Abstract. As a key source of hydroxyl (OH) radical, nitrous acid (HONO) has attracted much attention for its important role in the atmospheric oxidant capacity (AOC) increase. In this study, we made a comparative study on the ambient levels, variation patterns, sources and formation pathway in warm season (from June to October in 2021) on a basis of a continuous intensive observation in an urban site of Beijing. The HONO concentration showed a larger contribution to OH radical relative to ozone at daytime. The emission factor (EF) from the vehicle emissions, was estimated to be 0.017, higher than most studies conducted in Beijing. The homogeneous production of HONO via reaction of NO + OH, $P_{\text{net}_{\text{OH}+\text{NO}}}$, were 0.033-0.17 ppb/h. The average nocturnal NO₂ to HONO conversion frequency k_{HONO} were 0.0016-0.011% h⁻¹. In warm seasons, the missing source of HONO, P_{unknown} , around noontime were 0.29-2.7 ppb/h. Relatively low humidity and strong solar illumination were conducive to HONO formation in June, which might be due to light-induced heterogeneous reactions of NO₂. In July in Beijing, high humidity condition was beneficial to the heterogeneous reaction of NO₂, and due to the increase of precipitation, more HONO would enter the liquid phase. For days with high humidity and strong sunlight in June and August, photolysis of nitrate was also one important HONO source. For August and September, light-induced reactions of NO₂ on non-aerosol surfaces under relatively low humidity and strong light conditions could be an important HONO source. In addition, the presence of Cl ions and sulfate could enhance the photolysis of nitrate, and this was obvious in July; the presence of organic compounds also could have this effect, which was obvious in June. Not only the HONO concentration but also the HONO source has temporal patterns, even within a season, it varies from month to month. This work highlights the importance of HONO for AOC in warm season, while encouraging long-term HONO observation to assess the contribution of HONO sources over time compared to the capture of pollution processes.

1 Introduction

30 From 2013 to 2022, the annual average concentration of PM_{2.5} in China has been decreasing, but it is still much higher than the World Health Organization's guideline value (5 µg/m³). Ozone pollution, on the other hand, is becoming more and

more prominent (Liu et al., 2023b; Li et al., 2022). China's air quality problem has developed from being dominated by PM_{2.5} in the past to being affected by the photochemical pollutants PM_{2.5} and ozone, that is, "Air Pollution Complex" (Zhu et al., 2023). The atmospheric oxidation capacity (AOC) determines the production rates of secondary pollutants in the atmosphere, and is the essential driving force in forming complex air pollution (Liu et al., 2021b).

As a trace gaseous pollutant, nitrous acid (HONO) strongly impacts the AOC, the photolysis of which can contribute to more than 60% of the OH radicals at daytime (Czader et al., 2012). As an important source of OH radicals in both rural and urban environments, HONO outweighs the contribution of ozone photolysis (Gu et al., 2022; Elshorbany et al., 2012; Yang et al., 2021b). Thus, as an important source of oxidants for AOC, HONO can substantially influence the formation of secondary pollutants, exerting a considerable impact on air quality, climate change, and human health (Requia et al., 2018; Zhang et al., 2021b; Huang et al., 2018; Liu et al., 2023b).

Due to the importance of HONO to AOC, researchers have done lots of work on the transformation process of HONO, i.e., source and sink. For the source of HONO, it is complicated and has been debated for decades. To sum it up, source of atmospheric HONO mainly includes: (a) direct emission from combustion, soil, and livestock farming. The combustion includes vehicle exhaust, industrial exhaust, and biomass burning (Liao et al., 2021; Kurtenbach et al., 2001; Kirchstetter et al., 1996; Nie et al., 2015). The release from soil nitrite is one important primary source of HONO (Su et al., 2011; VandenBoer et al., 2015; Wu et al., 2019), the biological soil crusts can accelerate the HONO emission in drylands (Weber et al., 2015), fertilization behavior of agricultural fields remarkably enhance the emission of HONO (Xue et al., 2021), and denitrification is one major HONO production pathway in boreal agricultural fields (Bhattarai et al., 2021). Meanwhile, livestock farming is also identified as one important primary emission source of HONO (Zhang et al., 2023a). (b) Homogeneous reaction of OH + NO, which usually occurs in polluted areas, the contribution of this recombination pathway to HONO may be significant during daytime with high NO and OH concentration (Gu et al., 2022). (c) Heterogeneous conversion of NO₂ on various surfaces (Liu et al., 2023a; Yu et al., 2022a; Yang et al., 2021a), Finlayson-Pitts et al. (2003) reported that NO₂ could be converted to HONO on humid surfaces with first order in NO₂, Xu et al. (2015) highlighted the HONO source had a large variability with heterogeneous conversion of NO₂ at ground face, Aubin and Abbatt (2007) found that the heterogeneous conversion of NO₂ on hydrocarbon surfaces was an effective pathway to generate HONO. (d) photolysis of nitric acid and nitrate in particles at daytime, which were considered as important sources of HONO in both experiments and field observations (Wang et al., 2023b; Ye et al., 2019; Yang et al., 2018; Ye et al., 2017). And for the sinks of HONO, diurnal photolysis is the main consumption way (Keller-Rudek et al., 2013), the reaction of HONO with OH radical is also one sink that needs to be paid attention to (Cox et al., 1976).

Generally, HONO concentration in the atmosphere is closely related to the quality of the atmosphere. As the heterogeneous processes are considered as the main source of HONO, and most of which are poorly understood, therefore, many field observations of HONO were focus on haze polluted environments (Li et al., 2012; Spataro et al., 2013; Tong et al., 2015; Xu et al., 2015; Hou et al., 2016). In urban areas, the HONO concentration can be up to more than 10 ppb during severe pollution episode (Zhang et al., 2019b). In China, the Chinese government has implemented series of stringent clean air

actions to address the severe air pollution issue since 2013, significant reduction of $PM_{2.5}$ was observed in North and South China during 2013-2020 (Li et al., 2022). However, ozone levels have not been effectively reduced in China, the warm-season (from April to September) mean maximum daily 8 h average ozone (MDA8 O_3) increased by $2.6 \mu\text{g}/(\text{m}^3 \cdot \text{yr})$ (Liu et al., 2023b). In view of the atmospheric changes in $PM_{2.5}$ and ozone, recent field observations have begun to pay attention to the potential influence of HONO on $PM_{2.5}$, ozone, and coexistence of $PM_{2.5}$ and ozone (Zhang et al., 2023c; Zhang et al., 2023b; Xuan et al., 2023; Chen et al., 2023; Zhang et al., 2022; Lin et al., 2022; Li et al., 2021). However, most HONO observations were conducted in autumn and winter, and the period were relatively short, usually a few weeks covering one or several pollution processes. Based on the increase of ozone in warm-season, long-term observations during the warm season are needed, yet is rather limited.

In this work, we conducted one HONO observation in an urban site of Beijing, the time was from June to October 2021, covering the whole summer and part of autumn. According to the Technical Regulation on Ambient Air Quality Index in China, only one day of moderate pollution ($PM_{2.5}$, in October) and no more than four days of light pollution (ozone) per month were included, so we analysed the observation data on a monthly basis. The atmospheric levels and variations of HONO and related species during each month were analysed and compared. The impacts of HONO on atmospheric oxidant capacity in each month were also assessed.

2 Methods

2.1 Observation site and instruments

Figure 1: Location of the observation site in this work.

