## 12 **Abstract**

13 An improved divergence method has been developed to estimate annual methane (CH<sub>4</sub>)  
14 emissions from TROPospheric Monitoring Instrument (TROPOMI) observations. It  
15 has been applied to the period of 2018 to 2021 over the Middle East, where the  
16 orography is complicated, and the mean mixing ratio of methane (XCH<sub>4</sub>) might be  
17 affected by albedos or aerosols over some locations. To adapt to extreme changes of  
18 terrain over mountains or coasts, winds are used with their divergent part removed. A  
19 temporal filter is introduced to identify highly variable emissions and further exclude  
20 fake sources caused by retrieval artifacts. We compare our results to widely used  
21 bottom-up anthropogenic emission inventories: Emissions Database for Global  
22 Atmospheric Research (EDGAR), Community Emissions Data System (CEDS) and  
23 Global Fuel Exploitation Inventory (GFEI) over several regions representing various  
24 types of sources. The NO<sub>x</sub> emissions from EDGAR and Daily Emissions Constrained  
25 by Satellite Observations (DECOS), and the industrial heat sources identified by Visible  
26 Infrared Imaging Radiometer Suite (VIIRS) are further used to better understand our  
27 resulting methane emissions. Our results indicate possibly large underestimations of  
28 methane emissions in metropolises like Tehran (up to 50%) and Isfahan (up to 70%) in  
29 Iran. The derived annual methane emissions from oil/gas production near the Caspian  
30 Sea in Turkmenistan are comparable to GFEI but more than two times higher than  
31 EDGAR and CEDS in 2019. Large discrepancies of distribution of methane sources in  
32 Riyadh and its surrounding areas are found between EDGAR, CEDS, GFEI and our

33 emissions. The methane emission from oil/gas production in the east to Riyadh seems  
34 to be largely overestimated by EDGAR and CEDS, while our estimates, and also GFEI  
35 and DECSO NO<sub>x</sub> indicate much lower emissions from industry activities. On the other  
36 hand, regions like Iran, Iraq, and Oman are dominated by sources from oil and gas  
37 exploitation that probably includes more irregular releases of methane, with the result  
38 that our estimates, that include only invariable sources, are lower than the bottom-up  
39 emission inventories.

## 40 **1 Introduction**

41 Methane (CH<sub>4</sub>) is the second most important greenhouse gas of which the abundance  
42 kept increasing in the last decades (Turner et al., 2019; Saunio et al., 2020; Eyring et  
43 al., 2021), with a short-term stable concentration level between the years 2000 and 2006  
44 (Dlugokencky et al., 2009; Rigby et al., 2008). The relatively short lifetime of about a  
45 decade makes CH<sub>4</sub> emissions a short-term target for mitigating climate change. The  
46 TROPOspheric Monitoring Instrument (TROPOMI) on board the Sentinel 5 Precursor  
47 (S5-P) satellite provides an opportunity to measure CH<sub>4</sub> globally at a high resolution of  
48  $7 \times 7$  km<sup>2</sup> since its launch in October 2017 (upgraded to  $5.5 \times 7$  km<sup>2</sup> in August 2019)  
49 (Veefkind et al., 2012; Lorente et al., 2021). Previous studies have demonstrated the  
50 capability of TROPOMI to identify big CH<sub>4</sub> emitters (e.g., leakages from pipelines)  
51 through detecting large anomalies or to derive regional emission fields (de Gouw et al.,  
52 2020; Pandey et al., 2019; Zhang et al., 2020; Chen et al., 2023).

53 However, using observations from TROPOMI to quantify emissions are also facing  
54 challenges. On the one hand, some sources are located near the coast or in places with  
55 complex topography, where satellite observations are often of reduced quality. The  
56 observations of TROPOMI CH<sub>4</sub> contain uncertainties from retrieval assumptions for  
57 surface albedo, aerosols, and the sun-glint model over the ocean. On the other hand, the  
58 characteristics of the various sources are poorly understood. For instance, constant  
59 emitting sources from landfills *versus* intermittent leakage of oil/gas, makes it difficult  
60 to quantify their emissions (Varon, 2021).

61 The Middle East is one of the strong CH<sub>4</sub>-emitting regions in the world (Chen et al.,  
62 2023). Nevertheless, these emissions are particularly challenging to be quantified  
63 because of the aspects aforementioned. Lauvaux et al. (2022) found fewer detections  
64 of ultra-emitters (>25 kg/hour) in Middle Eastern countries like Iraq, Saudi Arabia than  
65 other hot-spot regions like the U.S. from TROPOMI observations. Chen et al., (2023)  
66 also revealed large discrepancies between a priori and posterior emission inventory  
67 derived from satellites over the Middle East.

68 In this study, we present an improved divergence method (Beirle et al., 2019, 2023; Liu  
69 et al., 2021; Sun et al., 2022; Veefkind., 2023) to quantify the emissions of CH<sub>4</sub> over  
70 the Middle East from 2018 to 2021 on a grid of 0.2° from TROPOMI retrieved XCH<sub>4</sub>  
71 by using the latest version of the scientific retrieval product (TROPOMI/WFMD v1.8)  
72 from the University of Bremen (Schneising et al., 2023). This inversion algorithm is  
73 based on the mass balance theory and is unique because of its speed and no need for a  
74 priori knowledge of the sources. The wind divergence was first removed from the daily  
75 wind fields to better adapt to the complicated orography in the Middle East, and a  
76 temporal filter was developed in this study to exclude incorrect sources caused by  
77 retrieval issues, respectively. For an area without influence from retrieval issues (e.g.,  
78 albedo), the persistence of sources can be further tested by the temporal filter.

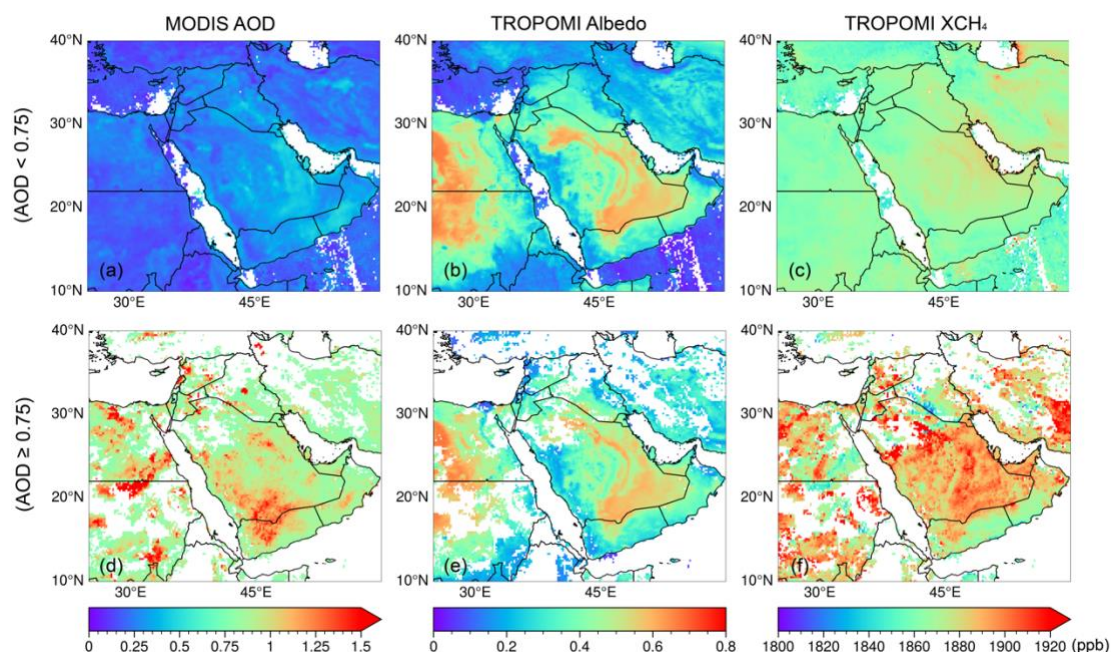

79 Before calculating the divergence, we exclude contaminated pixels with a high aerosol  
80 optical depth (AOD) using daily MODIS AOD observations and the global hourly  
81 Atmospheric Composition Reanalysis 4 (EAC4) dataset. To a grid cell that shows a  
82 strong spatial correlation between the divergence and its corresponding background  
83 divergence, a posterior correction is applied to remove the contribution from the  
84 inhomogeneous background. The final results are further compared to the total  
85 anthropogenic CH<sub>4</sub> emissions from Emissions Database for Global Atmospheric  
86 Research (EDGAR) v7.0 (Crippa et al., 2022) and CEDS v\_2021\_04\_21 (O'Rourke et  
87 al., 2021). Other auxiliary datasets, such as the methane emissions from the fuel  
88 exploitation predicted by GEFI v2 (Scarpelli et al., 2019) and total anthropogenic NO<sub>x</sub>  
89 emissions from EDGAR v6.1 and DECSO v6.2 (van der A et al., 2024; Ding et al.,  
90 2020; Mijling and van der A, 2012) are used for a better interpretation of our results.

