**Abstract.** Developing effective global strategies for climate mitigation requires an independent assessment of greenhouse gas emission inventory at the urban scale. In the framework of the Dutch Ruisdael Observatory infrastructure project, we have enhanced the Dutch Large-Eddy Simulation (DALES) model to simulate carbon dioxide (CO<sub>2</sub>) plume emission and threedimensional dispersion within the turbulent boundary layer. The unique ability to explicitly resolve turbulent structures at the hectometer resolution (100 m) makes DALES particularly suitable for detailed realistic simulations of both singular highemitting point sources and urban emissions, aligning with the goals of Ruisdael Observatory. The model setup involves a high-resolution simulation ( $100 \text{ m} \times 100 \text{ m}$ ) covering the main urban area of the Netherlands ( $51.5^{\circ}-52.5^{\circ}\text{N}$ ,  $3.75^{\circ}-6.45^{\circ}\text{E}$ ). The model integrates meteorological forcing from the HARMONIE-AROME weather forecasting model, background CO<sub>2</sub> levels from the CAMS reanalysis, as well as point source emissions and downscaled area emissions derived from 1 km  $\times$  1 km emission inventory from the national registry. The latter are prepared using a sector-specific downscaling workflow, covering major emission categories. Biogenic CO<sub>2</sub> exchanges from grasslands and forests are interactively included in the hectometer calculations within the heterogeneous land-surface model of DALES. Our evaluation strategy is twofold, comparing DALES simulations with: (i) the state-of-the art LOTOS-EUROS model simulations and (ii) Ruisdael surface observations of the urban background in the Rotterdam area at Westmaas and Slufter and in-situ rural Cabauw tower measurements. Our comprehensive statistical analysis confirmed the effectiveness of DALES in modeling the urban-scale CO<sub>2</sub> emission distribution and plume dispersion under turbulent conditions, but also revealed potential limitations and areas for further improvement. Thus, our new model framework provides valuable insights into the role of anthropogenic and biogenic contributions to local CO<sub>2</sub> levels, as well as the transport and dispersion of CO<sub>2</sub> emissions. This supports emission uncertainty reduction using atmospheric measurements and contributes to the development of effective regional climate mitigation strategies.

#### 20 1 Introduction

30

45

Climate change is a critical global environmental problem caused by rising concentrations of carbon dioxide (CO<sub>2</sub>) and other long-lived greenhouse gases (GHGs) (IPCC, 2021). To address this problem, international agreements like the Paris Agreement aim to mobilize political forces to reduce GHG emissions. Expanding urban areas play a key role, as they account for 60-70% of global CO<sub>2</sub> emissions (IPCC, 2023). A recent United Nations Framework Convention on Climate Change (IPCC, 2023) report also highlights the prominent role of urban CO<sub>2</sub> emissions in amplifying climate change, underscoring the urgent need to address them in mitigation efforts. However, urban environments pose challenges due to their complex, heterogeneous landscapes, diverse emission sources (e.g., transport, industry, biosphere interactions), and significant spatiotemporal variability caused by atmospheric turbulence. Tackling these challenges in the quantification of emissions requires high-resolution data to precisely identify emission hotspots, which is crucial for effective monitoring and mitigation.

To address the urgent question of how to reduce emissions most efficiently, many countries have developed national programs for monitoring atmospheric GHG concentrations. Initiatives such as CarboCount-CH (see http://carbocount.wikidot.com/, last access: 27 November 2024) in Switzerland, the GAUGE project in the UK (Palmer et al., 2018), and the European ICOS initiative (see https://www.icos-cp.eu/, last access: 27 November 2024), the North American Carbon Program (see https://www.nacarbon.org/nacp/, last access: 27 November 2024) in the US, and the CONTRAIL project (https://cger.nies.go.jp/contrail/about/index.html, last access: 27 November 2024) in Japan, reinforce global efforts to establish transparent and accurate CO<sub>2</sub> and CH<sub>4</sub> emission tracking.

On the other hand, as cities are major CO<sub>2</sub> sources, targeted monitoring is becoming a priority. Due to their complexity and growth, cities require detailed observation and analysis, though monitoring them is particularly challenging (Huo et al., 2022). Programs like ICOS Cities (see https://www.icos-cp.eu/projects/icos-cities, last access: 27 November 2024), Urban-GEMMS (see https://www.arl.noaa.gov/research/atmospheric-transport-and-dispersion/urban-gemms/, last access: 27 November 2024), and the C40 Cities Climate Leadership Group support high-resolution modeling for capturing the fine-scale variability of urban emissions. Furthermore, the Megacities Carbon Project (see https://earthobservatory.nasa.gov/images/86970/megacities-carbon-project, last access: 27 November 2024) tracks emissions in global cities, supporting efforts to refine urban GHG inventories and strengthen mitigation policies (Timmermans et al., 2013).

In the Netherlands, there is a similar need. According to the Nationally Determined Contribution climate action plan, the Dutch government aims to reduce CO<sub>2</sub> emissions by 55% by 2030 and achieve climate neutrality by 2050 (UNTC (United Nations Treaty Collection), 2016). Thus, comprehensive studies of urban emission sources and distribution in the environment are essential to meet these ambitious reduction targets. A notable initiative in this regard is the Dutch Ruisdael Observatory (see https://ruisdael-observatory.nl/, last access: 27 November 2024). This infrastructure project has been established to improve the accuracy of weather and air quality forecasts in a changing climate and provide society with this high-quality and highly detailed information to address existing climate problems. One of the aims is to model the entire Dutch atmosphere at a 100m resolution, combining simulations with meteorological and atmospheric composition data.

Despite significant progress in emission modeling at different scales (Sarrat et al., 2007; Meesters et al., 2012; Liu et al., 2017; Super et al., 2017; Brunner et al., 2019; Jähn et al., 2020; Brunner et al., 2023), a critical lack of realistic modeling of urban-scale CO<sub>2</sub> emissions still remains. Moreover, capturing sub-kilometer emission plume features, such as dispersion and inherent turbulence effects within the atmospheric boundary layer (ABL), might be important for accurate quantification of emissions. Hence, integrating anthropogenic emission inventories into frameworks like Large-Eddy Simulation (LES) models (Deardorff, 1972), which explicitly resolve a major part of atmospheric turbulence, addresses this need. Brunner et al. (2023) demonstrated that LES models effectively capture CO<sub>2</sub> plume dynamics from coal-fired power plants, highlighting the importance of model resolution. Thus, despite the computational demands associated with LES, the development of such a simulation framework has the potential to significantly enhance the capability of models to reproduce the observed CO<sub>2</sub> signal in urban areas (Sarrat et al., 2007; Liu et al., 2017; Super et al., 2017; Brunner et al., 2023). Along with that, incorporating dynamic ecosystem model, which account for CO<sub>2</sub> plant assimilation and soil respiration, can further enhance urban-scale simulation by means of LES (Vilà-Guerau de Arellano et al., 2014). Driving the ecosystem model for CO<sub>2</sub> fluxes with LES allows for resolving fine-scale atmospheric processes that influence CO2 exchange with higher accuracy than traditional mesoscale models, which rely on parameterized boundary layer dynamics. LES can help in resolving the observed rapid meteorological fluctuations in radiation and turbulence (seconds to minutes) that strongly impact on fluxes of heat, moisture, and CO<sub>2</sub> (see Vilà-Guerau de Arellano et al. (2014)). Thus, by explicitly simulating clouds and their effects on diffuse radiation, temperature, and moisture, we can improve the representation of key drivers of photosynthesis and respiration, thereby improving the modeled representation of the biogenic contribution to atmospheric CO<sub>2</sub> concentrations.

To achieve high-resolution modeling, detailed emission inventories are essential. Previous studies have provided valuable information on various emission inventories at different scales, from global (Guevara et al., 2019, 2024) to regional (Urraca et al., 2024), across Europe (Xiao et al., 2021; Kuenen et al., 2022), Asia (Jia et al., 2021), and North America (Brioude et al., 2012), etc. In the Netherlands, for CO<sub>2</sub> emissions, the National Institute for Public Health and the Environment (RIVM) provides registered annual individual emission sources from the industry, as well as area emission inventory from various categories mapped on a km-scale grid (https://data.emissieregistratie.nl/, last access: 27 November 2024). Yet, they are not sufficient for 100m-scale LES models and cannot be employed without a proper downscaling. Yet, this process presents significant challenges due to spatiotemporal uncertainties that emerge when downscaling coarse-resolution data. For point sources, which are supposed to be easier to apply to LES due to their precisely available emitting locations, accurate vertical allocation through plume rise is crucial and not trivial to estimate, though it is important to account for in simulations (Brunner et al., 2019). Hence, achieving the required level of accuracy in emission modeling involves the complex processes of downscaling in space and time, as well as accurate vertical allocation of emissions.