The observation campaign was conducted from June 18th, 2021 to October 25th, 2021. The observation site was located at Chinese Research Academy of Environmental Sciences (CRAES, $40^{\circ}04'N$, $116^{\circ}42'E$), in the north of Chaoyang District, an urban site (Ren et al., 2022; Zhang et al., 2021a) in Beijing, China (Figure 1). Briefly, Chaoyang District was located at the eastern area of Beijing and was one of the six main urban districts (Dongcheng, Xicheng, Haidian, Chaoyang, Shijingshan, and Fengtai) of Beijing. This site was located about 2 km to the north of the North Fifth Road, approximately 0.3 km away

90 from Beiyuan Road, with a high volume of traffic. And this site was located in a mixed-use commercial and residential area, with several shopping malls, residential areas, and office buildings nearby, and there were no obvious sources of industrial pollution. Thus, this site could be considered as an urban site.

HONO was measured with a water-based long-path absorption photometer (Chen et al., 2020), the potential interferences, e.g., hydrolysis of NO₂, was subtracted by deployed a dual-channel absorption system. A set of commercial
95 analysers (Thermo 42i, 43i, 48i, 49i, 5030i, USA) were used to measure the concentrations of NO_x, SO₂, CO, O₃, and PM_{2.5} online. Due to the employment of a molybdenum NO₂-to-NO converter, the 42i analyzer might overestimate NO₂ concentration for the potential conversion of NO_z (NO_z = NO_y - NO_x. e.g., HONO, HNO₃, peroxyacetyl nitrate (PAN), and so on). Based on this, we conducted field observations of NO₂ from May 19th to 31st, 2024, using two devices with different measurement principles (Figure S1). The observation results showed that when the NO₂ concentration was above 7 ppb,
100 there was no significant difference between the two devices. However, when it was below 7 ppb, the 42i values were significantly higher than those of the N500, with a corresponding slope of 1.14. Based on this data, we have adjusted all NO₂ values below 7 ppb during the observation period, as well as the corresponding analyses. The time resolution of the analysers above were 1min, and the detection limits were 0.4 ppbv, 0.5 ppbv, 0.04 ppmv, 1ppbv, and 0.5 μg/m³, respectively. In order to ensure the accuracy of the data, routine maintenance was carried out. The meteorological parameters (temperature, T;
105 relative humidity, RH; pressure, P; wind speed and direction, WS and WD) were obtained with an automatic weather station (MAWS301, Vaisala, Finland) with a time resolution of 1 hr. Mass concentrations of the inorganic compositions in PM_{2.5} (NO₃⁻, SO₄²⁻, Cl⁻) were detected with a Monitor for AeRosols and Gases in ambient Air (MARGA, Model ADI 2080, Applikon Analytical B.V., the Netherlands) with 1 hr resolution. Detailed descriptions of the instrument inlet design and the operating characteristics can be referred in previous studies (Wang et al., 2022).

110 2.2 Photolysis rate simulation and OH estimation

Photolysis frequencies of JNO₂ were measured by a filter radiometer (METCON, Germany) with a time resolution of 1 min. Photolysis rate constant of O₃, HONO, and other parameters were simulated according to the aerosol optical depth and solar zenith angle by the weather research and forecasting model coupled with chemistry (WRF-Chem, version 3.7.1), based on the TUV model (<http://cprm.acom.ucar.edu/Models/TUV/InteractiveTUV/>) (Zhang et al., 2019a). To reduce the imprecision
115 of model simulation, the observed JNO₂ value was used to correct simulated results, i.e., J(O¹D) and J(HONO).

The OH concentration was calculated with the following equation (Liu et al., 2019):

$$[OH] = a \times \left(\frac{J(O^1D)}{10^{-5} s^{-1}} \right)^b + c \quad (1)$$

where $a = 4.2 \times 10^6 \text{ cm}^{-3}$, $b = 1$, $c = 2.2 \times 10^5 \text{ cm}^{-3}$ (Lin et al., 2022), these coefficients adopted here were from the OH studies in the Pearl River delta (PRD) and Beijing, China (Rohrer et al., 2014; Tan et al., 2017, 2018). According to the
120 summarizing coefficients in different OH observation campaigns in the polluted areas of China (Liu et al., 2019), the comprehensive impact of reactants (e.g., VOCs and NO_x) on OH could not compete with that of UV light to OH, the

chemical environments of OH could be similar. This could be a reasonable way to derive OH concentration by the equation above. At night, $J(O^1D)$ was zero, the nighttime OH concentration here was $2.2 \times 10^5 \text{ cm}^{-3}$. On the daytime, the OH concentration was estimated based on the equation above.

125 3 Results and discussion

3.1 Observation data overview

3.1.1 Variations of meteorological parameters during observation period

Figure S2 shows the time series of meteorological parameters including RH, T, WS, WD, and JNO_2 from June 18th, 2021 to October 25th, 2021. During the observations, the temperature ranged from 3.1-37 °C with an average of 23 °C, and the RH
130 ranged from 7.1%-100% with an average of 59%. The average wind speed during the observation was 1.1 m/sec, and the maximum wind speed was 5.20 m/sec. The average and monthly average values of T, RH, and WS are shown in Table S1. As shown in Figure S3 and Table S1, the temperature in June, July, and August was higher, 26-29 °C, temperature begun to drop slightly in September, 22 °C, in October, temperature dropped significantly, 13 °C. Meanwhile, the solar radiation in September and October decreased as the sun moved south. The maximum value of $J(NO_2)$ during the observation was
135 $8.2 \times 10^{-3} \text{ s}^{-1}$, the values reached a maximum at noon (with high solar radiation) and decreased to zero at night. The average wind speed also slightly decreased in September and October. During the observation, June had the lowest RH and the maximum wind speed; and due to the increase in precipitation, July had the highest RH. For the daily variation of meteorological parameters, T and JNO_2 expressed the same variation pattern with O_3 , that was increasing after sunrise and decreasing after sunset, as shown in Figure S3. While the RH showed the opposite pattern that was increasing during night
140 and decreasing during the daytime. For the WS, it was higher from 8 to 20 o'clock in June, and for the rest of the observation period, WS begun to increase in the afternoon and subside after sunset.

3.1.2 Variations of pollutant species during observation period

Figure 2 shows the time series of basic parameters including HONO, NO_2 , NO, CO, O_3 , SO_2 , PM_{10} , $PM_{2.5}$, and HONO/ NO_2 from June 18th, 2021 to October 25th, 2021. The HONO concentration ranged from 0.05 ppb to 5.2 ppb, with an averaged
145 value of 1.1 ppb (the entire observation period). The concentration of O_3 ranged from 1ppb to 227 ppb, with an averaged value of 72 ppb (the entire observation period). The concentrations of NO_2 , NO, CO, SO_2 , and $PM_{2.5}$ were 0.56-53 ppb, 0.01-210 ppb, 0.1-1.6 ppm, 1.3-4.6 ppb, and 1-181 $\mu\text{g}/\text{m}^3$, respectively, with average values (the entire observation period) of 10 ppb, 7.9 ppb, 0.56 ppm, 1.9 ppb, 19 $\mu\text{g}/\text{m}^3$, respectively. The average and monthly average concentrations of the basic parameters are shown in Table 1. One haze episode (1 day) occurred across the observation period, the daily mass
150 concentration of $PM_{2.5}$ was 117 $\mu\text{g}/\text{m}^3$, higher than the National Ambient Air Quality Standard (Class II: 75 $\mu\text{g}/\text{m}^3$). And for O_3 , eight episodes (13 days) occurred across the observation period, with MDA8 O_3 higher than the Class II: 160 $\mu\text{g}/\text{m}^3$.

Overall, the high HONO concentration was always accompanied by high concentration of NO_x (NO, NO₂) or aerosols (PM_{2.5}).