## 91 **2 Data and Methodology**

### 92 *2.1 Selection of reliable TROPOMI XCH<sub>4</sub> data*

93 This study used the latest TROPOMI WFM-DOAS (TROPOMI/WFMD v1.8) XCH<sub>4</sub>  
94 product (Schneising et al., 2023). Quality filters were applied to reduce the size of a  
95 daily XCH<sub>4</sub> file before making it available to the public. Thus, the daily files contain  
96 only the pixels that had passed the quality check. In version 1.8, a de-stripping filter has  
97 been applied to each orbit.

98 The TROPOMI/WFMD algorithm has been designed for clear-sky scenes with minor  
99 scattering by aerosols and optically thin clouds (i.e., cirrus). Still, a few pixels could  
100 contain high aerosol loadings (MODIS AOD at 550 nm  $\geq 0.75$ , Fig. 1. d–f v.s. a–c),  
101 leading to biased high XCH<sub>4</sub>. We here use the daily observation of 10 km MODIS/Aqua  
102 AOD data at 550 nm, which has a similar overpass time as TROPOMI, to estimate the  
103 AOD values for pixels of TROPOMI. The pixels with AOD  $\geq 0.75$  are filtered, and 1.7%  
104 of pixels in 2019 are excluded with this criterion in the domain of 10–40N°, 20–50E°.  
105 Admittedly, not every TROPOMI pixel has a collocated MODIS AOD observation.  
106 Thus, we used the global hourly EAC4 dataset combined with MODIS daily  
107 observations to ensure every pixel of TROPOMI has an AOD estimate to reduce the  
108 systematic biases caused by high aerosol loadings while maintaining as many pixels as  
109 possible. The details about obtaining an AOD value for each pixel can be found in Part  
110 A of the Supplementary Information (SI).

111

112 **Figure 1.** Annual mean of (a) MODIS AOD, (b) albedo in TROPOMI XCH4 retrieval  
 113 and (c) TROPOMI XCH4 on a grid of  $0.2^\circ$  in 2019, which are the average of pixels  
 114 with  $AOD < 0.75$ . (d)-(f) are similar to (a)-(c) but based on the pixels with  $AOD \geq 0.75$ .  
 115 Only pixels with available MODIS AOD are used to generate the maps shown here.

116 Another aspect that is addressed is the distinction between land and water bodies,  
 117 especially over the coastlines. TROPOMI use different retrieval strategies for data over  
 118 land and ocean. The retrievals over ocean are only available in sun glint mode. We find  
 119 the data over ocean can be quite noisy. Furthermore, the data continuous from land to  
 120 ocean are checked. We selected pixels locating at several  $1^\circ \times 1^\circ$  areas covering half  
 121 land and half ocean at the coastlines of Oman, Yemen and along the Red Sea. We found  
 122 there are not many differences between pixels over land and ocean (see Figure S1 in  
 123 SI). Therefore, we built a water-land mask at the same spatial resolution as our emission  
 124 data ( $0.2^\circ \times 0.2^\circ$ ) based on Global Land Cover Characterization (GLCC) of the United  
 125 States Geological Survey (USGS) (United States Geological Survey, 2018a, b) to  
 126 distinguish water, land and the coast (transition grids from land to water). Only grid  
 127 cells that are marked as land and coast are used to build the regional background and  
 128 are used to calculate the daily divergence.

## 129 2.2 Methane bottom-up emission inventories and auxiliary emission datasets

130 In this study, EDGAR v7.0 is mainly used to evaluate the result of the derived methane  
 131 emissions because it covers the whole period of our study. EDGARv7.0 provides  
 132 estimates for emissions of the three main greenhouse gases ( $CO_2$ ,  $CH_4$ ,  $N_2O$ ) per sector  
 133 and country from 1970 to 2021 on a grid of  $0.1^\circ$ . The activity data for non- $CO_2$   
 134 emissions are primarily based on the World Energy Balances data (2021) of the IEA.

135 The activity data for certain sectors are further modified by other updated datasets. For  
136 example, International Fertiliser Association (IFA) and Gas Flaring Reduction  
137 Partnership (GGFR)/U.S. National Oceanic and Atmospheric Administration (NOAA),  
138 United Nations Framework Convention on Climate Change (UNFCCC) and World  
139 Steel Association (worldsteel) recent statistics are used for activity data of energy-  
140 related sectors, and agricultural sectors are further modified by FAO (2021). In addition,  
141 the latest version (v\_2021\_04\_21) of CEDS and the Global Fuel Exploitation Inventory  
142 (GFEI v2) are also used for comparisons in specific years. CEDS v\_2021\_04\_21  
143 consists of CMIP6 historical anthropogenic emissions data from 1980 - 2019 on a grid  
144 of 0.5°. The 0.5° data was further downscaled to 0.1° using 0.1° proxy data from  
145 EDGAR v5.0 emission grids (O'Rourke et al., 2021). GFEI v2 allocates methane  
146 emissions from oil, gas, and coal to a grid of 0.1° by using the national emissions  
147 reported by individual countries to UNFCCC and assign them to infrastructure  
148 locations. GFEI v2 inventory is available for 2019 and presents an update of GFEI v1  
149 which was made for 2016 (Scarpelli, et al., 2021).

150 Despite the fact that the three above-mentioned inventories have assembled various  
151 information from recent statistics, emissions in the Middle East are still uncertain and  
152 show large discrepancies because of the lack of reports from the industrial facilities. To  
153 validate the sources not reported in bottom-up inventories, target-mode instruments  
154 with very high spatial resolution (pixels < 60m) (e.g., GHGSat, PRISMA, EMIT) are  
155 widely used to pinpoint individual sources and reveal their characteristics. NASA's  
156 Earth Surface Mineral Dust Source Investigation (EMIT) mission was launched in 2020  
157 and methane plumes are recorded since 10<sup>th</sup> August 2022 (Source:  
158 <https://earth.jpl.nasa.gov/emit/data/data-portal/Greenhouse-Gases/>). It uses an  
159 advanced imaging spectrometer instrument that measures a spectrum for every point in  
160 the image. The high-confidence research grade methane plume complexes from point  
161 source emitters are released as they are identified (Brodrick et al., 2023). In addition,  
162 NO<sub>x</sub> emissions and gas flaring data are often used to analyze the emission of methane,  
163 especially for the energy-related sources. Thus, we further used NO<sub>x</sub> emissions and  
164 industrial heat sources identified by VIIRS (Liu et al., 2018) to better understand the  
165 derived methane emissions. The latest NO<sub>x</sub> emissions from EDGAR (v6.1, the most  
166 recent year is 2018) and the top-down NO<sub>x</sub> emission inventory from TROPOMI,  
167 DECSO (van der A et al., 2023; Ding et al., 2020), are used to assess uncertainties of  
168 various emission inventories. For clarity, we combined the source sectors of methane  
169 in EDGAR and CEDS, and the sectors of NO<sub>x</sub> in EDGAR into two categories: energy  
170 and others. The sectors for each category are listed in Table-1.

171

**Table 1. Sectors of CH<sub>4</sub> and NO<sub>x</sub> used in this study based on EDGAR**

Sector Species	Energy	Others
<sup>1</sup> EDGAR v7.0 CH <sub>4</sub>	1, Power industry (1A1a) 2, Refineries and transformation industry (1A1b+1A1ci+1A1cii+1A5biii+1B1b+1B2aiii6+1B2biii3+1B1c) 3, Combustion for manufacturing (1A2) 4, Fuel exploitation (1B1a+1B2aiii2+1B2aiii3+1B2bi+1B2bi i) 5, Chemistry process (2B) 6, Energy for building (1A4 +1A5) 7, Iron and steel production (2C2) 8, Fossil fuel fires (5B)	<b>Transportation</b> 1, Aviation (1A3a) 2, Railways, pipelines, off-road transport (1A3c+1A3e) 3, Shipping (1A3d) <b>Agricultural</b> 1, Manure management (3A2) 2, Agricultural soils (3C2+3C3+3C4+3C7) 3, Enteric fermentation (3A1) <b>Waste</b> 1, Agricultural waste burning (3C1b) 2, Solid waste incineration (4C) 3, Solid waste landfills (4A+4B)
<sup>2</sup> CEDS v_2021_04_21 CH <sub>4</sub>	1, Energy 2, Industrial 3, Solvents production and application	0, Agriculture 1, Transportation 2, Residential, commercial, other 6, Waste 7, International shipping
EDGAR v6.1 NO <sub>x</sub>	1, Power industry (1A1a) 2, Refineries and transformation industry (1A1b+1A1ci+1A1cii+1A5biii+1B1b+1B2aiii6+1B2biii3+1B1c) 3, Combustion for manufacturing (1A2) 4, Fuel exploitation (1B1a+1B2aiii2+1B2aiii3+1B2bi+1B2bi i) 5, Chemistry process (2B) 6, Energy for building (1A4 +1A5) 7, Iron and steel production (2C2) 8, Fossil fuel fires (5B) 9, Non-ferrous metals production (2C3-C5) 10, Food and paper (2H)	<b>Transportation</b> 1, Aviation (1A3a) 2, Railways, pipelines, off-road transport (1A3c+1A3e) 3, Shipping (1A3d) <b>Agricultural</b> 1, Manure management (3A2) 2, Agricultural soils (3C2+3C3+3C4+3C7) <b>Waste</b> 1, Agricultural waste burning (3C1b) 2, Solid waste incineration (4C)

172

<sup>1</sup>The codes in parentheses are based on IPCC 2006 used by EDGAR v7.0 to generate each sector.