This need motivates the continued development of related improvements in LES tools and associated national emission inventories. One such model that is developed for the Netherlands is the Dutch Atmospheric Large Eddy Simulation (DALES) model framework (Heus et al., 2010; Ouwersloot et al., 2017). Traditionally, this simulation technique was employed primarily to study atmospheric physics and ABL dynamics (Heus et al., 2010; van Heerwaarden et al., 2017), but not to simulate CO<sub>2</sub> emission transport and distribution.

Thus, both having a high-resolution emission inventory and extending DALES with an advanced emission routine would enable us to realistically simulate the Dutch environment, aligning with the objectives of the Ruisdael Observatory research project.

This study addresses four main objectives:

95

105

- Document the downscaling emission workflow program developed to prepare emission inventory for urban-scale realistic modeling of CO<sub>2</sub> emissions.
- 2. **Show** the capabilities of the state-of-the-art DALES 4.4 model, enhanced to simulate anthropogenic point sources and area-based CO<sub>2</sub> emissions, integrating biogenic CO<sub>2</sub> contribution from vegetation.
  - 3. Validate the framework and ability of DALES with the presented setup to simulate atmospheric CO<sub>2</sub> concentration variability using observations and lower-resolution simulations, demonstrating the benefits of 100m-scale simulations.
  - 4. Assess the importance of individual CO<sub>2</sub> components to unravel the overall CO<sub>2</sub> signal observed at measurement sites.

In reaching these goals, we provide valuable insights into the transport and dispersion of CO<sub>2</sub> plumes in turbulent environments. This enables us to quantify and evaluate emission inventories more accurately as well as investigate which scales should be resolved to adequately simulate the observed CO<sub>2</sub> concentration variability. This study is a step forward from the initial work, introduced and discussed in (de Bruine et al., 2021).

The manuscript is structured as follows: Sect. 2 provides an overview of the anthropogenic emission datasets. The description of the DALES model and the large-scale boundary conditions is provided in Sect. 3, followed by the description of the DALES emission module in Sect. 4. A detailed description of the downscaling workflow used to prepare emission model input is given in Sect. 5. Sect. 6 outlines the model experiment setup. The datasets used for model validation are described in Sect. 7. Sect. 8 presents the model simulation results, their validation, and a discussion of the drivers behind the observed variability. Finally, Sect. 9 and 10 provide an outlook on the further development of the tools and methodologies employed, and summarize our study with general conclusions.

# 110 2 Anthropogenic Emission Data

Anthropogenic emission sources are classified into 10 groups according to the Standard Nomenclature for Air Pollution (SNAP). The SNAP categories used in this study are summarized in Table 1 (EEA, 1999).

We differentiate between two types of anthropogenic emissions: point sources and spatially allocated diffuse sources, which are processed in separate procedures as explained below.

Point sources, which include emissions from power plants and industrial facilities, are the largest contributors to the anthropogenic CO<sub>2</sub> budget, accounting for approximately 50–60% of total anthropogenic CO<sub>2</sub> emissions. In the Netherlands, companies responsible for these large emission sources are mandated to report emissions annually by location to a pollutant register. Reported emissions from these sources are available on the National Emission Inventory (ER) portal, maintained by

Table 1. Classification of anthropogenic emissions (area and point sources) by SNAP Category used in our study

SNAP Category	Description	Comments			
SNAP 1	Power generation	Combustion in the production and transformation of energy.			
SNAP 2	Residential and commercial	Includes emissions from non-industrial combustion, e.g., household an			
		commercial heating/cooling.			
SNAP 3	Industrial combustion	Emissions from combustion in industrial facilities.			
SNAP 4	Industrial processes without combustion	Emissions from industrial manufacturing processes.			
SNAP 5	Fossil fuel extraction and distribution	Includes emissions from the extraction, processing, and distribution of			
		fossil fuels.			
SNAP 7	Road transport	Emissions from road transport (passenger cars, trucks, etc.).			
SNAP 8	Other mobile sources	Emissions from non-road mobile machinery (e.g., ship transport).			
SNAP 9	Waste treatment and disposal	Includes emissions from waste processing and treatment facilities.			
SNAP 10	Agriculture	Covers emissions from agricultural and food-related activities (live-			
		stock, fertilizers, fisheries).			

RIVM (https://data.emissieregistratie.nl/export, last access: 27 November 2024, hereafter referred to as the ER portal). This portal provides an annual total emission inventory database of GHGs as well as other specific variables relevant for air quality can be acquired.

Emission data are classified by sector/subsector, facilitating processing for each SNAP category. Emissions from industrial point sources are accessible through the ER portal, aggregated at the company level. A comprehensive list of registered emission sources, including thermal plume parameters such as exhaust temperatures and volumetric flow rates, as well as stack height of emission itself, can be accessed from the RIVM upon request.

Besides, gridded  $CO_2$  emissions with a spatial resolution of  $1 \times 1 \text{ km}^2$  over land and  $5 \times 5 \text{ km}^2$  over the North Sea are also available from the ER portal. The spatial resolution of  $1 \times 1 \text{ km}^2$  cannot be easily refined for all emission sources due to various reasons; for some emissions there is a lack of suitable data to do so, sometimes privacy protection rules play a role. For most emission sources spatial allocation is done by applying an allocation key dataset, e.g. all emissions related to citizens are commonly gridded based on population number. Some total emissions are estimated with calculation methods in which spatial data are implemented/available (e.g. AIS data of ship movements), in this case only aggregation to the desired spatial scale is needed. For industrial sources, stack coordinates are registered in industrial activity surveys related to the European Pollutant Release and Transfer Register regulation. An uncertainty of approximately 4% is reported for the total  $CO_2$  emissions in the emission inventory.

Comprehensive information on the methods used for the production and processing of the emission inventory, as well as uncertainties for different sectors, is provided in the National Inventory Report (Van der Net et al., 2024).

#### 3 The DALES Model

140

145

155

160

170

The Dutch Atmospheric Large-Eddy Simulation (DALES) model is a community-based numerical framework designed for atmospheric research, which focuses in particular on small-scale atmospheric turbulence processes, including clouds, and the physics of the ABL (Heus et al., 2010; Ouwersloot et al., 2017). DALES originates from the code developed by Nieuwstadt and Brost (1986). In this work, we use DALES version 4.4 that can be accessed here Karagodin-Doyennel (2024a).

DALES is based on LES techniques, which resolve eddies in turbulent flow down to a certain scale (typically the size of the grid cells), below which small-scale turbulent structures are parameterized. Therefore, no parameterization of processes such as ABL entrainment or plume mixing is required (Dosio et al., 2003). In addition, DALES incorporates state-of-the-art atmospheric physics and microphysics schemes to simulate various processes, including radiation, convection, and cloud formation. These components are crucial for accurately representing the exchange of momentum, heat, moisture, and other substances between the atmosphere and the Earth's surface.

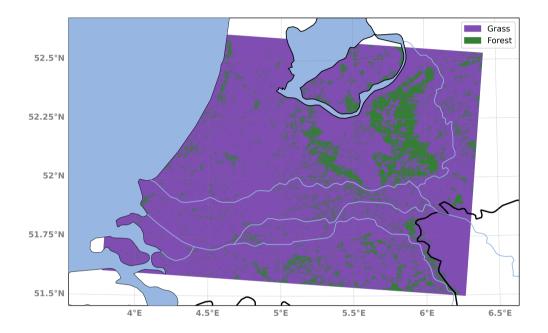

DALES has been well proven to accurately reproduce observed atmospheric turbulence and other dynamical processes, providing valuable insights into ABL phenomena, atmospheric dynamics, as well as cloud and aerosol microphysics (Sikma and Ouwersloot, 2015; de Bruine et al., 2019). DALES is formulated on a rectilinear *x-y* grid and configured to use the Arakawa C-grid (Arakawa et al., 2011, 2016). For this setup, Lambert Conformal Conic (LCC) coordinates are employed in DALES. Tracer advection is simulated using the Kappa mass-conserving scheme (Tatsumi et al., 1995). The Kappa scheme is a hybrid advection scheme that combines aspects of first-order upwind schemes and second-order centered schemes for parameters such as tracer mixing ratios that should never become negative. The filtered Navier-Stokes equations are solved on the DALES grid, allowing extremely fine spatial resolutions (up to 1 m) horizontally and from a few meters to several hundred meters vertically using stretched vertical grid. DALES is developed for the troposphere; therefore, the vertical grid begins at ground level and can be extended up to a height of about 11 km. DALES employs a temporal integration time as fine as 2 s.