155 **Figure 2: Temporal variations of hourly average PM_{2.5}, CO, O₃, SO₂, NO, HONO, NO₂, and HONO/NO₂ during the observation period.**

Table 1. The average and monthly average concentration of HONO, NO₂, NO, CO, O₃, SO₂, PM_{2.5}, HONO/NO₂, and HONO/NO₂ from June to October during the observation period.

3.2 HONO observation comparison and pollution patterns

160 3.2.1 HONO observation comparison

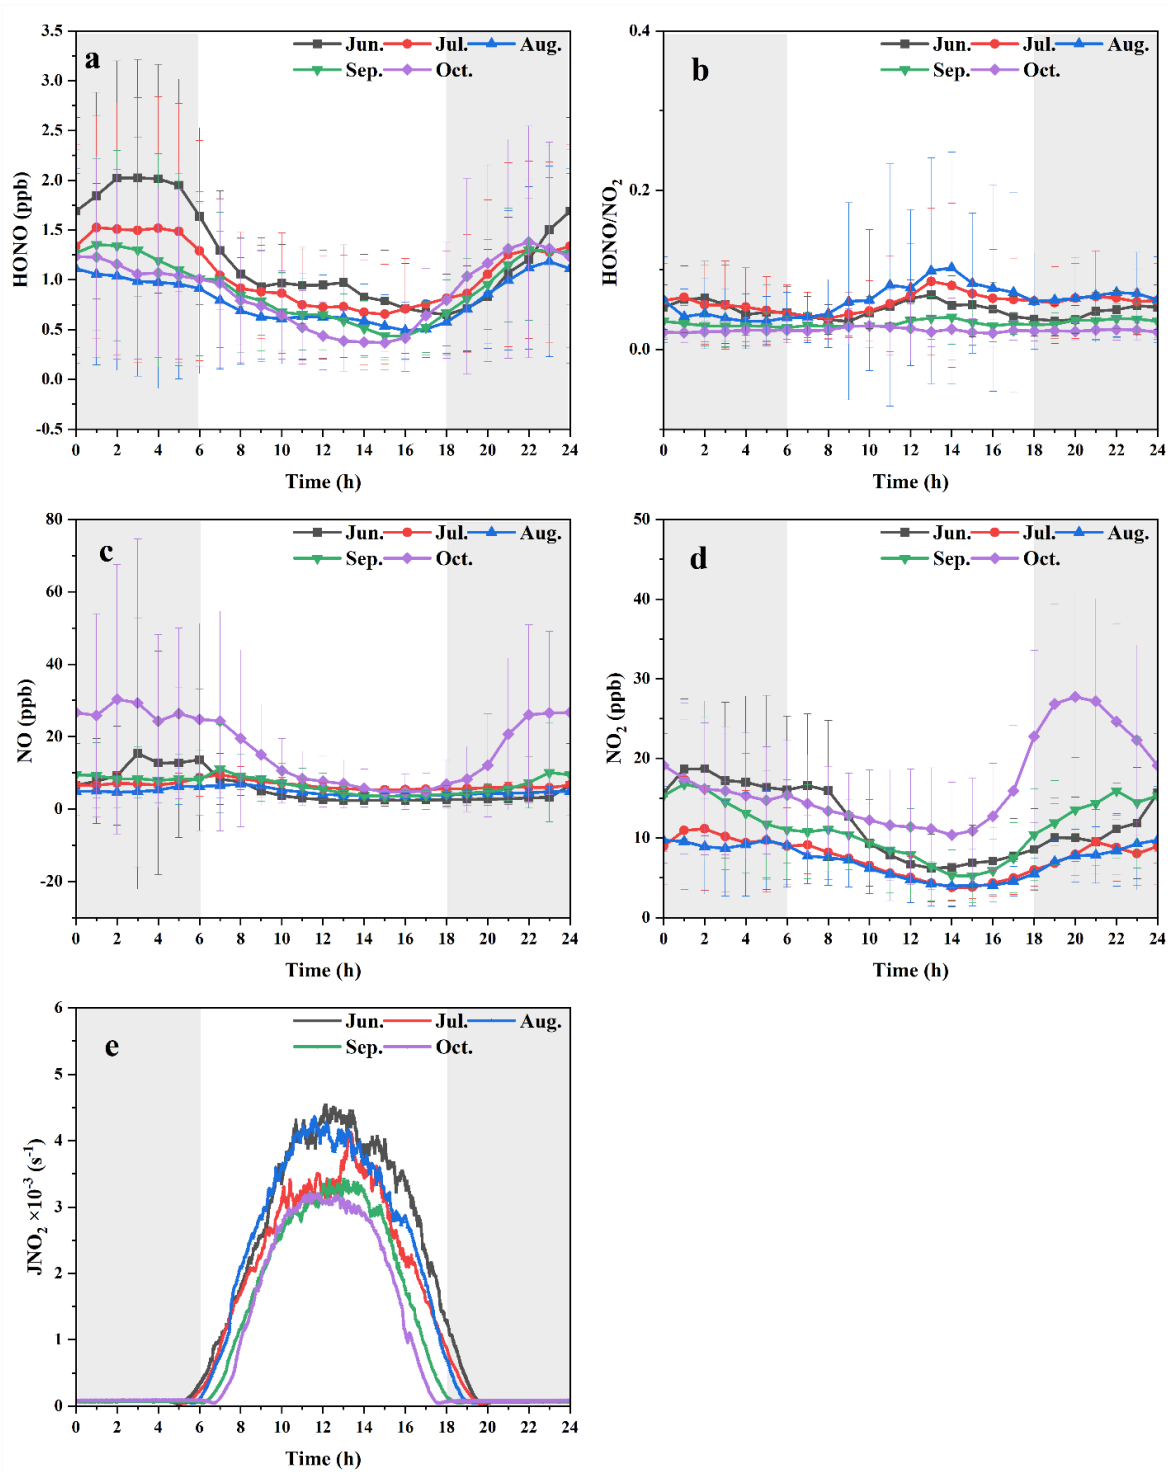

For comprehensive comparative analysis, a review of the HONO observations in Beijing was carried out in the past several years, and the results are shown in Table S2. Overall, the HONO measurement began to increase since 2016 in Beijing, the time was mainly concentrated in winter (Dec., Jan., and Feb.), and most of which were pollution process analyses. In this work, the observation period was in summer and autumn. When the air quality was relatively poor in early years, PM_{2.5} and HONO concentrations were both relatively high, now the air quality of Beijing was improved, both the concentration of PM_{2.5} and HONO decreased. However, during the observation period, PM_{2.5} concentration was low, HONO concentration was still relatively higher compared with other results performed in summer. According to previous studies (Murthy et al., 2020; Du et al., 2013), the narrowing of mixing layer could result in the accumulation of pollutants near the ground, while the increase of mixing layer height (MLH) favoured the dilution of pollutants. In general, the MLH was low in winter and high in summer. And the photochemistry was quite active in summer because of the strong solar radiation, in this case, HONO tended to undergo photolysis. Under the premise that the HONO sources remained constant, the concentration of HONO in summer should be lower than that in winter, and the HONO concentration in autumn should be higher than that in summer. However, our observations showed that HONO concentration in summer was comparable to that in winter and spring, and higher than that in autumn. Wang et al. (2023a) also found that in warm season, the PM_{2.5} and MDA8 O₃ increased along with the development of MLH (MLH < 1200 m), they analysed that the enhanced secondary chemical formation and increased atmospheric oxidant capacity could explain this phenomenon. Based on this, we discussed the HONO sources in the following sections.