173

<sup>2</sup>CEDS provides monthly sectoral methane emissions, in which the category is illustrated by the number.

174

### 175 2.3 Divergence calculation

176 The basic methodology has been described in Liu et al. (2021). Here, we have improved  
177 the procedure to estimate CH<sub>4</sub> emissions from TROPOMI retrieved XCH<sub>4</sub> consisting  
178 of three steps: (1) The use of daily MODIS/Aqua AOD 10 km L2 dataset (v6.1) and  
179 daily CAMS gridded AOD re-analysis data to filter unreliable retrievals of TROPOMI  
180 XCH<sub>4</sub>. (2) Derive the enhancements of XCH<sub>4</sub> in the PBL ( $X_d^{PBL}$ ) and non-divergent  
181 winds from ERA5 wind dataset, which are then used to calculate the spatial divergence  
182 and the preliminary methane emission. (3) Apply a posterior spatial correction to  
183 subtract the contribution of the residue of the regional background, and identify  
184 possible false sources by using a temporal filter.

185 Our method to estimate the preliminary methane emission  $E'$  over a certain period is  
186 based on the divergence method described by Beirle et al. (2019) for NO<sub>x</sub> emissions  
187 and specifically for methane by Liu et al. (2021):

$$188 \quad E' = \overline{D_d^S} = \overline{\nabla \cdot (X_d^{PBL} - X_d^B) \times A_d^{PBL} \vec{w}} \quad (1)$$

189 where  $D_d^S$  is the daily divergence of a source.  $X_d^{PBL}$  is the daily XCH<sub>4</sub> in the Planetary  
190 Boundary Layer (PBL) that is calculated by subtracting the vertical column of methane  
191 above the PBL from the TROPOMI observations. Estimating the XCH<sub>4</sub> in lower  
192 atmosphere is quite important since the enhancement due to the transport in the upper  
193 atmosphere is irrelevant to the ground emissions. This vertical column above the PBL,  
194 is based on the model results of EAC4 of CAMS at a relative high spatial resolution,  
195 0.75° horizontally and 60 layers vertically (Inness et al., 2019), with methane serving  
196 as a background species for chemical reactions. This EAC4 model run contains no *a*  
197 *priori* CH<sub>4</sub> emissions. Thus, the spatial distribution of CH<sub>4</sub> is mainly driven by transport  
198 and orography, which will be subtracted from TROPOMI observations to estimate the  
199 PBL concentration of CH<sub>4</sub>. It is important to note that the total dry air column from the  
200 EAC4 dataset is constrained by the TROPOMI retrieval for each pixel, which  
201 guarantees the mass conservation. We fixed the PBLH at 500 meters above the ground  
202 considering the PBLH from the reanalysis dataset has large uncertainties and is  
203 occasionally too shallow (Guo et al., 2021). The favorable height is suggested to be  
204 500-700 meters above the ground considering the systematic difference between EAC4  
205 dataset and TROPOMI observations (Liu et al., 2021).  $X_d^B$  is the regional background  
206 of  $X_d^{PBL}$ , which is defined as the average of the lower 10 percentile of its surrounding  
207  $\pm 3$  grid cells in the zonal direction and meridional direction ( $7 \times 7 = 49$  grid cells in total  
208 by taking the current grid cell as the center) considering the extensive variations of the  
209 orography in the Middle East. The daily regional background is built when more than  
210 10 grid cells have valid retrievals in this domain.  $A_d^{PBL}$  is the corresponding air density  
211 column in the PBL. The details to derive  $X_d^{PBL}$  and  $A_d^{PBL}$  can be found in Liu et al.  
212 (2021). The advantages of including  $X_d^B$  are (1) it can be used to diagnose the

213 contribution of inhomogeneous background, especially over mountains and coastal  
 214 regions, and (2) the system biases between CAMS and TROPOMI, which leads to  
 215 biased  $X_d^{PBL}$ , is included in both and can be greatly reduced by subtracting  $X_d^B$  from  
 216  $X_d^{PBL}$ .

217 The daily wind field ( $\vec{w}$ ) halfway the height of the PBL (PBLH) close to the overpass  
 218 time is obtained from the ECMWF. Wind speeds are constrained between 0 m/s to 10  
 219 m/s because the divergence method works when advective transport takes place, and  
 220 extremely high wind speed are unfavorable for a method based on the regional mass  
 221 balance. Local wind-field changes induced by complicated orography inevitably leads  
 222 to a certain pattern of wind divergence ( $\overline{D_d^W}$ ), which further influence

$$223 \quad D_d^S = \vec{w} \nabla (XCH_4^{PBL} - XCH_4^B) + (XCH_4^{PBL} - XCH_4^B) \nabla \vec{w} \quad (2)$$

224 Liu et al. (2021) corrected  $E'$  by using an empirical correction by using a spatial  
 225 correlation between  $\overline{D_d^S}$  and  $\overline{D_d^B}$  to account for the effect of inhomogeneous background  
 226 and  $\nabla \vec{w}$  over Texas, where the terrain is relatively flat and less affected by mountains.  
 227 To better reduce the effect of winds, we followed the method proposed by Sims (2018)  
 228 to iteratively remove the gradients of  $\nabla \vec{w}$  on each day to get a non-divergent wind field,  
 229  $V$  component (south-north) and  $U$  component (west-east), for the calculation of Eq. (1).

230 The positive values of  $\overline{D_d^S}$  due to orography-raised wind near Tehran in Fig. 2d are

231 largely reduced (Fig. 2f) by using a non-divergent wind field. The magnitudes of  $\overline{D_d^B}$  in

232 Fig. 2e also get close to  $\overline{D_d^S}$ . Before we applied this change, we tested the non-divergent

233 method in the GEOS-Chem simulation that was used in Liu et al., (2021). We found  
 234 that this step slightly improved the capability of the method in resolving the spatial  
 235 variability of sources (Figure S2), but underestimate the final emission by about 15%  
 236 in the GEOS-Chem simulation. In contrast, when deriving the emissions from  
 237 TROPOMI, using a non-divergent wind field especially improves the robustness over  
 238 coastal areas and typically increases emissions by 5-20% for most cases (Table S2  
 239 shows an example). The difference in change of emissions between GEOS-Chem  
 240 simulation and TROPOMI is primarily due to the correction of the final estimated  
 241 emissions. As was mentioned in the manuscript, the final emission based on the

242 divergence ( $\overline{D_d^S}$ ). (Fig. 2d) apparently contains the residual of the divergence of

243 background ( $\overline{D_d^B}$ ) (Fig. 2c), which is highly correlated with wind divergence ( $\overline{D_d^W}$ ).

244 However, this dependence is much smaller for the GEOS-Chem simulation and for the

245 emissions derived from TROPOMI by using non-divergent wind. The procedure and  
 246 the evaluation of removing the wind divergence from the original wind field are  
 247 explained in Part B in SI. Generally, using a non-divergent wind field can improve the  
 248 capability of the method in resolving the sources, both in a model simulation and in  
 249 TROPOMI observations.

