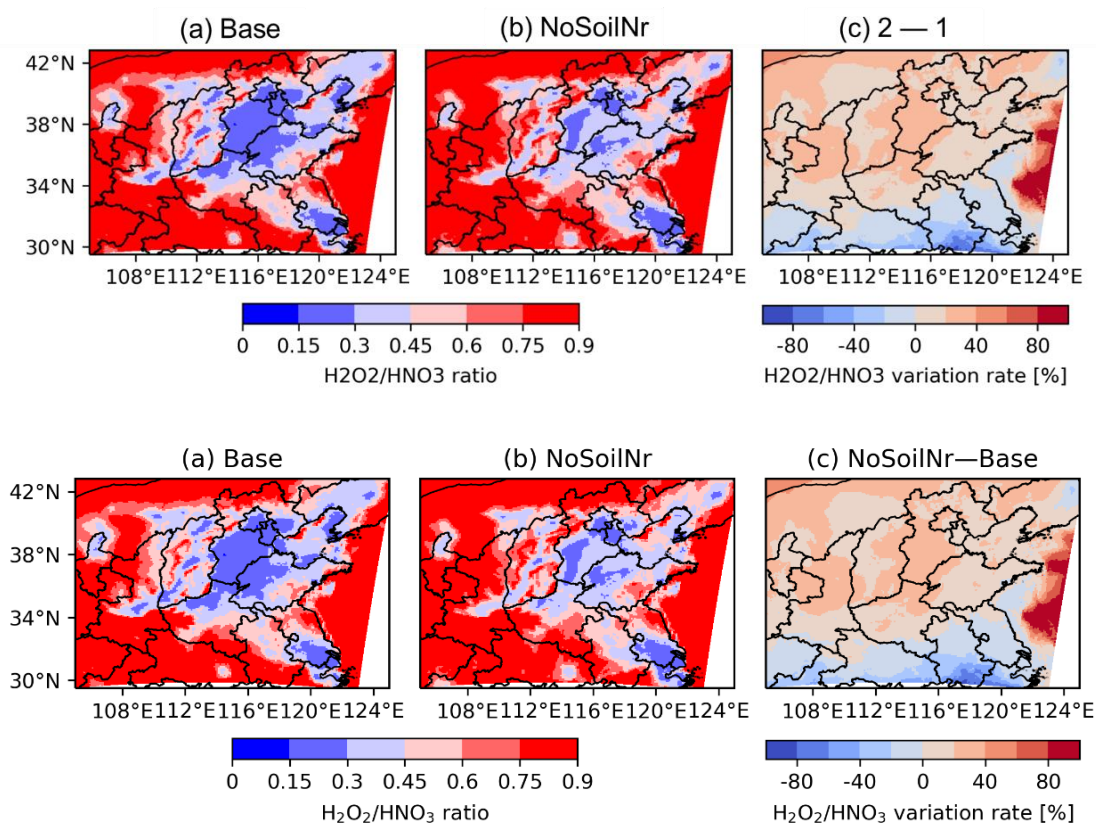

**Figure 4.** Diurnal variation of observed (in grey) and simulated (Default in red and Base in blue) surface (a) HONO and (b) nitrate concentrations at a rural station in Nanjing [in July 2018](#), with the mean value and temporal correlation coefficients (R) shown in the upper right corner.