3.2.2 HONO variation patterns

The average diurnal variation of the pollutants during the whole observation period and the averaged values in each month are shown in Figure S4 and Figure 3. It can be seen that the daily averaged pattern of pollutant HONO is that it decreased after sunrise and increased after sunset, this variation pattern was similar to previous studies (Lin et al., 2022; Lian et al., 2022; Zhang et al., 2019a; Zhang et al., 2023b; Zhang et al., 2022). This trend was the same as NO₂, NO, PM_{2.5}, and CO, that was, the overall was relatively stable, and it decreased slightly during the daytime. The diurnal variation of SO₂ was not large, and the overall concentration was very low, but it had a slightly increase during the daytime. The variation of O₃ showed the opposite trend, i.e., its concentration increased after sunrise, peaked in the afternoon and decreased at night. The rapid decrease of HONO in daytime was caused by rapid photolysis and the increase of boundary layer height. The ratio of HONO/NO₂ is often used to characterize the heterogeneous reaction of NO₂ to form HONO (Yang et al., 2021a; El Zein et al., 2013; Romanias et al., 2012). At night, the HONO/NO₂ ratio was similar to that of HONO, but the ratio increased obviously during the daytime, especially in summer (Jun., Jul., Aug.), and in summer, the light intensity was very strong, as

190 revealed in Figure 3b and 3e. This phenomenon indicated that HONO might have other potential sources related to the solar radiation, e.g., the conversation of NO_2 to HONO or nitrate photolysis.

And when HONO was analysed in months, the characteristics of each month were different. For the HONO/ NO_2 ratio in Figure 3b, August, July, June, and September were the months with a significant increase in the noon period, and there was no such phenomenon in October. However, it was important to note that the NO and NO_2 concentration in October were
195 the highest in the entire observation period compared to the low HONO concentration. The NO and NO_2 concentrations in June were not high, but the HONO concentration was the highest. The phenomenon could not be explained by the well-known sources of HONO (Xuan et al., 2023).

200 **Figure 3.** Diurnal variations in (a) HONO, (b) HONO/NO₂, (c) NO, (d) NO₂, and (e) JNO₂ in each month. The gray shading areas indicate nighttime, 18:00-06:00 LT.

3.3 Nocturnal HONO sources and formation

3.3.1 Direct emission of HONO

Previous studies showed that the primary emission sources of HONO included biomass burning and vehicles as well as soil emissions (Nie et al., 2015; Su et al., 2011). In this study, soil emission was a negligible source of HONO, since the observation site was located in an urban area, the surrounding soil was not used for agriculture, which greatly reduced HONO emission caused by fertilization process (Su et al., 2011). Except organic compounds (Simoneit, 2002), CO in the gas phase (Andreae, 2019) and potassium ions (K^+) in the aerosol phase (Xinghua et al., 2007) were well recognized inorganic tracers of biomass burning. Many CO sources other than biomass burning, such as industry and traffic, could contribute significantly to the CO loading. Apart from biomass burning emissions, there were no other significant sources of K^+ during the measurement. Therefore, K^+ was a suitable tracer of biomass burning. The average K^+ levels during the five months were 0.14, 0.11, 0.11, 0.15, and 0.13 $\mu\text{g}/\text{m}^3$, respectively, lower than 2 $\mu\text{g}/\text{m}^3$ (Xu et al., 2019), which indicated that biomass burning had little effect on this observation site. Hence, only vehicle emission was considered in this study.

The HONO/ NO_x ratio was used to derive the emission factor of vehicles in fresh plumes (Kurtenbach et al., 2001). Criteria followed by the fresh plumes were (Yun et al., 2017):

- (a) $\Delta\text{NO}/\Delta\text{NO}_x > 0.9$
- (b) good correlation between NO_x and HONO ($R^2 > 0.7$)
- (c) short duration of plumes < 1 h
- (d) positive correlation between CO and NO_x
- (e) no precipitation
- (f) global radiation < 10 W/m^2 , or $\text{JNO}_2 < 0.25 \times 10^{-3}$ s^{-1}

A total of 6 cases met the criteria mentioned above and the details were summarized in Table 2. The mean $\Delta\text{NO}/\Delta\text{NO}_x$ ratio of the selected fresh plumes was $(97 \pm 4.4)\%$, which indicated that the chosen air masses were considered to be truly fresh. The linear slope of HONO with NO_x were used as the emission factors of HONO. The correlation coefficients (R^2) between HONO and NO_x varied among the cases due to the unavoidably mixing with other air masses, and the range was from 0.72 to 0.93. The obtained $\Delta\text{HONO}/\Delta\text{NO}_x$ ratios were from 0.32% to 2.49%, with an average value of $(1.7 \pm 0.74)\%$. Thus, a mean $\Delta\text{HONO}/\Delta\text{NO}_x$ value of 0.017 was used as the emission factor (EF) in this work. The $\Delta\text{HONO}/\Delta\text{NO}_x$ values obtained in urban area of Beijing in previous studies were also summarized in Table S2, the EF reported so far was concentrated in the range of 0.003-0.013, which was slightly lower than the EF in this work. The vehicle engine types, catalytic converters use, and fuels could affect the emission factors of vehicles (Kurtenbach et al., 2001). According to Kessler and Platt (1984), diesel engines had a higher HONO/ NO_x ratio than gasoline engines. In our study, the higher HONO/ NO_x value possibly due to that the observation site was located outside the fifth ring road, and more heavy-duty diesel vehicles passed by on the surrounding road at night (regulations of the Public Security Traffic Management Bureau of

the Beijing Municipal Public Security Bureau, i.e., from 6 a.m. to 11 p.m. every day, trucks are prohibited from passing on the roads within the Fifth Ring Road (exclusive), and trucks with an approved load weight of more than 8 tons (inclusive) are prohibited on the main road of the Fifth Ring Road). Assuming that NO_x mainly arose from vehicle emissions, the mean $\Delta\text{HONO}/\Delta\text{NO}_x$ value of 0.017 was adopted to estimate the vehicle emissions P_{emis} (ppb/h) contribution to the HONO concentration (this factor may lead to an overestimation of the P_{emis} at daytime):

$$P_{\text{emis}} = \text{NO}_x \times \text{EF} \quad (2)$$

Then the concentration of HONO in air that is not due to direct vehicular emissions (the corrected HONO concentration, $\text{HONO}_{\text{corr}}$) can be obtained from the following equation:

$$\text{HONO}_{\text{corr}} = \text{HONO} - P_{\text{emis}} \quad (3)$$

Table 2. Emission ratios ($\Delta\text{HONO}/\Delta\text{NO}_x$) of fresh vehicle plumes.

Date (yyyy/mm/dd)	Time	$\Delta\text{NO}/\Delta\text{NO}_x$		$\Delta\text{HONO}/\Delta\text{NO}_x$	
		Slope (%)	R ²	Slope (%)	R ²

3.3.2 Homogeneous formation of HONO

The homogeneous production of HONO via reaction of $\text{NO} + \text{OH}$ was also important at night (Li et al., 2012). The net production rate of HONO (P_{net}) via homogeneous reaction could be calculated based on the following Equation (4):

$$P_{\text{NO+OH}}^{\text{net}} = k_{\text{NO+OH}}[\text{NO}][\text{OH}] - k_{\text{HONO+OH}}[\text{HONO}][\text{OH}] \quad (4)$$

where the rate constants of $k_{\text{NO+OH}}$ and $k_{\text{HONO+OH}}$ for reactions R1 and R2 at 298k were 9.8×10^{-12} and $6.0 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively (Liu et al., 2021a). $[\text{HONO}]$ and $[\text{NO}]$ were the hourly average concentration of HONO and NO at night. The OH concentration during the observation period was estimated according to the previous literature, $2.2 \times 10^5 \text{ molecules cm}^{-3}$ were applied here (Liu et al., 2019; Lin et al., 2022).