### 250 *2.3 Estimating emissions based on the divergence*

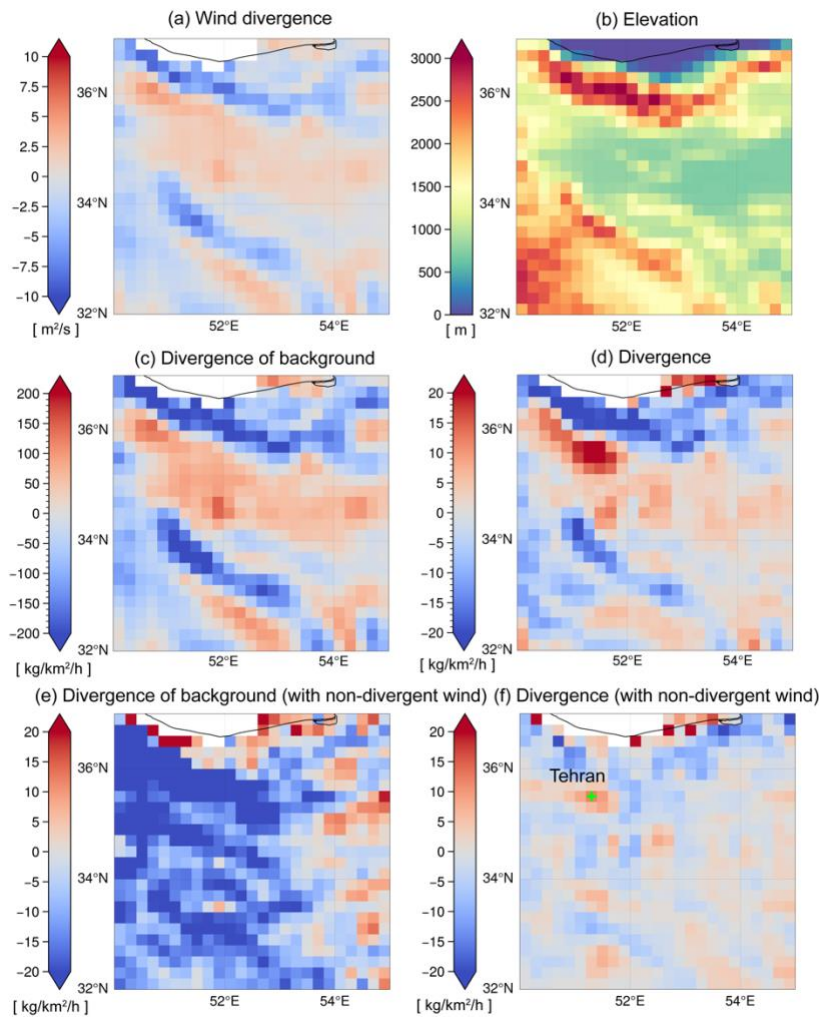

251 The inhomogeneous spatial distribution of  $\overline{D_d^B}$  indicates the possible residue of the  
 252 regional background we built in Sect. 2.2. Therefore, we evaluate the contribution from  
 253 the residue background for each grid cell with positive  $E'$  by checking the spatial  
 254 correlation between  $\overline{D_d^B}$  and  $\overline{D_d^S}$  in the domain that we defined to build the regional  
 255 background (its surrounding  $\pm 3$  grid cell). For grid cells with positive  $E'$ , a linear  
 256 regression is applied to its surrounding  $\pm 3$  cells:

$$257 \quad y_i = k \cdot x_i + b \quad (3)$$

258 where  $y_i$  stands for  $\overline{D_d^S}$  and  $x_i$  stands for  $\overline{D_d^B}$  of grid  $i$ .  $k$  and  $b$  are the slope and intercept  
 259 of the linear regression, respectively. If Eq. (3) is applicable to the center grid, it implies  
 260 the residue of the background still contributes to  $E'$  and should be subtracted. This  
 261 linear correlation can be distinctive over locations with large variations in orography  
 262 (e.g., mountains, coastal areas). If more than 68% of the grid cells and the grid cell itself  
 263 fall within the prediction lines of Eq. (3), estimated emissions are set to zero because  
 264  $\overline{D_d^S}$  can be fully predicted by  $\overline{D_d^B}$  according to Eq. (3). The grid cells are considered to  
 265 be influenced by residue background only when Eq. (3) is significant (p-value < 0.01),  
 266 and they are further corrected by the spatial correction:

$$267 \quad E^{corr} = E' - (k \cdot \overline{D_d^B} + b) \quad (4)$$

268 in which  $(k \cdot \overline{D_d^B} + b)$  is regarded as the contribution from the remaining background,  
 269 which should be subtracted from the preliminary estimated emissions,  $E'$ . In addition,  
 270 we find that areas with negative  $E'$  together with negative  $\overline{D_d^B}$ , implying no significant  
 271 sources exist. The final estimated emissions at grid cells with negative  $E'$  are also set  
 272 to zero (Liu et al., 2021).

274 **Figure 2.** (a) The spatial distribution of original wind divergence ( $\overline{D_d^W}$ ). (b) Elevation  
 275 map generated from the GMTED2010 data set at 30 arcsecs  
 276 ([http://topotools.cr.usgs.gov/GMTED\\_viewer/](http://topotools.cr.usgs.gov/GMTED_viewer/)). (c) Divergence of the background ( $\overline{D_d^B}$ )  
 277 calculated with original daily wind field in 2019. (d) Divergence of methane  
 278 enhancement ( $\overline{D_d^B}$ ) under 500 meters with original daily wind field. (e)-(f) are similar  
 279 to (c)-(d) but with the daily non-divergent wind field ( $U$  and  $V$ ). The green “+” in (f) is  
 280 used to generate the time series of  $D_d^B$  and  $D_d^S$  in Figure 5b.

281

#### 282 2.4 Build temporal filter to identify possible false sources

283 The artifacts caused by the variability of spectral albedo (e.g., specific soil types and  
 284 interferences in the spectral range of the retrieval windows) have been generally

285 reduced in the WFMD v18 product (Schneising et al., 2023). The unrealistic  
 286 enhancements are reduced/removed over most locations. However, the biases  
 287 mentioned above can still exist in some places, as shown in Figure 3. In the northeast  
 288 near Riyadh, the stripe-shaped XCH<sub>4</sub> enhancements (Fig. 3a) coincide with the  
 289 locations of high albedos (Fig. 3b) that cannot be explained by the changes of elevations  
 290 from southwest to northeast (Fig. 3c). The relevant correction has been done by  
 291 machine learning calibration in the WFMD v18 product, thus we found no universal  
 292 pattern that can be used to describe the relationship among XCH<sub>4</sub>, surface albedo and  
 293 aerosol. Therefore, we do not correct this kind of bias, following Liu et al. (2021), to  
 294 avoid double-correction. Alternatively, we try to find an objective way to filter false  
 295 emissions caused by retrieval artifacts.

296 A grid cell with a large  $E'$  but no significant linear correlation between  $\overline{D_d^S}$  and  $\overline{D_d^B}$   
 297 contains either a source or is caused by artifacts in the retrieval, such as the case shown  
 298 in Fig. 3. If the enhancement is a kind of artifact; for example, caused by a bright surface,  
 299 it behaves more like a constant over days. Therefore, temporal variations of  $D_d^S$  will be  
 300 mainly dominated by daily variations of the background, according to Eq (1).  
 301 Considering that the values of  $D_d^B$  are much higher than  $D_d^S$ , as  $XCH_4^{PBL}$  is used to  
 302 calculate  $D_d^B$  while  $(XCH_4^{PBL} - XCH_4^B)$  is used to calculate  $D_d^S$ , we normalize time  
 303 series of  $D_d^S$  and  $D_d^B$ , respectively. This normalization allows for a better comparison of  
 304 their temporal variations (amplitudes). The temporal filter is based on their normalized  
 305 time series and built as follows. Firstly, we remove the grid cells that have less than 10-  
 306 day records. Next, if more than half of the days in the time series of a grid cell have a  
 307 normalized positive  $D_d^S$  larger than  $D_d^B$ , the derived source (grid cell) is considered to  
 308 be real and not a retrieval artifact. . As an example, we take a grid cell (showing with a  
 309 green “+” in Fig. 3e) that is affected by the albedo near Riyadh. It has a larger  $\overline{D_d^S}$  than  
 310 its surrounding grid cells, but the linear regression is not applicable here (p\_value of  
 311 Eq. (3) is 0.2), suggesting the regional background we built is not biased. However,  
 312 only 20% (value of R in Fig. 4) of the total reliable days in 2019 have larger positive  
 313 normalized  $D_d^S$  (Fig. 4b), indicating the daily variation is not significantly different  
 314 from its background. Hence the reliability of this source needs to be checked. In contrast,  
 315 more than 50% of the total days of the grid cell, which is verified as a true source in  
 316 Tehran (a green “+” in Fig. 3e), have larger positive normalized  $D_d^S$ . In this way, the  
 317 emissions from an artifact or random noise from the retrieval can be objectively  
 318 identified. In this study, we set the temporal filter such that at least more than 50%  
 319 observations from the time series have a larger positive normalized  $D_d^S$  than the  
 320 normalized  $D_d^B$ .