DALES features an interactive land surface simulation, including photosynthesis as well as soil and autotrophic respirations, using the Land Surface Model (LSM) (Jacobs and de Bruin, 1997; Ronda et al., 2001; Jacobs et al., 2007; Balsamo et al., 2009; Vilà-Guerau de Arellano et al., 2014). Involving the LSM is particularly valuable for studying the effects of land cover heterogeneity on atmospheric dynamics, microphysics, and ABL development, as well as atmospheric influences from the biosphere.

LSM provides DALES with the capability to compute net biogenic  $CO_2$  fluxes, such as biospheric sinks through vegetation photosynthesis and respiration fluxes. This is achieved in DALES using a dedicated scheme that integrates canopy and soil resistances based on the A-gs (net  $CO_2$  assimilation rate (A), stomatal conductance (gs) model. The performance of A-gs has previously been evaluated, showing results similar to the widely used Farquhar biochemical growth model (van Diepen et al., 2022). Initially proposed by Jacobs and de Bruin (1997) and later refined and simplified by Ronda et al. (2001), the A-gs scheme adopted by DALES enables the calculation of stomatal conductances for both  $CO_2$  and water, facilitating  $CO_2$  exchange between vegetation and the atmosphere. The transport of  $CO_2$  into the leaf is the result of gross assimilation and dark respiration. Autotrophic respiration is considered based on  $R_{10}$ , which represents respiration at  $10^{\circ}C$  (Jacobs et al., 2007).

Hence, the scheme incorporates a parameterization for soil respiration of CO<sub>2</sub> and the influence of soil moisture on canopy conductance.

Ultimately, the scheme provides information on net  $CO_2$  assimilation (photosynthesis) and soil respiration, taking into account factors such as temperature and vegetation type. While the A- $g_s$  scheme in DALES was primarily focused on grassland ecosystems, this work enhances the scheme by incorporating parameters specific to forest. Parameters for the A- $g_s$  model used in DALES for both vegetation types are provided in Table A1, and the map distinguishing regions with grassland and forest is shown in Figure 1.

**Figure 1.** Map of vegetation types used by the LSM in DALES. The map corresponds to the target LES domain (100x100 m), used in this study. The purple color represents grassland areas, and green represents forested areas.

Distinguishing between forest and grassland is particularly important in the central-eastern region of the Netherlands, where forests are prevalent. Large forested areas within urban areas are also considered. This distinction improves the accuracy of computed CO<sub>2</sub> and momentum fluxes due to forest-specific surface roughness.

#### 3.1 DALES boundary conditions

180

185

In our work, several datasets are used for lateral and vertical boundary conditions for meteorology and chemistry. The meteorological lateral boundary conditions (LBCs) in DALES are nudged toward data from the HARMONIE-AROME mesoscale weather forecast model developed at KNMI (Bengtsson and Coauthors, 2017). To nudge DALES lateral boundaries to HARMONIE-AROME, we use a distinct dataset from the Winds of the North Sea in 2050 (WINS50) project (see https://www.wins50.nl/, last access: 27 November 2024, for additional details), which provides coverage over the Netherlands at an hourly temporal

resolution (see https://dataplatform.knmi.nl/dataset/wins50-wfp-nl-ts-singlepoint-3, accessed: 27 November 2024, for further details). It uses common meteorological variables such as wind speed, wind direction, temperature, air pressure, relative humidity, as well as sea surface temperature.

To incorporate background  $CO_2$  concentration, LBCs are applied based on the Copernicus Atmospheric Monitoring System (CAMS) air quality forecast of the CAMS Global Greenhouse Gas Reanalysis (EGG4) product. This product is based on the delayed-mode analysis, which provides refined, post-processed dataset that offers more accurate representation of greenhouse gases in the atmosphere. We use these data for a geographical area spanning  $50.5^{\circ}$  to  $54.0^{\circ}N$  and  $1.75^{\circ}$  to  $9.125^{\circ}E$  at a resolution of  $0.125^{\circ} \times 0.125^{\circ}$  ( $\sim 14$  km), updating every 6 hours (for further details on the CAMS EGG4 product, visit https://ads.atmosphere.copernicus.eu/datasets/cams-global-ghg-reanalysis-egg4?tab=overview, last access: 11 March 2025).

LSM also requires initial state data for initialization, encompassing parameters such as land use, vegetation properties from ERA5 data, and soil hydraulic parameters for 42 soil types, including soil moisture content at different states, hydraulic conductivity at saturation Van Genuchten model parameters used to describe soil water retention and hydraulic properties (see Vilà-Guerau de Arellano et al. (2015)).

Note that in this study, the DALES with periodic lateral boundaries is used. This periodicity applies to mean wind, turbulence, and tracers, meaning that any quantity exiting the east boundary reenters at the west boundary, and vice versa; the same applies to the north-south boundaries. The upper boundary incorporates a damping sponge layer that gradually reduces turbulence and tracers to minimize artificial reflections. At the bottom, surface heterogeneity affects the fluxes, which are treated by the LSM.

Overall, due to its accuracy, fine spatial and vertical resolution (100 m horizontal and 20 m within the ABL), and near-realistic modeling approach (including a heterogeneous surface, anthropogenic emissions, and periodic boundaries), DALES is well-suited for conducting targeted simulations that isolate and examine specific aspects of atmospheric physics and dynamics under controlled conditions. Since DALES had not previously been utilized for modeling CO<sub>2</sub> mole fractions, coupling with an emission inventory required additional development to incorporate a program that converts and integrates emissions data for accurate horizontal representation, as well as for vertical allocation in the model.

# 210 4 Emission module in DALES

190

195

200

205

215

To integrate and simulate the transport of anthropogenic emissions within DALES, we developed a module for reading emission datasets, applying vertical allocation of emissions, inter-hour interpolation to integrate a smooth change of emission, and finally applying emissions to scalar  $CO_2$  tracers. In the simulation setup used in this study, the scalar tracer for atmospheric transport of  $CO_2$  in DALES is expressed in units of  $\mu g g^{-1}$ . The expression used to transfer area emission profiles into model scalar tracers is as follows:

$$CO_2 tracer_j = CO_2 tracer_j + \frac{area\_emis\_int_j}{3600 \cdot \rho_i \cdot dzf_i \cdot dx \cdot dy \cdot 1 \times 10^{-6}}$$
(1)

where  $CO_2$  tracer is the scalar  $CO_2$  tracer [ $\mu$ g g<sup>-1</sup>]; area\_emis\_int is the temporally interpolated 3-D field of emission input [kg hour<sup>-1</sup>];  $\rho_j$  is air density [kg m<sup>-3</sup>];  $dzf_j$  is the thickness of the full level [m]; dx and dy are grid spacing in x and y directions [m];  $1 \times 10^{-6}$  is the conversion factor from kilograms to micrograms; j denotes the vertical layer index from 1 to  $k_{emis}$ , where emissions are allocated (for area emissions,  $k_{emis}$  equals the closest layer to 150 m, according to the results of Brunner et al. (2019)). It should be noted that since the emission input has an hourly temporal resolution, an inter-hour interpolation factor is calculated, and temporal linear interpolation of emissions is applied.

For area emissions, the representation of area emission plume rise is simplified by setting the plume bottom to 0 and the plume top height to  $\sim$ 150 m following Brunner et al. (2019). Emissions are evenly distributed among model layers between the emission bottom and the top heights, so that each layer receives an equal share of the total emission values. It is important to note that area emissions from several SNAP categories have no vertical component, and all emissions from those categories are applied in the model at the lowest LES layer. These categories are: SNAP5, since oil/gas extraction occurs at ground level; SNAP7 traffic emissions; and SNAP10 agriculture, since it involves emissions at near-ground level, like those from soil and livestock.

In cases of point sources, the plume bottom and emission altitude can be calculated interactively. The effective emission height can be significantly higher than the geometric height of a stack due to the buoyancy of the emission flux (Briggs, 1984). Therefore, plume rise is influenced by several factors, including stack geometry, flow properties (such as exhaust temperature and volumetric flow rate), and meteorological conditions (such as air temperature, wind speed, and atmospheric stability) (Brunner et al., 2019). To account for this in the simulation, the DALES emission module includes an online algorithm that calculates plume rise based on the interaction between model meteorology and source-specific data at each model time step.

# 4.1 Online algorithm for calculating plume rise height

220

225

230

235

240

250

The algorithm implemented in DALES to calculate the plume height above the stack as well as the vertical boundaries of the plume after it has risen to equilibrium was originally proposed by Briggs (1984). We implemented a revised, up-to-date version of this algorithm, as outlined in Gordon et al. (2018) and Akingunola et al. (2018).