The nocturnal variations of HONO, NO, and $P_{\text{OH+NO}}^{\text{net}}$ during the observation period in each month were shown in Figure 4. Since the values of $K_{\text{HONO+OH}}$ and $K_{\text{NO+OH}}$ were similar, HONO and NO concentrations were critical to $P_{\text{OH+NO}}^{\text{net}}$. During the observation period, average values of $P_{\text{OH+NO}}^{\text{net}}$ were 0.050, 0.045, 0.033, 0.052, and 0.17 ppb/h, respectively, for June, July, August, September, and October. $P_{\text{OH+NO}}^{\text{net}}$ had significantly high value in October, which was due to the high NO concentration, as shown in Figure 4a. From 18:00 LT to 22:00 LT in October, $P_{\text{OH+NO}}^{\text{net}}$ showed an obvious increase, and the HONO concentration also showed an increase trend, which indicated that homogeneous reaction during this period was the

main source of HONO. However, it should be noted that the $P^{\text{net}}_{\text{OH}+\text{NO}}$ in October was the highest, but the concentration of
 260 HONO was particularly lower compared with that in June, July, and September (from 23:00 LT to 6:00 LT), especially that
 in June, which indicated that the homogeneous reaction in these three month (June, July, and September) was not the main
 source of HONO.

As shown in Figure 4b, the HONO concentration ranged from 0.96 to 1.5 ppb in the whole observation period. In order
 to verify the contribution of homogeneous reaction, the accumulated HONO concentration was compared with the integrated
 265 $P^{\text{net}}_{\text{OH}+\text{NO}}$ at night in each month. Overall, the contribution of HONO produced by homogeneous reaction to the accumulated
 HONO concentration during the observation period was 3.4%, 3.5%, 3.4%, 4.6%, and 15%, respectively. And this
 phenomenon suggests that the nocturnal homogeneous process is not the main source of HONO.

270 **Figure 4. Homogeneous reaction of OH and NO at night. The error bars represent the standard derivation of NO, HONO, and $P^{\text{net}}_{\text{OH}+\text{NO}}$.**

3.3.3 Nighttime heterogeneous conversion of NO_2

Heterogeneous conversion of NO_2 on ground or aerosol surface has been recognized as an important HONO source
 (Finlayson-Pitts et al., 2003; Liu et al., 2020). Nighttime $\text{HONO}_{\text{het-night}}$ concentration could be estimated from the
 heterogeneous reaction (R3, the mechanism of heterogeneous formation of HONO, and this was first order in NO_2 and H_2O
 275 (Alicke et al., 2002), and the conversion frequency of HONO ($k_{\text{HONO,het-night}}$) could be expressed as Equation 7. We

determined the HONO formation by assuming a linear increase of its mixing ratio during a time interval (t_2-t_1). Since the mechanism summarized in R3 was first order in NO_2 , the HONO formation was proportional to the NO_2 concentration. The conversion frequency was also assumed to be independent of gas phase water (Kleffmann et al., 1998), the average nighttime conversion frequency was determined by Equation 5,6, and 7. In order to eliminate the influence of direct emission and diffusion, CO was chosen as the reference species used for normalization:

$$k_{\text{HONO}}^0 = \frac{[\text{HONO}_{\text{corr,night}}]_{t_2} - [\text{HONO}_{\text{corr,night}}]_{t_1}}{(t_2 - t_1)[\text{NO}_2]} \quad (5)$$

$$k_{\text{HONO}}^X = \frac{\left(\frac{[\text{HONO}_{\text{corr,night}}]_{t_2}}{[X]_{t_2}} - \frac{[\text{HONO}_{\text{corr,night}}]_{t_1}}{[X]_{t_1}}\right)[X]}{0.5(t_2 - t_1)\left(\frac{[\text{NO}_2]_{t_2}}{[X]_{t_2}} + \frac{[\text{NO}_2]_{t_1}}{[X]_{t_1}}\right)} = \frac{2\left(\frac{[\text{HONO}_{\text{corr,night}}]_{t_2}}{[X]_{t_2}} - \frac{[\text{HONO}_{\text{corr,night}}]_{t_1}}{[X]_{t_1}}\right)}{(t_2 - t_1)\left(\frac{[\text{NO}_2]_{t_2}}{[X]_{t_2}} + \frac{[\text{NO}_2]_{t_1}}{[X]_{t_1}}\right)} \quad (6)$$

$$k_{\text{HONO,het-night}} = \frac{1}{2}(k_{\text{HONO}}^0 + k_{\text{HONO}}^{\text{CO}}) \quad (7)$$

where $[\text{NO}_2]$ was the mean value of NO_2 concentration between time t_2 and t_1 , k_{HONO}^0 was the conversion frequency which was not scaled, and k_{HONO}^X was the conversion frequency scaled with reference gases X (CO). Then the NO_2 to HONO conversion rate (k_{HONO}) was calculated by the combination of k_{HONO}^0 (not scaled k_{HONO}) and $k_{\text{HONO}}^{\text{CO}}$ (CO scaled k_{HONO}), which could reduce the impact of uncertainties in diffusion process and emissions on the conversion rate.

Table 3. The conversion frequency k_{HONO} , $k_{\text{HONO}}[\text{NO}_2]$, and $\text{P}^{\text{net}}_{\text{OH}+\text{NO}}$ in each month during the observation period.

	June	July	August	September	October
$k_{\text{HONO,het-night}}$ (hr^{-1})	$0.011 \pm 0.3\%$	$0.01 \pm 0.2\%$	$0.0093 \pm 0.15\%$	$0.0081 \pm 0.06\%$	$0.0016 \pm 0.02\%$
$k_{\text{HONO,het-night}}[\text{NO}_2]$ (ppb/hr)	0.15 ± 0.02	$0.089 \pm 0.6\%$	$0.079 \pm 0.4\%$	0.11 ± 0.01	$0.032 \pm 0.1\%$
$\text{P}^{\text{net}}_{\text{OH}+\text{NO}}$ (ppb/hr)	$0.034 \pm 0.2\%$	$0.035 \pm 0.3\%$	$0.034 \pm 0.2\%$	$0.046 \pm 0.4\%$	0.15 ± 0.06

The averaged values of $k_{\text{HONO,het-night}}$ during the observation period were 0.011 hr^{-1} , 0.01 hr^{-1} , $0.0093\% \text{ hr}^{-1}$, 0.0081 hr^{-1} , and 0.0016 hr^{-1} , respectively, for June, July, August, September, and October, with 0.008 hr^{-1} on average. The averaged value was slightly higher than that reported by Xuan et al. (2023) and Jia et al. (2020), 0.0073 hr^{-1} and 0.0078 hr^{-1} from August to September, 2018. The varied values of k_{HONO} in each month indicated the different environmental conditions in each month, e.g., surface features, aerosol concentrations (Su et al., 2008). As shown in Table 3, June had the highest $k_{\text{HONO,het-night}}[\text{NO}_2]$, but the lowest $\text{P}^{\text{net}}_{\text{OH}+\text{NO}}$, this indicated that the heterogeneous conversion from NO_2 was more important for HONO formation at night in June. However, October had the lowest $k_{\text{HONO,het-night}}[\text{NO}_2]$, but the highest $\text{P}^{\text{net}}_{\text{OH}+\text{NO}}$, and this indicated HONO produced by homogeneous reaction was more important than heterogeneous conversion from NO_2 .