321 However, we should also be aware that the threshold of the temporal filter used in this  
 322 study is relatively rigid, possibly excluding sources that occasionally release a large  
 323 amount of methane, like intermittent oil/gas leakage and inappropriately burned waste

324 gases. The preserved sources that pass the temporal filter are suggested to be more  
325 constant than that did not pass the temporal filter. For grid cells not affected by retrieval  
326 issues, the role of the temporal filter is more like an indication of the persistence or  
327 regional significance of a source, and the emissions without the temporal filter might,  
328 in some cases, be more realistic. The role of the temporal filter will be further discussed  
329 in Sect. 3

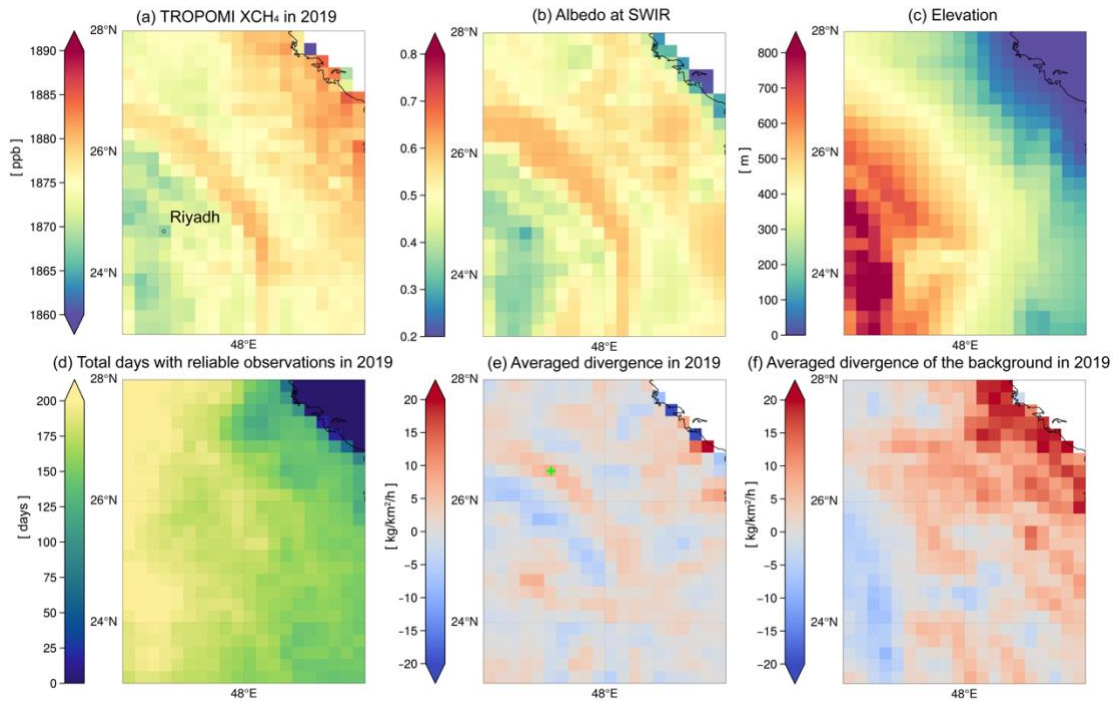

330 The divergence method requires sufficient temporal records (typically more than 7 days  
331 with valid observation for a grid cell) to derive robust results. Thus, the divergence on  
332 a single day does not provide a realistic emission for that day, and taking the standard  
333 deviations for individual days does not reflect the uncertainty or variability of a source.  
334 In addition, this method is not suitable for sources with a few intermittent releases, such  
335 as sudden leaks in oil and gas production.  $\overline{D_d^S}$  can be a quite large positive value for this  
336 kind of source. However, a small number of large releases in a time series may lead to  
337 a removal of this source by the temporal filter (see the case of Fig. 6 in Sect. 4), which  
338 is built for automatically detecting retrieval artifacts over a large domain. In order to  
339 keep as many real sources as possible, we apply a Monte Carlo experiment to each  
340 possible source to estimate the uncertainty of the derived emissions and to evaluate the  
341 robustness/reliability of a source. The procedure is as follows:

- 342 (1) We randomly choose 80% of the sampling days from a time series in a year as a  
343 subset. We derive a new emission,  $E_i$ , and count the ratio,  $R_i$ , of the number of days  
344 that have larger normalized  $D_d^S$  than normalized  $D_d^B$ .
- 345 (2) Repeat step (1) 30 times for a time series that has more than 20 sampling days while  
346 10 times for the one that have fewer days to derive the set of emissions,  $\{E_i\}$ , and  
347 the set of ratios,  $\{R_i\}$  for each possible source.  $R_i$  is used as the temporal filter in  
348 each subset.
- 349 (3) Take one-standard deviation of the set  $\{E_i\}$  as an uncertainty of a source. If the  
350 median value ( $R$ ) of  $\{R_i\}$  is greater than 0.5, this source is regarded having high  
351 confidence, which means these emissions are constantly released and likely not  
352 caused by a retrieval artifact.

353 We also investigate the choice of the percentage of the time series and the number of  
354 the iterations. 80-70% percent can be a reasonable range that ensure the  
355 representativeness as well as randomness of sampling days. We have tested the number  
356 of iterations from 10 to 50 times. The uncertainty map such as Fig. 5c become stable

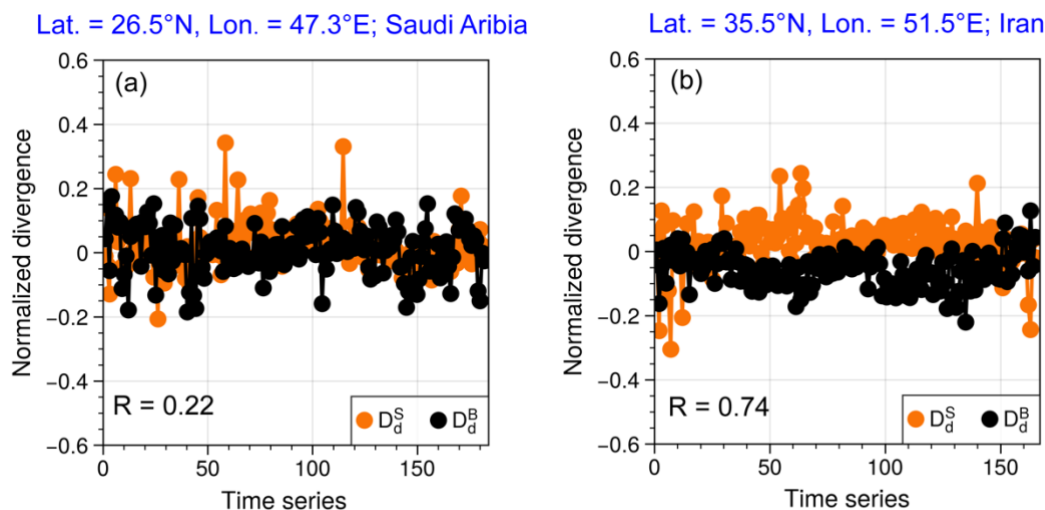

357 after 20 iterations, and 30 iterations can ensure the robustness as well as the efficiency  
 358 of the calculation.

359

360 **Figure 3.** Gridded  $0.2^\circ \times 0.2^\circ$  annual average of (a) TROPOMI observed  $XCH_4$  and  
 361 corresponding (b) TROPOMI apparent albedo at the short-wave infrared wavelength  
 362 (SWIR). (c) The gridded elevation map that is generated from the GMTED2010 data  
 363 set at 30 arcsec ([http://topotools.cr.usgs.gov/GMTED\\_viewer/](http://topotools.cr.usgs.gov/GMTED_viewer/)). (d) The total number  
 364 of valid observation days in 2019. (e) Averaged daily divergence ( $\overline{D_d^S}$ ) and (f)  
 365 divergence of the background ( $\overline{D_d^B}$ ) in 2019. The green “+” in (e) is used to generate  
 366 the time series of  $D_d^B$  and  $D_d^S$  in Figure 4(a).

367

368 **Figure 4.** The time series of normalized  $D_d^S$  (orange line) and  $D_d^B$  (black line) of the  
 369 grid cell in (a) Saudi Arabia and (b) Iran. The “R” in the lower left corner stands for the  
 370 ratio of the number of days with a larger positive normalized  $\overline{D_d^S}$  than  $\overline{D_d^B}$  related to the  
 371 total number of sampled days.