Initially, since the calculated stack height may not align exactly with a model grid point, the air temperature  $(T_a)$  and wind speed  $(U_a)$  at the stack height are determined from DALES data using linear interpolation. Once the atmospheric variables are obtained, the buoyancy flux  $(F_b)$  at the stack height, responsible for the updraft of turbulent eddies, is calculated based on the difference between the emission temperature  $(T_s)$  and  $T_a$  using the expression (1) from Akingunola et al. (2018). This calculation indicates that the emitted plume is buoyant and rises only when  $T_s$  exceeds  $T_a$ . The plume parameters are assumed to be in steady-state conditions as information about their temporal changes is unavailable.

Further, the residual buoyancy flux  $(F_1)$  is estimated based on atmospheric conditions and emission characteristics. With an iterative process, continuing until  $F_1$  becomes negative, we compute the local stability parameter  $(S_j)$  for each subsequent model level using the expression (5) from Akingunola et al. (2018). Note that the iteration initializes at the stack height  $(h_s)$ .

The  $F_{1,j+1}$  is calculated sequentially for each atmospheric layer based on the value of S, selecting the final value that shows the greatest decrease in flux, as recommended by Briggs (1984), as follows:

$$F_{1,j+1} = \begin{cases} \min\left(F_{1,j} - 0.015 \cdot S_j \cdot F_{1,j-1}^{1/3} \cdot ((z_{j+1} - h_s)^{8/3} - (z_j - h_s)^{8/3}), \\ F_{1,j} - 0.053 \cdot S_j \cdot U_m \cdot ((z_{j+1} - h_s)^3 - (z_j - h_s)^3)), & \text{if } S_j >= 0 \\ F_{1,j}, & \text{if } S_j < 0 \end{cases}$$

$$(2)$$

where the mean wind speed  $U_{\rm m}$  is calculated as  $(U_{{\rm zh}j+1}+U_{{\rm zh}j})/2$ , as recommended by Gordon et al. (2018) (where U is  $\sqrt{u^2+v^2}$ , representing the total horizontal wind speed). In the first iteration,  $u_{{\rm zh}j}=U_{\rm a}$  and  $z_j-h_{\rm s}=0$ . The stack height is subtracted from each z value, representing the vertical distance relative to the top of the stack. Initial values for  $F_1$  are set as  $F_{1,j-1}=F_{1,j}=F_{\rm b}$ .

Finally, the exact plume rise height  $(h_{\text{max}})$  is determined based on the condition that  $F_{1,j+1}$  at  $h_{\text{max}}$  equals 0, indicating that  $h_{\text{max}}$  is the altitude at which the buoyancy flux of emitted plume dissipates entirely (Akingunola et al., 2018). Thus, the expression for  $h_{\text{max}}$  can be derived from (2) and  $F_{1,j+1}=0$  and applied in the layer where  $F_{1,j+1}$  becomes negative, as follows:

$$h_{\text{max}} = \begin{cases} \min\left(\frac{F_{1,j}}{(0.015 \cdot S \cdot F_{1,j-1}^{1/3})^{3/8}} + (z_j - h_s), \\ \frac{F_{1,j}}{(0.053 \cdot S \cdot U_{\text{low}})^{1/3}} + (z_j - h_s)\right), & \text{if } F_{1,j+1} < 0 \\ z_{j+1} - h_s, & \text{if } F_{1,j+1} = 0 \end{cases}$$

$$(3)$$

260 If  $F_{1,j+1} = 0$ , then  $h_{\text{max}}$  equals the altitude of  $F_{1,j+1}$ .

275

Using the plume rise height  $h_{\text{max}}$ , the top  $(z_{\text{t}})$  and bottom  $(z_{\text{b}})$  of the plume are then calculated using expressions (8) from Akingunola et al. (2018).

The illustration of resulting plume top distributions for midday (0:00 UTC) and midnight (12:00 UTC) times are depicted in Fig. 2.

Despite the exhaust temperature and volumetric flow rate remaining constant in the algorithm, a pronounced difference in plume top distributions between night (00:00 UTC) and day (12:00 UTC) times is visible. This difference is primarily due to local atmospheric conditions. During the night (00:00 UTC), the plume tops are confined below 500 m. In contrast, during the day (12:00 UTC), the plume tops exhibit greater variability, with some tops reaching up to 1500 m.

At night, the atmosphere is more stably stratified, with little turbulence and reduced vertical mixing. This stable stratification acts as a natural barrier, preventing plumes from rising higher into the atmosphere. Additionally, the boundary layer is lower at night, further constraining the height of plume rise. In contrast, during the daytime, solar heating causes surface warming, leading to increased atmospheric turbulence and stronger vertical mixing. This creates a deeper and more unstable boundary layer, spurring plumes to rise higher. The convective upflow during the day enhances the buoyancy of plumes, contributing to the broader distribution of plume tops observed at 12:00 UTC. Hence, the difference in plume top heights between night and day is largely driven by variations in atmospheric stability, turbulence, and boundary layer dynamics.

It is important to note that, as with area emissions, point source emissions are equally distributed vertically from plume bottom to plume top with grid cells fully covered by the plume. However, since the parameterization provides the exact plume

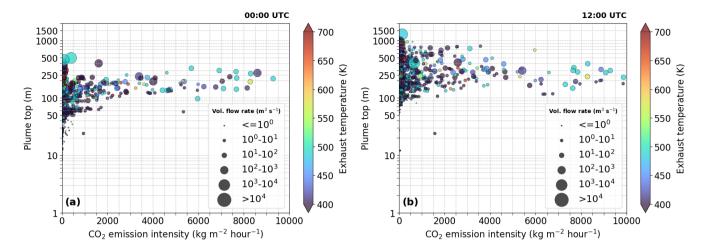

Figure 2. Modelled plume top  $(z_t)$  distribution as a function of the corresponding  $CO_2$  emission intensity (kg m<sup>-2</sup> hour<sup>-1</sup>) at (a) 0:00 UTC and (b) 12:00 UTC. Dot colour: exhaust temperature (K); Dot size: volumetric flow rate (m<sup>3</sup> s<sup>-1</sup>).

bottom and plume rise heights, these altitudes may fall between the edges of model layers. The fractions of layers covered by the plume for the plume top and bottom are calculated.

To include the point source emission profile into the scalar  $CO_2$  tracer and account for the vertical allocation of emissions using the calculated plume vertical boundaries, we use a similar expression as in Eq. (1), but applying it separately for three cases:  $z_b = z_t$ ,  $z_b - z_t = 1$ , and  $z_b - z_t > 1$ , respectively. Note that in the case of  $z_b - z_t = 1$ , the plume fraction factors are not applied and the total emission is divided by 2 and equally distributed.

Thus, the use of the plume rise algorithm ensures a more accurate representation of CO<sub>2</sub> plume vertical distribution, contributing to a more realistic dispersion of pollutants. The plume rise height is strongly influenced by turbulent conditions and variations in buoyancy flux (see Fig. 2), which are calculated based on the differences between plume thermal parameters, ambient meteorology, and atmospheric stratification and stability.

It should be mentioned that the emissions from the point and area sources utilized in our study represent the total national annual emissions, quantified in kilograms of CO<sub>2</sub> per year. Thus, these data need to be spatially and temporally disaggregated before being used as input in DALES. This is achieved through a downscaling workflow procedure, which is described in the following section.

# 5 Emission downscaling workflow

280

285

290

295

Coupling the  $CO_2$  emission inventory with a high-resolution model like DALES requires alignment between the spatiotemporal resolutions and coordinate systems of the emission inventory and the model. In this study, DALES input uses a LES grid with 100 m horizontal resolution and emission input should have hourly temporal resolution, to account for the diurnal variations. Therefore, to accurately simulate  $CO_2$  emissions, the emission data must be disaggregated in both space and time.

Consequently, a translation of the coordinate system to LCC coordinates is required, as original emission datasets from the national registry are provided in Dutch Rijksdriehoek (RD) coordinates. Thus, we developed a downscaling workflow to process the prior emission inventory into DALES-compatible input.

300

305

310

315

The workflow is structured as a comprehensive program with several stand-alone modules, each responsible for different aspects of emission data processing. The full description of the program and all included modules can be accessed in Karagodin-Doyennel (2024b). Since DALES computes point sources and area emissions differently, the model input is separated into these two components. Initially, the workflow focuses on preparing point source data for DALES (in *point\_source\_explicit\_input\_netcdf.py*). For individual sources with precise emission locations, emissions are straightforwardly reassigned from RD to LCC coordinates. Since DALES also calculates plume rise and emission altitudes interactively for point sources (as was discussed in Sect. 4.1), additional information on chimney height, exhaust temperature, and volumetric flux is required to calculate plume rise and the plume vertical borders, between which CO<sub>2</sub> is injected into the model atmosphere.