In general, the importance of the two generation pathways of nocturnal HONO might change due to the time and environmental factors. The North China has four distinct seasons, temperature and relative humidity varies with the seasons, pollutants in the gas phase and particle phase in the environment can also be affected, and the factors of observation location

and observation time should be taken into account when evaluating the relative contribution of the generation pathways to HONO.

3.4 HONO daytime budget

305 3.4.1 Budget analysis of HONO

According to the source and sink pathways of HONO mentioned on introduction section, the sources of HONO on the daytime (7:00-18:00 LT) include: (1) direct emission of HONO (P_{emis}), (2) homogeneous reaction of NO with OH ($P_{OH+NO}=k_{OH+NO}[OH][NO]$), (3) the unknown sources during the daytime ($P_{unknown}$) (4) the vertical (T_v) and horizontal (T_h) transport processes of HONO, which were thought to be negligible for the relatively homogeneous atmospheres with calm winds and the intense radiation (Dillon et al., 2002; Sörgel et al., 2011); the sinks of HONO on the daytime include: (1) dry deposition of HONO ($L_{dep}=\frac{V_{HONO}}{H}[HONO]$), (2) photolysis of HONO ($L_{phot} = J_{HONO}[HONO]$), (3) reaction of OH with HONO ($L_{OH+HONO} = k_{OH+HONO}[HONO][OH]$).

The budget of HONO can be calculated by the following equation (8), (9), and (10):

$$\frac{dHONO}{dt} = (P_{emis} + P_{OH+NO} + P_{unknown}) - (L_{dep} + L_{phot} + L_{OH+HONO}) \quad (8)$$

$$315 \quad P_{unknown} = \frac{dHONO}{dt} + L_{dep} + L_{phot} + L_{OH+HONO} - P_{emis} - P_{OH+NO} \quad (9)$$

$$P_{unknown} = \frac{\Delta HONO}{\Delta t} + k_{OH+HONO}[OH][HONO] + J_{HONO}[HONO] + \frac{V_{HONO}}{H}[HONO] - k_{OH+NO}[OH][NO] - P_{emis} \quad (10)$$

where $\frac{dHONO}{dt}$ represents the difference between HONO sources and sinks; $\frac{\Delta HONO}{\Delta t}$ was the observed change of HONO, the rate constants of k_{NO+OH} and $k_{HONO+OH}$ at 298k were 9.8×10^{-12} and $6.0 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively (Liu et al., 2021a). A value of $V_{HONO} = 1.6 \text{ cm/s}$ was adopted here for the deposition rate of HONO (Zhang et al., 2019b), the value of $H = 200 \text{ m}$ was used here as the mixing layer height (Hu et al., 2022). The OH concentration and J_{HONO} were calculated with the method mentioned in section 2.2. According to the model simulation results, the averaged J_{HONO} values were in the range of $0.78 \times 10^{-3} - 1.4 \times 10^{-3} \text{ s}^{-1}$. The daytime hourly averaged values of OH concentration in the five months were in the ranges of $2.9 \times 10^6 - 8.9 \times 10^6 \text{ molecules/cm}^3$.

325 Figure 5 illustrated the details production/loss rates and proportion of HONO during the observation period. And Table S3 showed the averaged production/loss rates of HONO around noontime (10:00-15:00 LT). The dominant loss pathway of HONO during the five months was the photodecomposition (L_{phot}), the averaged values of L_{phot} were 1.1-3.9 ppb/hr around noontime. The following loss pathway of HONO was dry deposition (L_{dep}), the averaged values of L_{dep} were 0.13-0.27 ppb/hr around noontime. The loss pathway with the least contribution was the reaction of OH with HONO ($L_{OH+HONO}$), the averaged values of $L_{OH+HONO}$ were 0.029-0.15 ppb/hr at the same time. For the production pathways of HONO around noontime, the averaged values of homogeneous reaction rate between NO and OH (P_{OH+NO}) were 0.64-1.5 ppb/hr. The

averaged values of P_{emis} were 0.16-0.33 ppb/hr. For the high value of P_{emis} in October, the possible reasons maybe that the corresponding diffusion conditions were weakened due to the decrease in wind speed, and the change of epidemic control policies in this area in October resulted in the increase of the traffic emissions. The averaged values of $P_{unknown}$ were 0.29-2.7 ppb/hr, the contribution of which to the production of HONO were 78% (June), 55% (July), 64% (August), 68% (September), and 30% (October), respectively. In summary, photodecomposition was the largest removal pathway around noontime during the whole observation period; $P_{unknown}$ contributed the most to the production of HONO in June, July, August, and September, homogeneous reaction of NO and OH dominated the HONO production in October at daytime; June had the highest $P_{unknown}$, and October had the lowest $P_{unknown}$.

The obtained average $P_{unknown}$ values in Summer (from June to August), 2.3 ppb/hr, was at the middle level of those reported literatures in urban areas, as shown in Table 4. The $P_{unknown}$ values in Autumn (from September to October) (1.0 ppb/hr) was at the lower-middle level of those reported literatures in urban areas.

Table 4. The $P_{unknown}$ values in this work and reported literatures.

3.4.2 Possible unknown source at daytime

Based on the assumption that nighttime heterogeneous conversion of NO₂ continued in the same way at the daytime, the nighttime heterogeneous production of HONO was adopted here, and $P_{\text{het}} = k_{\text{HONO}}[\text{NO}_2]$ (Alicke, 2002;Sörgel et al., 2011). Dark heterogeneous formation accounted for 6.5% (June), 4.9% (July), 2.9% (August), 6.5% (September), and 11% (October) of missing sources of HONO at daytime, respectively, which was almost negligible at daytime. And the average value of P_{unknown} normalized by NO₂ at daytime (10:00-15:00 LT) was 0.025-0.61 h⁻¹, as shown in Table S3, much greater than the conversion rates at nighttime. This phenomenon implied that P_{unknown} could not be explained by the nocturnal mechanism of NO₂ to HONO.

According to the reported possible HONO sources in literatures (Zhang et al., 2023c;Zhang et al., 2022;Lian et al., 2022), light-induced heterogeneous conversion from NO₂ to HONO and photolysis of nitrate were responsible for the P_{unknown} , solar illumination and relative humidity were the two most frequently considered meteorological factors. Thus, a correlation analysis was performed to explore the potential unknown sources of HONO at daytime, and the details are shown in Table S4.

Wang et al. (2017a) analyzed the data of Beijing from 20 June to 25 July 2016 (summer) and found that, compared to JNO₂ or RH alone, the correlation between P_{unknown} and product of JNO₂ and RH was good. Based on this phenomenon, it was thought that photolytic and heterogeneous reaction occurring upon wet surface were important unknown sources of HONO. In our work, good correlation between P_{unknown} and product of JNO₂ and RH was also found in June, as shown in Table S4, June had the lowest RH and the highest JNO₂ value, this phenomenon implied that these combined meteorological factors were conducive to the formation of HONO. However, this phenomenon was not evident in other four months, as they had relative higher RH (due to the precipitation) and lower JNO₂ value.

In August and September, it could be seen that low NO₂ and PM_{2.5} conditions could lead to high P_{unknown} , corresponding to high JNO₂ value and relatively low RH (20-40%). This phenomenon suggested that there were other possible unknown sources of HONO, and this might be due to the light-enhancing effect of NO₂ on non-aerosol surfaces.

Light-induced heterogeneous conversion from NO₂ to HONO was responsible for the P_{unknown} (Yu et al., 2022a;Jin et al., 2022;Yang et al., 2021a). Thus, the correlation between P_{unknown} and NO₂ in the presence of light was analysed, $\text{JNO}_2 \times \text{NO}_2 \times \text{PM}_{2.5}$ ($R = 0.62, P < 0.05$) $>$ $\text{NO}_2 \times \text{PM}_{2.5}$ ($R = 0.57, P < 0.05$), $\text{JNO}_2 \times \text{NO}_2 \times \text{OC}$ ($R = 0.58 P < 0.05$) $>$ $\text{NO}_2 \times \text{OC}$ ($R = 0.57, P < 0.05$) in June, this confirms the light-induced heterogeneous enhancement effect in this observation.