372

### 373 **3 Results**

#### 374 *3.1 Deriving the final emissions with the temporal filter*

375 After we derived emissions based on the divergence, the possible false sources are  
 376 further identified by the temporal filter. The strict temporal filter is introduced to  
 377 objectively exclude artifacts related to retrieval issues. However, to a grid cell that is  
 378 not affected by retrieval issues, the temporal filter acts more like an indication of the  
 379 persistence of a source. Namely, methane is intermittently released from this source.  
 380 Here we selected two areas in the Middle East to illustrate the role of the temporal filter  
 381 in the emission estimation. Our methane annual emissions are then compared with three  
 382 widely-used methane emission inventories in the same year, 2019. Other auxiliary  
 383 datasets such as NO<sub>x</sub> emission inventories, methane plume complexes detected by  
 384 EMIT imaging spectrometer and heating sources identified by VIIRS are also used to  
 385 better evaluate our derived emissions.

386 Figure 5a and c show all possible sources and their relative uncertainties, respectively.  
 387 Fig. 5b shows the final emissions after excluding the grid cells with emissions less than  
 388 3 kg/km<sup>2</sup>/h, which is used as detection threshold of a source in this study. It is estimated  
 389 by using the detection threshold of TROPOMI XCH<sub>4</sub> (Hu et al., 2018, Schneising et al.,  
 390 2023) and the approach in Jacob et al., (2022). The detection threshold of methane  
 391 source from TROPOMI is depending on many factors such as source types, inversion

392 methods and temporal coverage over a location etc., which can vary from  $\sim 0.5$  kg/km<sup>2</sup>/h  
393 to 12.5 kg/km<sup>2</sup>/h (Lauvaux et al., 2022; Dubey et al., 2023; Jacob et al., 2016; 2022).  
394 Fig. 5a suggests presence of small sources around the center of Riyadh, where a number  
395 of heating sources are detected by VIIRS. Additionally, small sources are detected in  
396 the south to Riyadh, where dairy farms and industry areas are located. The spatial  
397 distributions over two areas are similar to the DECSO NO<sub>x</sub> emissions, indicating  
398 existence of human activities. However, we found that sources below the detection  
399 threshold show large uncertainties (>20%) in this study, which means the method is not  
400 robust to distinguish these small sources from the regional background.

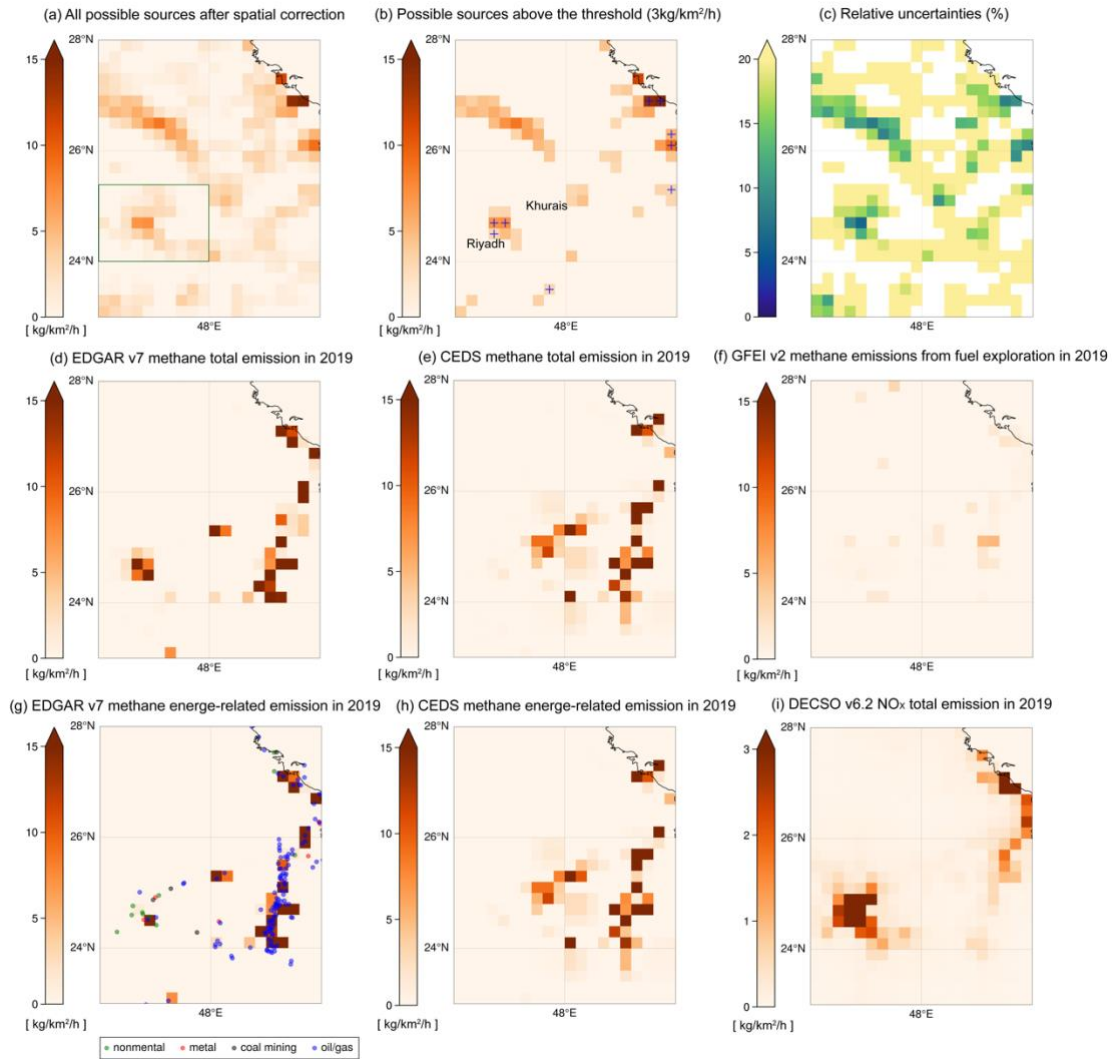

401 Both constant sources and artifacts (the “stripe” in the north of Riyadh) show small  
402 relative uncertainties (Fig.5c) due to continuous regional enhancement of XCH<sub>4</sub>. Only  
403 a few sources pass the temporal filter in the middle of Saudi Arabia (marked by blue  
404 “+” in Fig. 5b, indicating they are with high confidence). However, some facilities are  
405 found over the Khurais oil field in Google Earth image while it fails to pass the temporal,  
406 indicating they might be true but not constant. Another similar case is in the middle of  
407 the Syria Arab Republic, where many methane plumes along the Euphrates River are  
408 detected by the EMIT instrument (Fig. 6b) but reported quite low by three bottom-up  
409 emission inventories. They are reported as non-continuous sources (fail to pass the  
410 temporal filter) in our emission inventory (Fig. 6a). Thus, applying the strict temporal  
411 filter in an area without retrieval issues is aim at identifying continuous sources. In  
412 addition, except for the capital, Riyadh, both EDGAR and CEDS show that the primary  
413 type of sources in Saudi Arabia is energy related. The locations of oil/gas-related fires  
414 also match well with the sources of methane in the eastern area in Fig. 5g. However,  
415 our estimates (Fig. 5b) and methane emissions from the fuel exploitation reported by  
416 GFEI v2 (Fig. 5f) are quite low (lower than the TROPOMI detection threshold) in the  
417 eastern oil/gas production area. This finding is similar to the result of Lauvaux et al.  
418 (2022) that fewer ultra-emitters of methane are detected by using the TROPOMI CH<sub>4</sub>  
419 operational product (Lorente et al., 2021) in Middle Eastern countries such as Kuwait  
420 and Saudi Arabia, which could be attributed to fewer accidental releases and/or  
421 stringent maintenance operations. Using the locations and frequency of flares to  
422 estimate the methane emission in bottom-up emission inventories could have led to  
423 overestimation of the methane emissions in this region.