Unfortunately, not all point sources contain complete data. For instance, in the emission inventory for the year 2018,  $\sim$  68% point sources had gaps in data, such as missing exhaust temperature, volumetric flow rate, or stack height. In this case, a gap filling approach is employed for point sources using ordinary linear regression based on emission categories. This applies polynomial regression models to estimate missing or zero values in plume characteristics, based on the logarithm of emission values. For volumetric flow rate and stack height, linear regression models of polynomial order 1 are applied, with a logarithmic transformation for both. Temperature, which depends mainly on the emission process, uses a constant regression model (polynomial order 0) as it remains relatively stable across emission rates. Figure 3 represents the results of the gap filling procedure. Thus, the program returns the predicted values for the missing entries. Note that point sources with incomplete data available for regression are incorporated into area emissions.

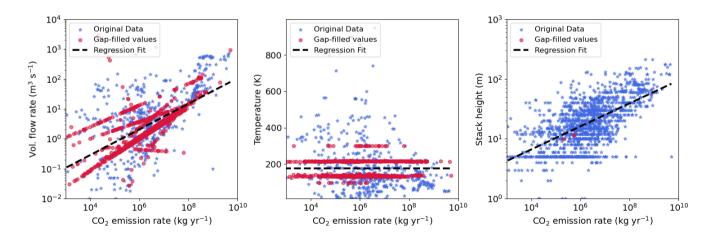

Figure 3. Scatter plots of three plume parameters: volume flow rate (a), temperature (b), and stack height (c) as a function of emission rate (kg  $yr^{-1}$ ). Each subplot combines the original data (blue stars) with the gap-filled values (red circles). A regression fit represents an overall dependence across the dataset.

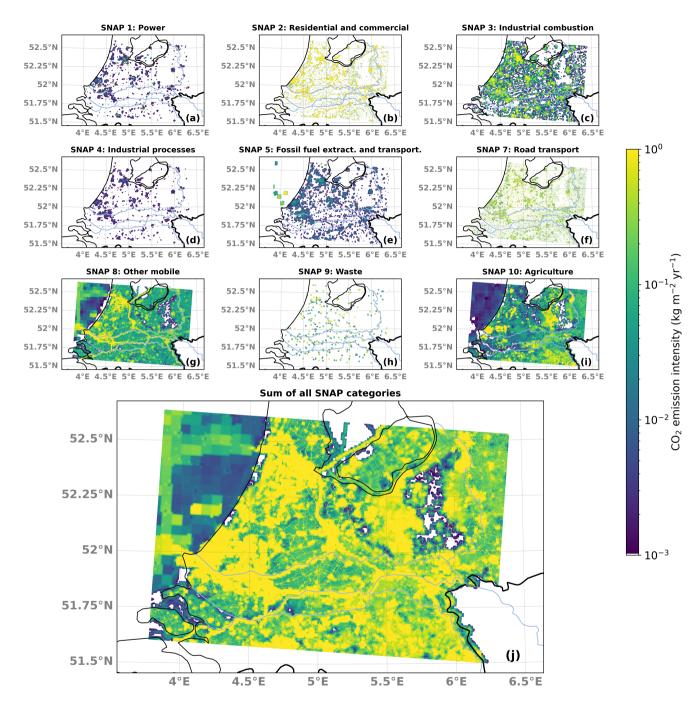

Since the original emission data represent annual sums, temporal disaggregation down to the hour level is required. For this, we applied Emissions Database for Global Atmospheric Research (EDGAR) temporal profiles for anthropogenic emissions specified by SNAP category (TNO, 2011; Crippa et al., 2020). This accounts for emission variations at daily, weekly, and monthly time scales, capturing variations such as traffic rush hour patterns, seasonal differences in heating needs for households, and specific for different countries.

Unlike point source emission processing, the workflow procedure to prepare a high-resolution area emission inventory involves a more complex approach, as the exact coordinates of emissions are unknown. Initially, all point source emissions are subtracted from the area emissions, yielding "residual" area emissions (in *ruisdael\_area\_residuals.py*). Originally, in the national emission inventory, area emissions include contributions from both diffuse sources (e.g., transportation, residential heating, agriculture) and point sources (e.g., industrial facilities, power plants). However, since we process point source and area emissions separately, it is essential to remove the point source contributions from the area emissions to avoid double-counting.

Subsequently, these residual area emissions are translated into GeoPackage (gpkg) format (in *ruisdael\_area\_csv2gpkg.py* ), which is an open, standards-based format for geospatial data storage. This format is chosen for its ability to precisely define spatial extent and select relevant subdomains within the Netherlands for simulation purposes. This eliminates the need for additional software (e.g., QGIS), reducing manual intervention.

The most computationally demanding operation in the workflow is the reprojection of area emissions to a high-resolution grid and from RD coordinates to the target LCC coordinates (in *ruisdael\_area\_RD2HARM.py*). The program intersects the RD grid cells with LCC coordinates and reassigns emissions to the new grid based on the proportional overlap of the grid box fractions. The emissions are then aggregated at the target resolution according to these proportions. This method is exact and scale-independent.

In Figure 4, we show the contributions of different sectors to the total  $CO_2$  emissions, as well as the overall  $CO_2$  emissions from all SNAP categories combined. It is important to mention here that the current simulation setup has no sectorial split and DALES uses combined emissions input from all SNAP categories. Over the sea, the resolution of the input emissions is much coarser  $(5\times5 \text{ km}^2)$  than over the land  $(1\times1 \text{ km}^2)$ , as evidenced by the large squares over the North Sea. Marine emissions are included in the SNAP8 category, representing ship traffic, as well as in SNAP10, which accounts for fisheries-related emissions, as they are more closely related to the food production sector rather than transport activities. Although point sources are barely visible at 100 m resolution (see Figure 4(j) for more details), we present a combined view of area and point sources to provide a complete picture of emissions to verify the annual total within the selected domain. It is important to mention that the Rotterdam harbor, including its port infrastructure, and the Amsterdam area, together with the IJmuiden port, have the highest density of point source emissions within the simulation domain. The majority of point sources fall into the SNAP1 (power generation) and SNAP3 (industrial combustion) categories, as these sectors rely on large stationary facilities, such as power plants, refineries, and industrial manufacturing sites. The point source/area emission contribution ratio to the total  $CO_2$  emissions in the simulation domain is  $\sim 55\%/45\%$ , with point sources having the higher contribution, as expected. The total sum of these emissions is approximately 109 Mt/year for the selected domain, which aligns well with

**Figure 4.** Annual surface CO<sub>2</sub> emission inventory (kg year<sup>-1</sup>) over the target LES simulation domain (51.5° - 52.5°N, 3.75° - 6.45°E; resolution 100 m) for the year 2018, categorised by SNAPs: (a) SNAP 1: Power; (b) SNAP 2: Residential and commercial; (c) SNAP 3: Industrial combustion; (d) SNAP 4: Industrial processes; (e) SNAP 5: Fossil Fuel extraction and transportation; (f) SNAP 7: Road transport; (g) SNAP 8: Other mobile; (h) SNAP 9: Waste; (i) SNAP 10: Agriculture. (j) the aggregated CO<sub>2</sub> emissions across all SNAP categories. These emission maps aggregate both area and point source emissions.

publicly available CO<sub>2</sub> emission estimates for the Netherlands in 2018 (Ruyssenaars et al. (2021); https://ourworldindata. org/co2/country/netherlands?country=~NLD, last access: 27 November 2024). Since LES simulations are computationally expensive, the simulation domain only covers a part of the Netherlands. The selected domain includes the main focus area of the Ruisdael Observatory project (central part of the Netherlands), which is the most urbanized area of the country, responsible for the majority of carbon emissions (~70% of total national emissions). This ensures that all major CO<sub>2</sub> sources in the region are included in the domain. To minimize the influence of CO<sub>2</sub> surface fluxes and emissions from outside the Netherlands, besides selecting a specific simulation domain, weather conditions with a stable northeasterly wind were selected for model evaluation (see Sect. 7.1). This minimizes the effect of CO<sub>2</sub> emissions from Germany, which are not considered as seen in the lower right corner of the domain. Having the Groningen gas production area outside the simulation domain may omit its CO<sub>2</sub> contribution due to the wind direction, but this impact is expected to be minimal due to the low GHG emission intensity of Dutch gas production. However, it should be noted that emissions outside the domain are accounted for in the CAMS EGG4 dataset. Further, the vertical distribution of area emissions is accounted for (as described in Sect. 4).