Wang et al. (2023b) and Ye et al. (2017) found that photolysis of particulate nitrate (NO₃⁻) was a source of HONO and NO₂ in the troposphere. And the photolysis of nitrate was affected by RH, coexistence of inorganic components, and coexistence of organic components (Gen et al., 2022;Cao et al., 2022). As shown in Table S4, we found significant correlation between P_{unknown} and $\text{JNO}_2 \times [\text{NO}_3^-]$ in June ($R = 0.48, P < 0.05$) and July ($R = 0.29, P < 0.05$). Gen et al. (2019) and Zhang et al. (2020) found that the photolysis rate of nitrate particles under high relative humidity conditions could reach an

380 order of 10^{-5} . In our work, we also found that the correlations between P_{unknown} and $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{RH}$ in June ($R = 0.50$, $P < 0.05$) and July ($R = 0.30$, $P < 0.05$) were higher than the conditions without RH.

Through heterogeneous photochemical simulation experiments, Wingen et al. (2008) found that an enhanced NO_2 yield was observed as the chloride to nitrate ratio increased. Jin et al. (2022) performed the nitrate photolysis experiments with a flow tube reactor, and found that surprising yields of HONO and NO were formed during the photolysis experiment of
385 NH_4NO_3 in the presence of halogen ions (Cl^- , Br^- , I^-), this phenomenon indicated the important role of halogen ions in nitrate photolysis process. Thus, we analysed the correlation between nitrate and P_{unknown} in the presence of Cl^- ion. As shown in Table S4, the correlation between P_{unknown} and the corresponding factors was as follows: $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{Cl}^-$ ($R = 0.46$, $P < 0.05$) $>$ $J\text{NO}_2 \times [\text{NO}_3^-]$ ($R = 0.29$, $P < 0.05$) in July; $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{RH} \times \text{Cl}^-$ ($R = 0.44$, $P < 0.05$) $>$ $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{RH}$ ($R = 0.30$, $P < 0.05$) in July. Our observation data also illustrated the facilitating effect of halogen ions on nitrate photolysis.

390 Bao et al. (2018) found that a large amount of HONO and NO_x were formed during the photolysis experiment of nitrate in the presence of sulfate. Significant positive correlations also occurred in our observations in July: $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{SO}_4^{2-}$ ($R = 0.32$, $P < 0.05$) $>$ $J\text{NO}_2 \times [\text{NO}_3^-]$ ($R = 0.29$, $P < 0.05$); $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{RH} \times \text{SO}_4^{2-}$ ($R = 0.33$, $P < 0.05$) $>$ $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{RH}$ ($R = 0.30$, $P < 0.05$).

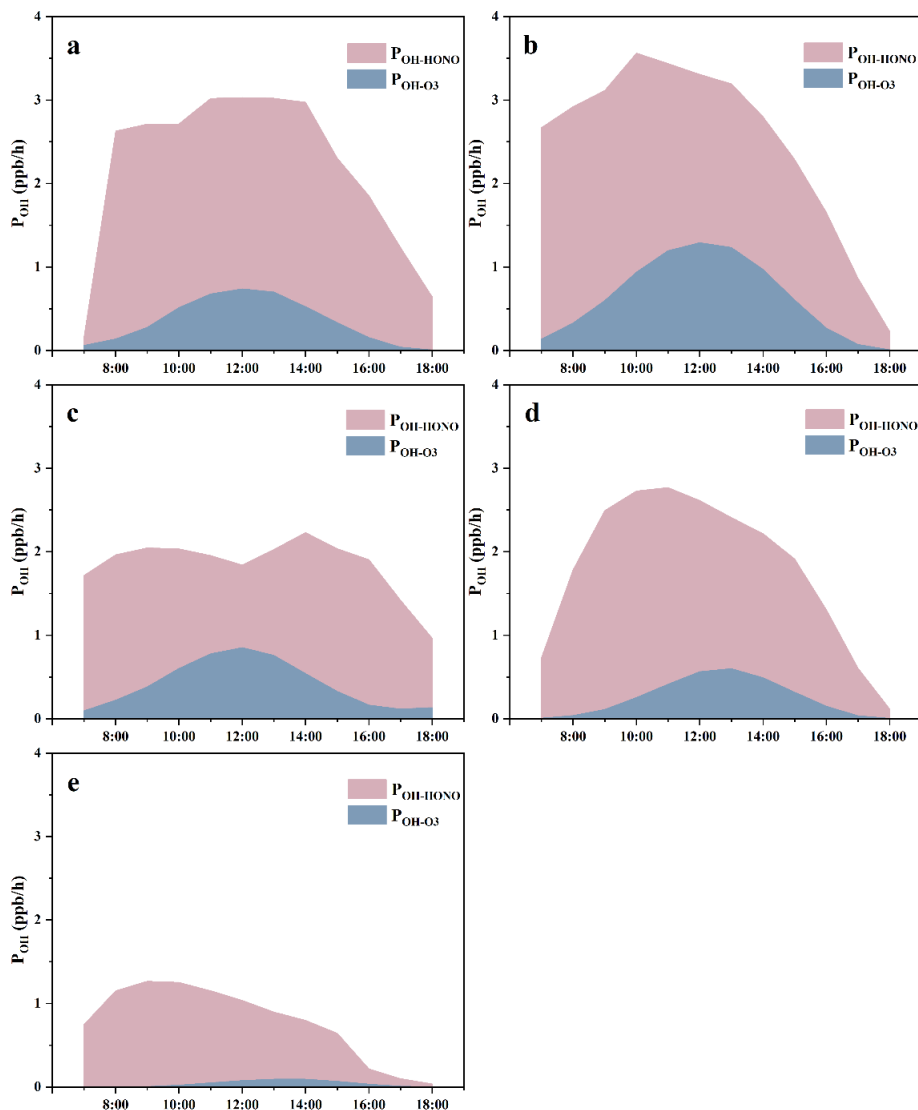

Yang et al. (2018) and Ye et al. (2019) found that the presence of organic components significantly enhanced the
395 denitrification rate of nitrate. In this work, organic carbon (OC) was used as a proxy for organic components, and the correlation was analysed. As shown in Table S4, the enhancement of the correlation between P_{unknown} and NO_3^- in the presence of OC was observed, $J\text{NO}_2 \times [\text{NO}_3^-] \times \text{OC}$ ($R = 0.55$, $P < 0.05$) $>$ $J\text{NO}_2 \times [\text{NO}_3^-]$ ($R = 0.48$, $P < 0.05$) in June.

Overall, based on the analysed above, the relatively low humidity and strong solar illumination in June were conducive to the formation of HONO, probably due to the light-induced heterogeneous reaction of NO_2 . Due to the increase of
400 precipitation in July, the heterogeneous transformation under high humidity conditions was conducive to the formation of HONO, but due to the high Henry coefficient of HONO, more uptake happened for HONO in the air, resulting in the decrease of HONO concentration in the gas phase. The photolysis of nitrate in June and July was also an important source of HONO, probably due to the relatively high humidity and stronger light intensity. In August and September, light-induced formation reactions on non-aerosol surfaces under strong light and low humidity conditions could be one important HONO
405 source. The results of July analysis showed that the presence of Cl ions and sulfate significantly enhanced the photolysis of nitrate, resulting in the formation of HONO. The presence of organic compounds enhanced the photolysis of nitrate, which was more pronounced in June. And not only the concentration of HONO but also the source of HONO had temporal patterns, even within the same season, the situation was different from month to month, and this should be considered in model studies.