424 In contrast, Figure 7 show the case over Tehran and its surroundings. Most sources in  
425 this area pass the strict temporal filter, indicating they are quite constant. Five areas are  
426 identified as hotspots of methane sources in Fig. 7b. Fig. 7d-f shows the spatial  
427 distributions of methane sources estimated by EDGAR, CEDS and GFEI in 2019. The  
428 bottom-up emission inventories show lower methane emissions than our results. The  
429 dominant category of methane sources in this area is not energy-related but others like  
430 waste treatment and agriculture (see classification in Table-1), as suggested by EDGAR  
431 and CEDS. A number of heat sources due to metal or non-metal industry production are  
432 also identified by VIIRS over these hotspots. A good match in locations between

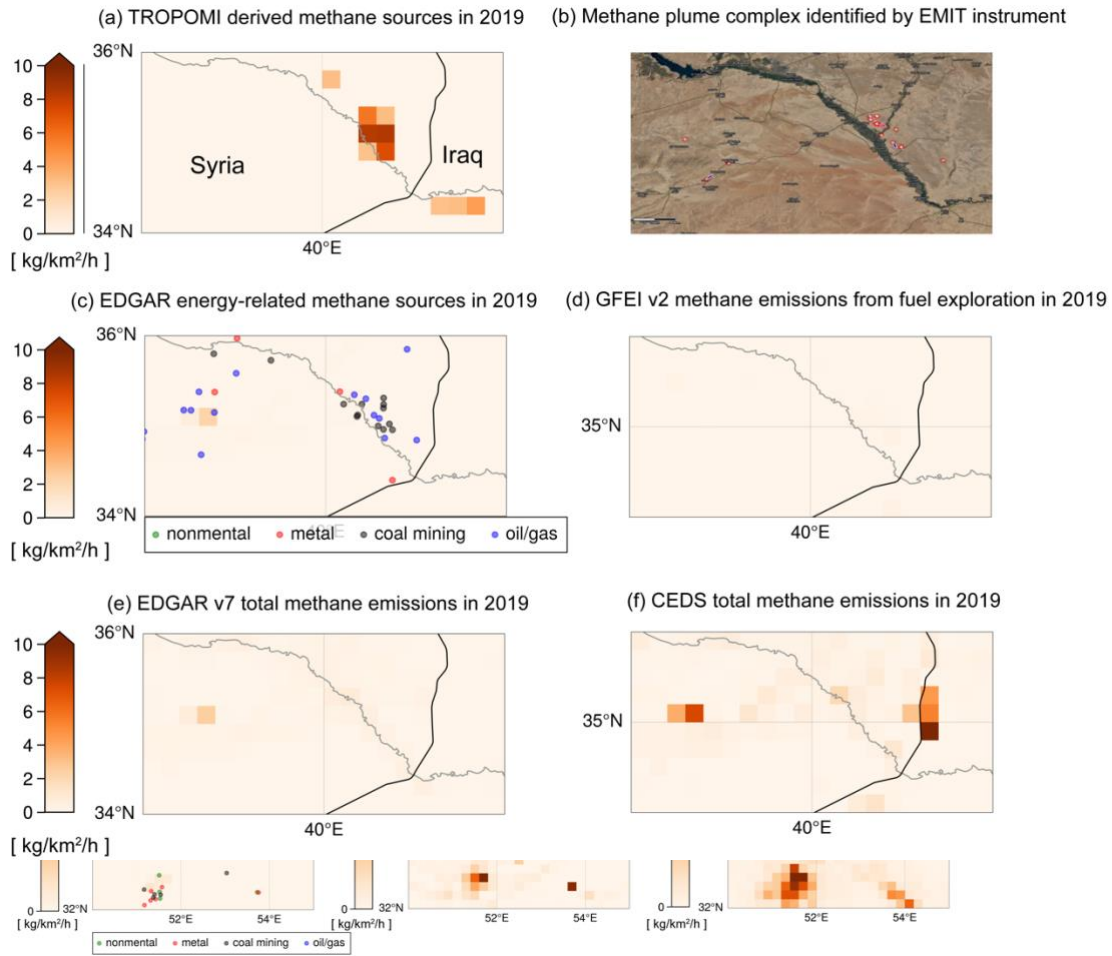

433 methane and NO<sub>x</sub> sources over Tehran, Isfahan, and Atarabad is found when we further  
434 examine NO<sub>x</sub> source distributions in EDGAR and DECSO. One possible reason for the  
435 consistence over these areas can be that the methane emissions may come from waste  
436 treatment in cities, where landfilling is the most common way of municipal solid waste  
437 (MSW) disposal in Iran (Pazoki et al., 2015). Fig. 7c presents a case of methane plume  
438 identified by EMIT instrument on 23<sup>th</sup> April 2023 near Kashan power plant that is  
439 apparently not reported in current inventories. Actually, some facilities have been found  
440 in Google Earth images near Kashan, which are also identified by our method in Fig.  
441 7b. Another hotspot area located between Tehran and Kashan is near Kavir National  
442 Park, where we currently have no clear explanation for the emissions.

443

 473 emission in 2019. (i) Averaged annual DECISO v6.2  $NO_x$  total emission in 2019.

474 3.2 Annual CH<sub>4</sub> emissions over the Middle East based on TROPOMI

475 In Figure 8, we select five hotspot regions in the Middle East to further assess the annual  
476 regional emissions from 2019 to 2022. Before we calculate the emissions of each region,  
477 we checked spatial patterns of XCH<sub>4</sub> and albedo from TROPOMI, as well as land  
478 features, to ensure no suspicious retrieval artifact is included as a source. The emissions  
479 are based on all possible sources and only confident sources are shown. The results of  
480 all possible sources (pink bars) may be more representative of the total emissions in  
481 these areas, and the emissions passing the temporal filters (blue bars) can be used to  
482 estimate the contribution of constant sources. Here we should clarify that the constant  
483 source in our paper does not refer to one with a constant emission factor but indicates  
484 a source that continually releases methane for most days of a year. The areas used to  
485 calculate annual emissions (bars in Fig. 8) are shown as dark green rectangles in the  
486 insets on the top. The emission map in each panel of Fig. 8 is the annual methane  
487 emissions of EDGAR v7.0 in 2019. The energy-related sectors and the other categories  
488 (waste, agriculture, and transportation) of EDGAR v7.0 methane emissions from 2018  
489 to 2021 are displayed by the first stacked green/yellow bars in Fig. 8a–e. The category-  
490 based annual emissions of CEDS in 2018 and 2019 are shown in the last stacked  
491 purple/orange bars. The estimate of GFEI for the fuel exploration in 2019 is shown as  
492 a red asterisk overlapped on the third column. We should clarify that our estimate for  
493 the total emission in each year is the sum of sources that are higher than 3kg/km<sup>2</sup>/h in  
494 the study area, but the total emission reported by a bottom-up emission inventory  
495 includes grid cells with emissions across all ranges. Thus, theoretically our estimates  
496 will underestimate the real emissions.

497 The main type of methane sources in Tehran and Isfahan given by EDGAR and CEDS  
498 is waste, and the energy-related sources are not oil/gas production based on VIIRS  
499 detected fire types and EDGAR’s prediction (Fig. 7g). The derived methane emissions  
500 are also more constant. Smaller differences are found between the blue and pink bars  
501 than Riyadh, West of Turkmenistan and Iran & Iraq (Fig. 8c-e). Our estimates in Tehran  
502 are 12-30% higher and 33-52% higher than EDGAR’s and CEDS’s estimates for  
503 constant sources, respectively. Our result (220 kt/yr for 2018-2021) is much lower than  
504 the emission estimated by de Foy et al., (2023) (953 kt/yr for 2017-2021) over Tehran,  
505 which is 8.3 times higher than EDGAR v6.0’s estimates (114 kt/yr) used in that paper.  
506 The possible reasons could be different assumptions of the regional background and the  
507 methods to calculate the emission of the area. The Gaussian model used by de Foy et  
508 al., (2023) treated an urban area as one large source and integrated the emissions along  
509 the “plume”, whereas our total emission for a certain area is the sum of individual  
510 sources that are derived from the divergence method. GEFI’s estimate for the fuel  
511 exploration is 2-3 times higher than EDGAR’s and CEDS’s estimates, indicating  
512 possible underestimations of the two inventories in Tehran. The sources in Isfahan,  
513 another Iranian metropolis, are also constant over time (very small difference between

514 blue and pink bars). However, our derived emissions are about 3 times higher than the  
515 two inventories. Sources in our inventory are distributed over a wider area in Isfahan,  
516 and their spatial distributions are similar to NO<sub>x</sub> sources of EDGAR and DECSO,  
517 indicating the emissions are very likely from activities in the city. Although Isfahan has  
518 been attempting to gradually transform the landfill-based disposal system into a modern  
519 system with less production of greenhouse gases, the high methane emissions we  
520 derived might also imply that waste management is still a challenge (Abdoli et al.,  
521 2016). A similar result was found by Chen et al. (2023), in which they found waste  
522 emissions could be underestimated by more than 50% in certain Middle Eastern  
523 countries like Iran, Iraq, and Saudi Arabia.