Finally, annual emissions are disaggregated down to the hourly level using the EDGAR temporal profiles as discussed above for point sources (in *create\_hourly\_emissions\_3D.py*). Note that the temporal integration time of DALES is approximately 2 seconds, so further inter-hour linear interpolation of emission input to smooth the hour-to-hour changes is necessary and applied directly in the model code (see Sect. 4). The final input files are date-specific and cover the complete simulation domain.

Figure 4 demonstrates the application of refinement methods using proxy or activity data for certain emission categories, which are explained further.

#### 5.1 Refinement of area emissions: spatial disaggregation procedure

355

360

365

370

375

380

A spatial disaggregation procedure has been developed to refine  $CO_2$  emissions for relevant categories using several high-detail activity data proxies, where such proxy data are applicable. The importance of the refinement procedure lies in its ability to enhance the accuracy and specificity of emission locations. In the current version of the workflow, proxy data for residential and traffic emission categories are applied. To refine residential emissions from the residential combustion (SNAP 2) category, we employ demographic data from the Central Bureau of Statistics (CBS)  $^1$ . These datasets provide statistical information on a large number of parameters, including demographics, gas/electricity use, housing, energy, etc., for each  $100 \times 100 \text{ m}^2$  square across the Netherlands.

To refine area emissions from the SNAP 2 category, we use information about the average annual consumption of natural gas or total population density if gas usage is unknown. To refine the road transport (SNAP 7) category, we use a road shapefile that contains detailed data on traffic intensity and nitrogen oxides ( $NO_x$ ) emissions at the road level. This shapefile includes attributes such as the length of each road segment, and  $NO_x$  emission intensities from light, medium, and heavy vehicles, respectively. These attributes provide essential information on emission intensity across different road segments. We utilize

 $<sup>^{1}</sup>$ Data with  $100 \times 100 \text{ m}^{2}$  resolution are freely available from the CBS website (https://www.cbs.nl/nl-nl/dossier/nederland-regionaal/geografische-data/kaart-van-100-meter-bij-100-meter-met-statistieken, last access: 27 November 2024)

the combined  $NO_x$  emissions from these three vehicle types to determine the spatial distribution of traffic emission intensities within grids to derive  $CO_2$  emission weights for road segments relative to traffic intensity. Thus, using these weights enables the refinement of  $CO_2$  emissions from a  $1\times1$  km<sup>2</sup> resolution to the target level (100 m). Annual  $NO_x$  emission traffic shape file can be accessed in the Zenodo repository  $^2$ .

The refinement process for both SNAP 2: Residential and commercial and SNAP 7: Traffic is illustrated in Figure 5.

385

390

**Figure 5.** Illustration of the spatial redistribution of annual  $CO_2$  area emissions (kg m<sup>-2</sup> yr<sup>-1</sup>) from a coarse resolution of  $1\times1$  km<sup>2</sup> to a finer resolution of  $100\times100$  m<sup>2</sup> suitable for DALES, made for two SNAP categories: Residential combustion (SNAP 2) and Road transport (SNAP 7). This illustration focuses on the area surrounding the city of Amsterdam. (a) and (d):  $CO_2$  emission fields (kg m<sup>-2</sup> yr<sup>-1</sup>) at coarse resolution ( $1\times1$  km<sup>2</sup>); (b): the gas usage/population density (N m<sup>-2</sup>); (e): Aggregate NO<sub>x</sub> emission data (kg m<sup>-2</sup> yr<sup>-1</sup>) from three vehicle types: small, medium, and heavy; (c) and (f): Resulting refined  $CO_2$  emission fields (kg m<sup>-2</sup> yr<sup>-1</sup>) at fine resolution ( $100\times100$  m<sup>2</sup>).

Figure 5 demonstrates that spatial information gained in the emission disaggregation process substantially improves the representation of emissions at the hectometer resolution required in the DALES numerical experiments. Without refinement, downscaling from 1 km to 100 m resolution would inaccurately retain 1 km shapes of objects, misallocating emissions. Using proxy data such as  $NO_x$  emissions and household statistics further enhances the fidelity of emission downscaling, making estimates more spatially accurate in representing real-world conditions.

<sup>&</sup>lt;sup>2</sup>Annual NO<sub>x</sub> emission traffic shape file (1.0) [Data set]. Zenodo. https://doi.org/10.5281/zenodo.14961517, last access: 6 March 2025

# 6 Experiment design to budget the CO<sub>2</sub> contributions

#### 6.1 Systematic experiments CO<sub>2</sub>

To assess the contributions of different sources to the overall CO<sub>2</sub> concentration based on their origin, we devised a comprehensive model experiment featuring four distinct passive scalar CO<sub>2</sub> tracers with the following setups:

- CO<sub>2</sub>bg: Represents the background concentration derived from CAMS.
- CO<sub>2</sub>bg\_emiss: Combines the background concentration with all anthropogenic emissions.
- CO<sub>2</sub>bg\_emiss\_resp: Combines the background concentration, anthropogenic emissions, and net soil respiration.
- CO<sub>2</sub>sum: Combines all contributions of atmospheric CO<sub>2</sub> included in DALES: CO<sub>2</sub>bg, CO<sub>2</sub>emiss, CO<sub>2</sub>resp, and the net CO<sub>2</sub> assimilation (CO<sub>2</sub>photo).

The  $\mathbf{CO}_2\mathbf{bg}$  tracer uses  $\mathbf{CO}_2$  molar fractions from CAMS, reprojected onto the DALES domain boundaries.  $\mathbf{CO}_2\mathbf{sum}$  in DALES is the final  $\mathbf{CO}_2$  tracer, which can be compared to observations, as it includes all considered components of atmospheric  $\mathbf{CO}_2$  variability. Note that LSM uses the  $\mathbf{CO}_2\mathbf{sum}$  tracer to calculate the ambient  $\mathbf{CO}_2$  mixing ratio.

The impact of photosynthesis can be isolated by subtracting CO<sub>2</sub>bg\_emiss\_resp from CO<sub>2</sub>sum due to the linearity of passive tracer transport in DALES. This experimental setup allows the anthropogenic and biogenic components of CO<sub>2</sub> variability to be derived and evaluated separately. Note that the current implementation does not include a sectoral split; however, this can be easily adjusted to analyze the contributions of specific sources.

As mentioned above, in this experiment DALES is configured with the simulation domain spanning from  $51.5^{\circ}$  to  $52.6^{\circ}$ N and from  $3.75^{\circ}$  to  $6.45^{\circ}$ E, with a horizontal resolution of 100 m (see Sect. 5). The vertical resolution ranges from approximately 25 meters (within the ABL) to a few hundred meters. This is due to the use of a stretched vertical grid with 128 layers, an initial layer thickness of 25 meters (dz<sub>0</sub> = 25), and a stretching factor of 0.017 ( $\alpha$  = 0.017), which causes the layer thickness to increase geometrically with height.

# 6.2 Selected period of simulation

420

We assess the capability of DALES to simulate daytime CO<sub>2</sub> variability for the summer period from 25 June 2018 to 28 June 2018. The selection was made based on the availability of model input data (particularly to nudging large-scale meteorology) and the CO<sub>2</sub> measurements for validation.

The period was characterized by stable summer conditions, with predominantly clear skies and relatively warm temperatures. Winds were light to moderate, with a prevailing northeasterly flow (see Fig. 6), contributing to weak atmospheric mixing during the late evening and early morning hours. These meteorological conditions were ideal for evaluating  $CO_2$  variability, facilitated the detection of both anthropogenic emission and biogenic contributions to the  $CO_2$  mole fractions.

To ensure model stability, several periods affected by the initialization spin-up were disregarded. DALES initialization typically occurs during the first four hours of the simulation, where the fields evolve from small turbulent motions to fully

turbulent conditions, with radiative transfer initialized, as suggested by Savazzi et al. (2024). We also excluded the times corresponding to the initialization of the HARMONIE forecast, which occurs at the start of each simulation day. It is advisable to exclude the first six hours (Fischereit et al., 2024). Furthermore, periods with stable atmospheric boundary layer (SABL) were excluded from the analysis. An accurate representation of the nocturnal SABL in DALES would require an increase in resolution from 100 to <10m (Dai et al., 2021; Umek et al., 2022), which is not feasible given the domain size and setup used in this study. Thus, the period from 23:00 to 06:00 UTC each day that covers all mentioned limitations was excluded from the analysis. This approach ensures that biases related to model initialization and known limitations are significantly mitigated.