410 3.4.3 OH production rate at daytime

As HONO was the efficient source of OH radical at daytime (Zhang et al., 2023c; Yu et al., 2022b), the OH production rate from HONO ($P_{\text{OH-HONO}}$) was calculated in this work.

Figure 6 showed that the OH production rate from HONO usually occurred before noontime, and this was caused by the existing HONO and its photolysis, this phenomenon was obvious in July, September, and October. And for $P_{\text{OH-O}_3}$, the
415 highest value was around noontime, which coincided with $J(\text{O}^1\text{D})$ trend, this phenomenon was obvious in June, July, and August. In September and October (autumn), the highest value of $P_{\text{OH-O}_3}$ occurred a little later after noontime. The average $P_{\text{OH-HONO}}$ during 8:00-16:00 LT was 2.7 ppb/h (June), 2.9 ppb/h (July), 2.0 ppb/h (August), 2.3 ppb/h (September), and 0.93 ppb/h (October), respectively; And the average $P_{\text{OH-O}_3}$ during 8:00-16:00 LT was 0.45 ppb/h (June), 0.82 ppb/h (July), 0.51 ppb/h (August), 0.33 ppb/h (September), and 0.048 ppb/h (October), respectively; the contribution of HONO to OH was
420 significantly greater than that of ozone. The important role of HONO to OH in the atmospheric oxidizing capacity should benefit the production of photochemical ozone (Xuan et al., 2023; Jia et al., 2023; Zhang et al., 2023b; Zhang et al., 2022), the formation of new particles (Stolzenburg et al., 2023), and the formation of secondary aerosols (Zhang et al., 2023c; Xuan et al., 2023; Liu et al., 2021a).

425 **Figure 6. Averaged OH production rates from photolysis of HONO and ozone in (a) June, (b) July, (c) August, (d) September, and**
 430 **(e) October.**

3.5 The correlations between HONO, $PM_{2.5}$, and O_3

In view of the importance of HONO to atmospheric oxidizing capacity (Zhong et al., 2023; Zhang et al., 2023b; Song et al., 2023), the correlations between HONO, $PM_{2.5}$, and O_3 were analysed. According to the Technical Regulation on Ambient
 430 Air Quality Index (on trial) in China (633—2012, 2012), $PM_{2.5}$ concentrations were divided into three zones: $\leq 35 \mu\text{g}/\text{m}^3$, 35-
 75 $\mu\text{g}/\text{m}^3$, and $\geq 75 \mu\text{g}/\text{m}^3$; and analysed at nighttime and daytime, respectively.

As shown in Figure 7, $PM_{2.5}$ concentrations were positively correlated with HONO, i.e., the increase of $PM_{2.5}$ pollution was accompanied by the increase of HONO concentration during the daytime. At night, except in September, the same

pattern was presented. One possible explanation of this phenomenon was that the increase in particle pollution in summer and autumn might lead to the formation of HONO and an increase in its concentration. Another possible explanation was that high HONO concentrations could lead to higher oxidative capacity and therefore higher rates of aerosol formation. There was also a possible explanation as both PM_{2.5} and HONO were stem from the same sources (i.e., their concentrations would both increase during pollution events). However, when it came to ozone, we could see a different phenomenon. In June and July, ozone showed a decreasing trend as particle and HONO concentrations increased during the daytime, but when at night, ozone concentrations tend to increase. In August and September, ozone showed an increasing trend as particle and HONO concentration increased both during the daytime and nighttime. In October, ozone showed an increasing trend at daytime, but a decreasing trend at night. Wang et al. (2017b) summarized the ozone abundance and its relationship to chemical processes and atmospheric dynamics in China, the ozone formation and concentration could be affected by various factors, including precursors, meteorological factors, and regional transport, et al., the formation of OH radical by HONO photolysis was a pathway involved in the RO_x and NO_x cycle of ozone formation, ozone was not directly related to HONO.

Wang et al. (2023a) analysed the relationships between ozone, PM_{2.5}, and mixing layer height in warm season, and found that the enhanced atmospheric oxidant capacity could promote the secondary transformation of particles, and weakened the dilution effect of mixing layer height rise on pollutants. The contribution of observed HONO to atmospheric oxidant capacity exceeded that of ozone, so it was necessary to pay more attention to the sources of HONO in warm season.

Figure 7. Distributions of HONO and O₃ mean concentrations under different PM_{2.5} pollution conditions. The upper panel was the daytime average value (7:00-18:00 LT), and the bottom panel was the nighttime average value (19:00-6:00 LT).

4 Conclusions

Continuous field observation of HONO in warm seasons was conducted in an urban site of Beijing, from June to October
455 2021. The monthly average HONO concentration was in the range of 0.89-1.28 ppb, showing a larger contribution to OH
radical relative to ozone at daytime, above three times as that of ozone in each month. Compared with previous field
observations in the urban sites of Beijing, the contribution of vehicle emissions to HONO (0.017) was relatively high. The
monthly nocturnal conversion rate of NO₂ to HONO was in the range of 0.0016-0.011 hr⁻¹, accounted for 2.9%-11% of
missing sources of HONO at daytime; the average value of P_{unknown} normalized by NO₂ at daytime (10:00-15:00 LT) was
460 0.025-0.61 hr⁻¹, much greater than the conversion rates at nighttime, which indicated that nocturnal heterogeneous
conversion from NO₂ to HONO was almost negligible at daytime. Light-induced heterogeneous conversion of NO₂ to
HONO under medium and low RH condition and photolysis of nitrate were responsible for P_{unknown} at daytime, RH and solar
illumination were two important influencing factors. In addition, differences in the components of particles, e.g., halogen
ions, sulfate, organic aerosol, could also lead to changes in the concentration of HONO formation.

465 Based on the field observations in summer and winter, Liu et al. (2021b) evaluated the atmospheric oxidizing capacity
in the megacity of Beijing, and found that the atmospheric oxidizing capacity showed a clear seasonal pattern, which was
stronger in summer than that in winter. The dominant oxidant contributor to atmospheric oxidizing capacity at daytime was
OH radical, and ozone was the second most important oxidant. Our work showed that in summer and autumn, the
contribution of HONO to OH radical was significantly greater than that of ozone, this further illustrated the importance of
470 HONO. As mentioned in Section 3.4.1, the contributions of P_{unknown} to the production of HONO were 78% (June), 55%
(July), 64% (August), 68% (September), and 30% (October), respectively. According to the OH production from HONO, the
OH production rate from the missing HONO was also very important to atmospheric oxidation capacity. Thus, further
investigation was required to figure out the source of HONO. In recent years, the concentration of atmospheric particulate
matter in China decreased significantly, but the ozone concentration showed a fluctuating upward trend, the atmospheric
475 oxidation capacity increased significantly, especially in the warm season. Given the contribution of HONO to atmospheric
oxidation capacity, its sources should be studied in more detail.

Code and data availability. The data used in this study are available upon request from the corresponding author.

Author contributions. JLL and HL conceived and led the studies. JLL, CFL, HZ, WGW, and HL performed observation
480 studies and data analysis. MML, YXY, YFS, CC, YCG, YSX, JG, and MFG discussed the results and commented on the
paper. JLL prepared the article with contributions from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.

Financial support. This research has been supported by National Key Research and Development Program of China (No.
2023YFC3706102), National Natural Science Foundation of China (NSFC, No. 41931287, No.42130606, No. 42175133, No.
485 42307139).