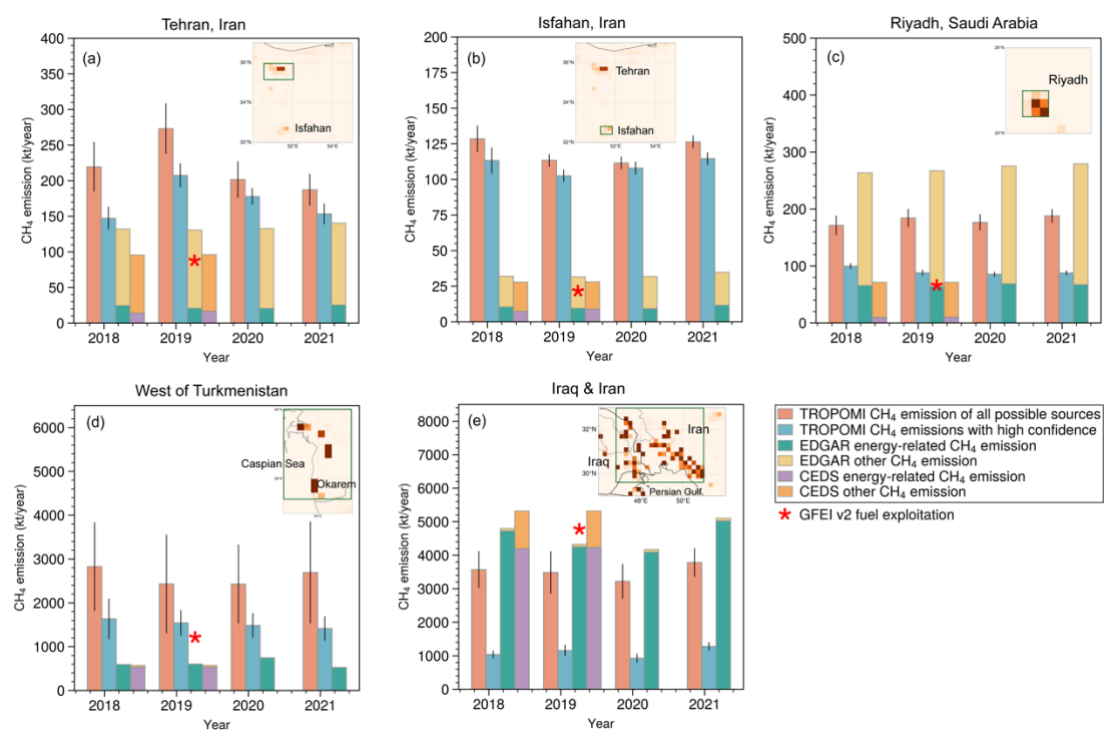

524 The total constant emissions we derived for Riyadh are half that of EDGAR but close  
525 to CEDS's estimate. As shown in Fig. 5, the spatial distributions of various inventories  
526 can be very different. The domain we used to calculate the total emission is defined by  
527 the spatial distribution of EDGAR, but oil/gas-related flares are located in the northeast  
528 of Riyadh (blue dots in Fig. 5g). However, including these cells only increases total  
529 emissions by 5–8% because they are smaller than 3kg/km<sup>2</sup>/h therefore below the  
530 detection threshold of TROPOMI. Moreover, ~50% of the emissions in Riyadh are  
531 constant (have constant emission factor), which can be another reason of the large  
532 discrepancy between different inventories.

533 Western Turkmenistan near the Caspian Sea and the coastal regions of Iran and Iraq are  
534 two well-known oil/gas production areas in the Middle East. The energy-related sectors  
535 (green bars) contribute more than 92% in the two regions based on EDGAR estimates.  
536 The constant emissions derived from TROPOMI (blue bars) in the west of  
537 Turkmenistan are quite comparable to GFEI's estimate but nearly two times higher than  
538 estimates of EDGAR and CEDS. Although total methane emissions estimated by  
539 EDGAR and CEDS are very similar, the spatial distributions of sources are different  
540 (Figure S3). The constant sources of oil/gas there contribute to ~55% of the total  
541 emissions over the four years based on our estimates, which agrees with Varon et al.  
542 (2021), who concluded the sources here are intermittent, and the persistence rate is  
543 ~40%. Our estimates will be four times higher than the total emissions of these two  
544 inventories if all possible sources are included. The large uncertainty also implies that  
545 resolving the sources here can be quite difficult because of the few observations near  
546 the coast and the variabilities of the sources.

547 The annual variations in the coastal area of Iraq and Iran are consistent in EDGAR's  
548 and our estimates (the offshore emissions in bottom-up emission inventories are  
549 ignored because the observation of TROPOMI over ocean can be quite difficult). It  
550 increased to surpass the total emission of 2018 in 2021 after a modest decline from  
551 2018 to 2020. The fraction of constant sources is much less than in Western  
552 Turkmenistan. Our estimates are comparable to EDGAR if all possible sources are  
553 included. However, the total emissions from constant sources are quite low, and they

554 are comparable to the other methane emissions estimated by CEDS, which mainly come  
 555 from waste and are quite low in EDGAR estimates. Chen et al. (2023) found that oil/gas  
 556 emission derived from their inverse modeling with the TROPOMI observation is 43%  
 557 and 58% lower than in their bottom-up emission inventory over Iran and Iraq,  
 558 respectively. Lauvaux et al. (2022) also showed fewer ultra-emitters of methane are  
 559 detected by using the TROPOMI CH<sub>4</sub> operational product (Lorente et al., 2021) in  
 560 Middle Eastern countries such as Kuwait and Saudi Arabia, which could be attributed  
 561 to fewer accidental releases and/or stringent maintenance operations. Thus, for an area  
 562 with many occasionally released methane, using a constant emission factor or flaring  
 563 data as an index may lead to an overestimation of methane leakage from the oil/gas  
 564 industry. In addition, we checked plume complexes detected by EMIT, and find that the  
 565 max value of each plume complex can differ by an order of magnitude, implying the  
 566 large variabilities of released methane here. The coarse spatial resolution of our  
 567 emission data may smooth plume complexes and can be another reason of predicted  
 568 lower emissions.

569

570 **Figure 8.** Regional total methane annual emissions estimated by EDGAR v7.0 and  
 571 TROPOMI from 2018 to 2021. The areas used to generate bars in (a–e) are shown in  
 572 dark green rectangles in embraced emission maps of total emissions of EDGAR in 2019.  
 573 The ranges in latitudes and longitudes can be found in Table S1 in SI. A green bar  
 574 represents the energy-related emissions, and a yellow bar represents the remaining  
 575 methane emissions in EDGAR v7.0. A purple bar represents the energy-related  
 576 emissions, and an orange bar represents the remaining methane emissions in CEDS  
 577 v\_2021\_04\_21. The blue bar is the total emission of sources that pass the temporal filter  
 578 and are higher than 3kg/km<sup>2</sup>/h. The pink bar represents the total emission of all possible

579 sources that are higher than 3kg/km<sup>2</sup>/h. All the emissions over water (the Caspian Sea  
580 and the Persian Gulf) are ignored because of too few observations and large  
581 uncertainties. An error bar represents the sum of uncertainties associated with each  
582 source in this area. The calculation of the uncertainty of a source (grid cell) is presented  
583 in Sect. 2.4.

584

## 585 **4 Conclusions**

586 An improved divergence method using non-divergent wind fields with a temporal filter  
587 has been developed to better estimate CH<sub>4</sub> emissions from observations of the  
588 TROPOMI instrument over areas with complicated orography and/or high albedo, like  
589 the Middle East. The non-divergent wind largely reduces the biases caused by drastic  
590 topography changes. The residue of the background (e.g., sources in Tehran, located in  
591 a valley) is further subtracted from the emission through spatial correction. The  
592 temporal filter is built to further exclude false sources due to retrieval issues. It also can  
593 be used to test the persistency of sources over an area free of artifacts. We found that  
594 emissions from wastes (e.g., landfills, wastewater) or agriculture (e.g., livestock farms)  
595 can be quite persistent in time compared to the oil/gas-related sources in the Middle  
596 East.

597 We further compared our annual regional total emissions with EDGAR v7.0, CEDS  
598 v2021\_04\_21 and GFEI v2 for various regions in the Middle East with different source  
599 categories from 2018 to 2021. The oil/gas productions at the coast of Iran and Iraq are  
600 quite intermittent compared to the west of Turkmenistan where our estimate for  
601 constant sources is quite comparable to the emission from the fuel exploitation  
602 estimated by GFEI v2. The continuous release of methane from waste or farms can  
603 contribute considerably to the total methane emissions in several metropolises in the  
604 Middle East, which can be two times higher than EDGAR's and CEDS's estimates.

605 In future work, the role of the temporal filter can be largely reduced with new improved  
606 retrieval products of TROPOMI CH<sub>4</sub>. This will especially allow better estimates of  
607 intermittent methane emissions.

## 608 *Acknowledgments*

## 609 *Competing interests.*

610 The authors declare that they have no competing interests.

611 ***Funding.***

612 ESA project IMPALA, grant number: 4000139771/22/I-DT-bgh

613 ***Author contributions.***

614 ML, RVA, and MVW designed the experiment and analyze the results. ML performed  
615 all calculations and visualized the results. The codes for estimating methane emissions  
616 are mainly developed by ML and are supported by LB, HE and PV. HK and JD help to  
617 visualize the results. The wind fields are extracted by HE. YL provides the category-  
618 related VIIRS data. All co-authors contributed to review the manuscript.