# 7 Model evaluation data

425

430

435

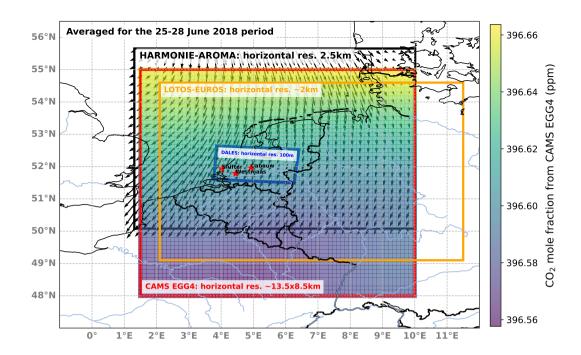

440

445

#### 7.1 In-situ observations

To evaluate and validate the developed modeling framework, we use data from several measurement sites across the Netherlands (see Fig. 6).

We use hourly-averaged in-situ measurements of near-surface atmospheric CO<sub>2</sub> concentrations around the city of Rotterdam are made at two urban background stations, which are part of the Dutch Ruisdael Observatory, located at Westmaas (51.786°N, 4.45°E, Sampling height is 10 m) and Slufter (51.933°N, 3.999°E, Sampling height is 10 m) near the shore of the North Sea (see Fig. 6). Besides, the longest measurement time series is from the Cabauw tower (51.9703°N, 4.9264°E). The Cabauw Atmospheric Observatory measures atmospheric CO<sub>2</sub> concentrations at four distinct elevations: at 27, 67, 127, and 207 m above the ground. These measurements are essential for a comprehensive characterization of local vertical gradients of CO<sub>2</sub> within the lower ABL, enabling detailed investigations into the vertical distribution and temporal variability of GHGs. The hourly-averaged CO<sub>2</sub> mole fraction data from Cabauw (Hazan et al., 2016) are freely available from the ICOS Carbon Portal (https://data.icos-cp.eu/portal/ last access: 27 November, 2024) for both ICOS and non-/pre-ICOS periods (Frumau et al., 2024a, b, c, d). These locations allow us to test and assess the model performance for the different contributions to CO<sub>2</sub>. Slufter is located on the 2e Maasvlakte, close to the shore of the North Sea, while Westmaas resides south of Rotterdam in an agricultural area. The dominant wind direction in the Netherlands is from the South-West, so on many occasions both stations are upwind from the industrial-urban complex of the Rotterdam Rijnmond area. Yet, during the simulated period, the average wind direction was from the North-East (see Fig. 6), when Westmaas is located downwind of Rotterdam. The Cabauw tower is situated in a rural area with a mixed contribution of vegetation (generally grassland) and dispersed anthropogenic emissions, originating either from dispersed local area sources or distant urban areas.

**Figure 6.** A map of the Netherlands with the measurement sites used to assess the simulations of atmospheric CO<sub>2</sub>. The map shows surface CO<sub>2</sub> mole fractions from CAMS, averaged over June 25-28, 2018. Red stars indicate measurement locations, from left to right: Slufter (51.933°N, 3.999°E); Westmaas (51.786°N, 4.45°E); and the Cabauw tower (51.9703°N, 4.9264°E). The blue dashed line represents the borders of the DALES domain. The orange rectangle represents the borders of the LOTOS-EUROS domain. The black rectangle represents the borders of the HARMONIE-AROMA domain. The arrows indicate the wind direction averaged over June 25-28, 2018. The length of the arrows represents the wind speed.

# 7.2 LOTOS-EUROS simulation

455

460

The LOTOS-EUROS chemistry-transport model is used in comparison to DALES to assess the added value of using a high-resolution turbulence resolving model for simulating the observed variability in atmospheric CO<sub>2</sub> in the Randstad area. LOTOS-EUROS is a state-of-the-art regional-scale community model developed jointly by TNO and RIVM (Schaap et al., 2008; Manders et al., 2017), designed to simulate the dispersion and transformation of air pollutants in the atmosphere, including aerosols, ozone, and trace gases. It accounts for anthropogenic and biogenic emissions, using complex chemical and physical processes for detailed forecasts of air quality and trace gas concentrations. The model links emission sources to atmospheric processes and transport, offering a comprehensive view of pollutant behaviour and distribution (for more information about LOTOS-EUROS, visit https://airqualitymodeling.tno.nl/lotos-euros/, last access: 27 November, 2024).

For our study, LOTOS-EUROS was employed to model  $CO_2$  variability with a finer resolution than its standard configuration. Although the standard resolutions of LOTOS-EUROS are approximately 7-25 km<sup>2</sup>, the simulations used in this work were performed at a horizontal resolution of  $\sim$ 2 km. Turbulence is parameterized in LOTOS-EUROS, enabling us to evalu-

ate the benefits of using explicit turbulence in comparison with DALES. While the vertical resolution of LOTOS-EUROS is similar to DALES (~20 m within the ABL), terrain-following vertical layers are used in LOTOS-EUROS, whereas in DALES the surface is assumed to be flat to simplify the turbulence and thus topographical variations are not explicitly accounted for. Yet, for the large part of the Netherlands, the effect of topography is rather small. The CO<sub>2</sub> setup of LOTOS-EUROS uses emissions from the CoCO<sub>2</sub> project (https://coco2-project.eu/, last access: 27 November, 2024) similar to DALES except for the high-resolution emission disaggregation explained earlier in this section. It should be noted that, contrary to DALES, biogenic CO<sub>2</sub> fluxes in LOTOS-EUROS are not simulated internally but are handled instead using external datasets. In the CoCO<sub>2</sub> project setup, biogenic fluxes from the VPRM (Vegetation Photosynthesis and Respiration Model) dataset provided by DLR (Deutsches Zentrum für Luft- und Raumfahrt, the German Aerospace Center) are used as offline input in LOTOS-EUROS (Denier van der Gon et al., 2021).

#### 7.3 Evaluation methods

480

485

To evaluate the model performance against observations, we employed a comprehensive statistical analysis that incorporates multiple performance metrics. We used linear regression and the R<sup>2</sup> coefficient to assess the relationship between modeled and observed CO<sub>2</sub> mole fractions, quantifying the proportion of variance explained by the model. The R<sup>2</sup> was calculated using the Python statistics package *sklearn.metrics*.

Additionally, we utilized the Taylor diagram, which includes metrics such as normanized standard deviation, correlation, and Root Mean Square Difference (RMSD), to evaluate the model's ability to reproduce observed variability. Furthermore, we calculate the Mean Bias Error (MBE) and the Root Mean Square Error (RMSE) to quantify systematic deviations and overall discrepancies, respectively. MBE was computed as the average difference between the modeled and observed values, while RMSE was calculated using *sklearn.metrics*. In addition, a bootstrap analysis of Mean Absolute Error (MAE) was done to assess the significance of the differences between DALES/LOTOS-EUROS and observations in MAE, since the MAE estimate itself has uncertainty. This involves resampling observed and modeled data with replacement multiple times to generate different subsets.

These statistical methods allowed for a comprehensive evaluation of the model performance in replicating observed CO<sub>2</sub> concentrations at various altitudes.

#### 8 Results and validation

#### 8.1 Comparison of simulation results

Figure 7 shows near-surface hourly-averaged CO<sub>2</sub> measured in parts per million (ppm), from DALES (upper panel) and LOTOS-EUROS (lower panel) for different times (6, 10, 16, 22 UTC) on the June 26, 2018. As expected, DALES shows a more detailed representation of CO<sub>2</sub> sources and their transport across the region than LOTOS-EUROS. In the morning hours (6 UTC, Figure 7a), elevated mole fractions are observed along the main roads, caused by increased traffic emissions

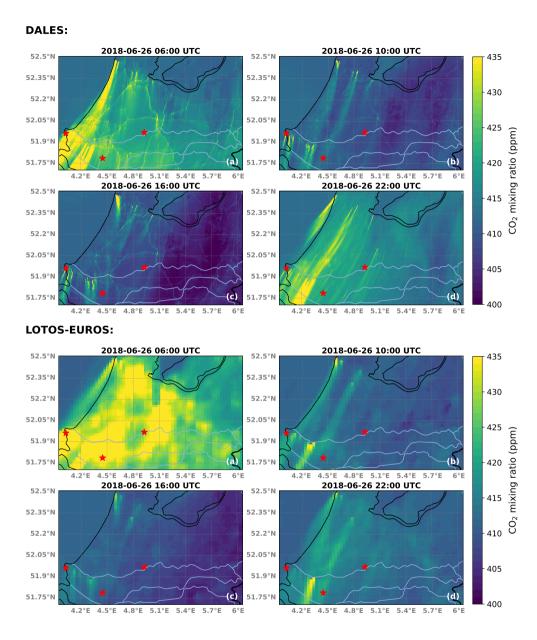

Figure 7. Simulated near-surface (12.5 m height) hourly-averaged  $CO_2$  mole fraction (ppm) for different day times on 26-06-2018 (in UTC for the end of the averaging period). (a) 6 UTC, (b) 10 UTC, (c) 16 UTC; (d) 22 UTC. The domain covers the region from approximately 51.7° to 52.35°N and 4° to 6.0°E. Red stars mark the measurement sites, from left to right: Slufter, Westmaas, and Cabauw tower (see Figure 6). Upper panel: DALES at 100 m horizontal resolution; Lower panel: LOTOS-EUROS at  $\sim$ 2km horizontal resolution.