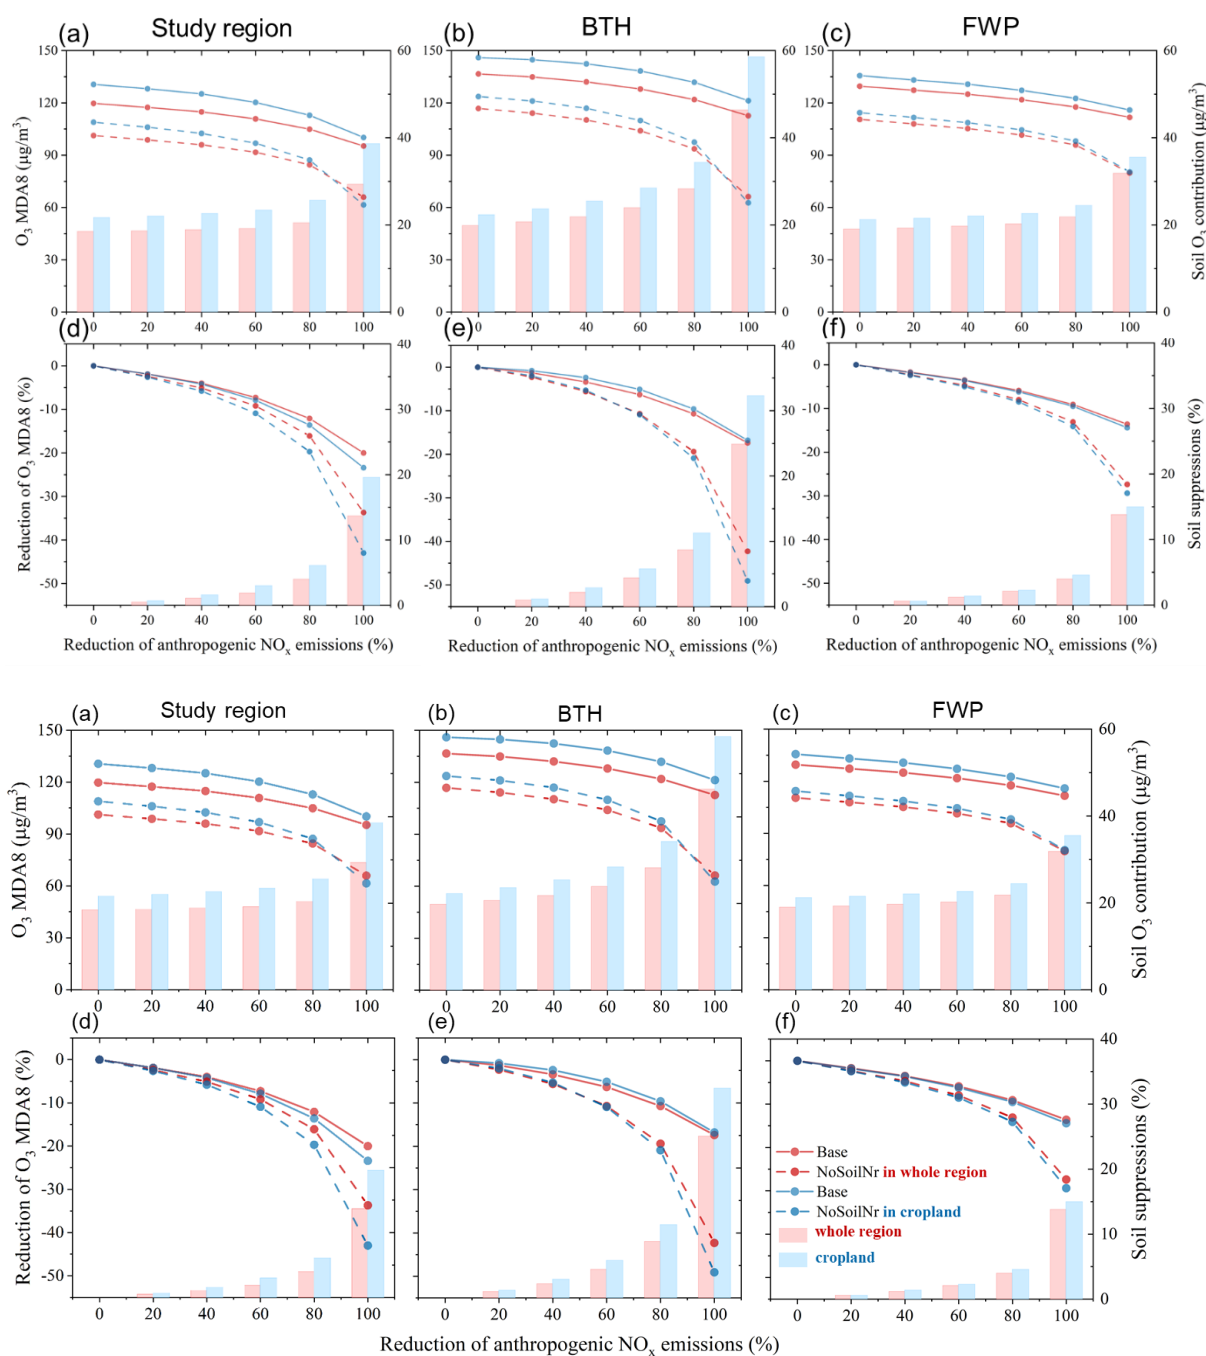

**Figure 5.** Simulated effects of soil emissions on air quality in North China in July 2018. The first and second rows show the contributions of soil NO<sub>x</sub> and soil HONO emissions on monthly average concentrations of NO<sub>2</sub>, HONO, MDA8O<sub>3</sub>, max-1h ·OH, and nitrate, respectively. The third row shows the combined effect of soil Nr emissions on the species listed above. Statistics in the upper right corner of each panel are the mean values averaged over the study region.

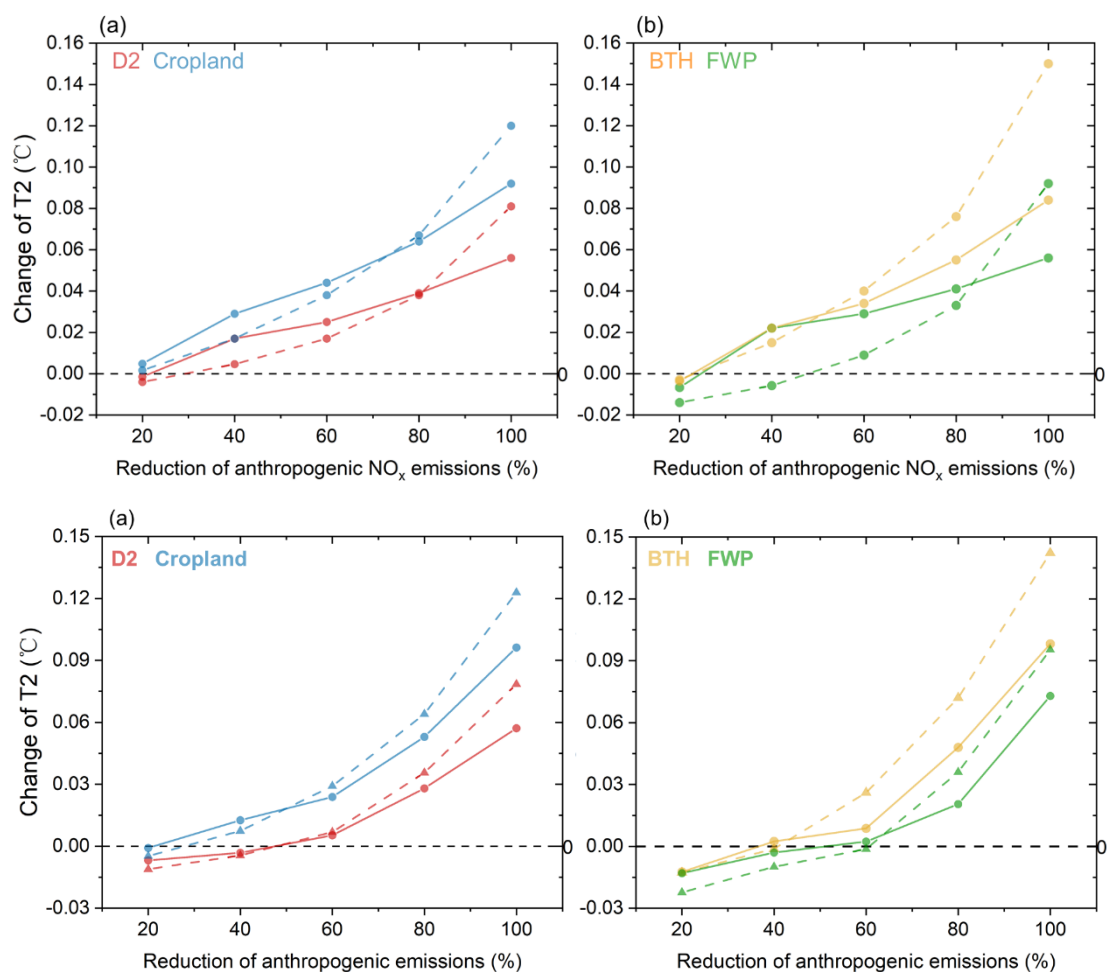

**Figure 6.** Distribution of the  $O_3$  formation regimes (represented as  $H_2O_2/HNO_3$  ratios) in North China in July 2018 for (a) Base simulation with the addition of soil Nr emissions and (b) NoSoilNr simulation without the addition of soil Nr emissions. (c) Changes in the distribution of  $O_3$  formation regimes due to the soil Nr emissions

**Figure 7.** Role of soil Nr emissions in O<sub>3</sub> pollution regulation in North China in July 2018. The responses of MDA8 O<sub>3</sub> concentrations to the reductions of anthropogenic NO<sub>x</sub> emissions (20%, 40%, 60%, 80% and 100%) relative to July 2018 levels, in the presence (solid line) and absence (dotted line) of soil Nr emissions in the study region, BTH and FWP region. (The lines in panels a-c and d-f are MDA8 O<sub>3</sub> concentrations and the relative reductions in MDA8 O<sub>3</sub> under different anthropogenic NO<sub>x</sub> emission

reductions, respectively. The red bars (right y-axis) in panels a-c show the corresponding O<sub>3</sub> contribution from soil Nr emissions, which is determined as the difference between the solid and dotted lines, and the blue bars are the same as the red bars but for statistics in cropland. The red bars (right y-axis) in panels d-f show the suppression of O<sub>3</sub> pollution mitigated due to the existence of soil Nr emissions, which are determined as the difference between the solid and dotted lines, and the blue bars are the same as the red bars but for statistics in cropland.)

**Figure 8.** The responses of air temperature at 2m (T2) to the reductions of anthropogenic  $\text{NO}_x$  emissions (taking into accounting the  $\text{SO}_2$ ,  $\text{NO}_x$ , primary  $\text{PM}_{2.5}$ , VOCs, and CO reduced by 20%, 40%, 60%, 80%, and 100%) relative to July 2018 levels in the presence (solid line) and absence (dotted line) of soil Nr emissions (a) in the study region, (b) BTH and FWP region.