during the morning rush hours, as well as in urban and industrial areas. The latter show up as bright plumes of elevated CO<sub>2</sub>. This is due to the combination of stable thermodynamic conditions and shallow boundary layers. The southwestern part of the region shows a noticeable intensification of CO<sub>2</sub>, likely due to point source industrial emissions, which dominate over other emission sources. Although LOTOS-EUROS reflects these emissions well, they appear to be more dispersed, with less recognizable differences between source types. Furthermore, LOTOS-EUROS shows slightly higher near-surface CO<sub>2</sub> (up to 10 ppm more) than DALES around urban areas compared to DALES at 6 UTC. This might be explained by less vertical mixing in LOTOS-EUROS than in DALES at this height and the absence of a vertical component of emissions in LOTOS-EUROS.

495

500

505

510

520

525

At local noon (10 UTC, Figure 7b), both models show a reduction in CO<sub>2</sub> mole fraction across urban areas and emission plumes, consistent with enhanced atmospheric mixing as the boundary layer thickness increases. The CO<sub>2</sub> decrease of about 5-10 ppm over land is explained by biogenic CO<sub>2</sub> uptake through photosynthesis. Both models show similar trends in this reduction, though variations in spatial detail remain.

In the late afternoon (16 UTC, Figure 7c), there is greater spatial variability and a more pronounced decrease in background level, which is quite similar in both models ( $\sim$ 15 ppm), although the overall range of CO<sub>2</sub> molar fractions remains similar to earlier in the day. DALES continues to show concentration signals that can more easily be attributed to local emissions, particularly along the transportation routes associated with the peak of traffic in the evening. LOTOS-EUROS captures these patterns but presents them in a more smoothed manner due to its coarser resolution.

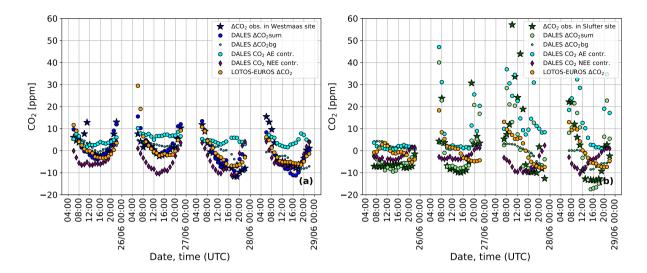

Around local midnight (22 UTC, Figure 7d), the simulated CO<sub>2</sub> mole fraction distribution shows more stable conditions. Reduced atmospheric mixing at night leads to a higher CO<sub>2</sub> mole fraction around urban areas. However, traffic emissions are much decreased at this time, as expected. Both models reflect this nocturnal pattern, though LOTOS-EUROS continues to show higher near-surface concentrations during night, although less pronounced than seen for the morning hours.

Thus, diurnal variations in atmospheric CO<sub>2</sub> near the ground are generally well represented in both models, reflecting changes in background, anthropogenic emissions, and biogenic activity under varying atmospheric conditions. DALES provides a more detailed representation of individual emission sources and spatial variability, while LOTOS-EUROS, due to its coarser resolution, resolves the different source types less well. However, before it can be concluded that DALES provides a more accurate representation of CO<sub>2</sub>, both models need to be compared against actual measurements, which we will turn to next.

# 8.2 The modelled CO<sub>2</sub> against ground-based urban measurements in Westmaas and Slufter

The evaluation of modeled CO<sub>2</sub> has been conducted using ground-based urban measurements at the Westmaas and Slufter sites during the daytime hours from June 25 to 28, 2018. Here, for these time series, we show the deviation from the mean, after subtracting the CO<sub>2</sub> mean level over the considered period. This approach highlights the CO<sub>2</sub> variability relative to a baseline, emphasizing deviations from average conditions. In addition, the time series of all anthropogenic emissions (AE) and the net ecosystem exchange (NEE) influence on CO<sub>2</sub> calculated from DALES has been added to show separately the local anthropogenic and biogenic contributions to CO<sub>2</sub> overall variability. Since the measurements at Westmaas and Slufter were performed at one height (10 m), model data are interpolated horizontally to the exact latitude and longitude of the

measurements, but vertically the model data had to be extrapolated using the first two model layers, since the lowest model layer is slightly above 10 m. The time series of  $CO_2$  mole fractions for the Westmaas and Slufter sites are presented in Figure 8.

**Figure 8.** Time series of the observed and modeled near-surface atmospheric CO<sub>2</sub> mole fraction as deviation from the mean from Westmaas and Slufter at 10 m height for the period of June 25-28, 2018. (a) from Westmaas: observations (dark blue stars) and model predictions (DALES CO<sub>2bg</sub> in light blue dots, CO<sub>2sum</sub> in blue circles, AE contribution to the CO<sub>2</sub> mole fraction from DALES in light blue circles, the modeled NEE contribution to CO<sub>2</sub> mole fractions from DALES in purple diamonds, and LOTOS-EUROS CO<sub>2</sub> in orange). (b) from Slufter: observations (dark green stars) and model predictions (DALES CO<sub>2bg</sub> in light green dots, CO<sub>2sum</sub> in light green circles, AE contribution to the CO<sub>2</sub> mole fraction from DALES in light blue circles, the modeled NEE contribution to CO<sub>2</sub> mole fractions from DALES in purple diamonds, and LOTOS-EUROS CO<sub>2</sub> in orange). All presented values are calculated by subtracting the CO<sub>2</sub> mean value (the average CO<sub>2</sub> mole fraction over selected times (7-22 UTC) during the 25-28 of June 2018 period). The values are hourly-averaged, with time corresponding to the end of the averaging period.

At Westmaas (Figure 8a), the observed near-surface  $CO_2$  (dark blue stars) exhibits diurnal variability, with lower concentrations during the daytime due to vegetation uptake (reaching values below -10 ppm) and enhanced vertical mixing, and higher concentrations in the early morning/late evening (10 to 15 ppm above the mean) due to stabilization of ABL and soil respiration (NEE enhancement up to +5 ppm). DALES  $CO_{2sum}$  simulation (blue line) effectively captures the observed daytime declines, with a small (<2 ppm) discrepancy from the measurements. The local AE contribution (light blue line in Figure 8a) shows moderate variability throughout the period, fluctuating between 5 and 10 ppm. This is generally balanced by  $CO_2$  NEE, leading  $CO_{2sum}$  to a good agreement with observations for most of the period (see purple line). However, deviations of approximately  $\pm 5$  ppm persist in the early morning/late evening, which may result from overestimations in vertical mixing or offsets in background concentrations, which can be up to 2.5% ( $\sim$ 1% on average) in recent years, as noted in Bennouna et al. (2024). In contrast, LOTOS-EUROS (orange line) tends to show larger deviations from the observations during these periods (by 3–5 ppm on average), although its general pattern follows the observations.

530

535

In contrast, at the Slufter site (Figure 8b), both models exhibit greater disagreement with the observations (dark green stars). However, DALES results indicate that the large observed variability is primarily due to local AE contribution, which dominates CO<sub>2</sub> variability at this location during 26–28 June as seen by large CO<sub>2</sub> spikes (up to +60 ppm) (see Figure 12b). This allows DALES CO<sub>2sum</sub> to better capture the daytime variability. The contribution of NEE also plays a role (up to -10 ppm), but its influence on CO<sub>2</sub> variability is largely overshadowed by AE. The LOTOS-EUROS model (orange line) captures some of the observed variability, such as the late evening fluctuations on 25 and 27 June, but fails to reproduce the finer-scale daytime spikes visible in the observations (see Figure 12).

545

550

555

Note that the Slufter site presents additional challenges to the models due to its coastal location, where the interaction between land, sea, and atmospheric dynamics introduces complex and unique  $CO_2$  variability. These interactions, possibly involving sea breeze effects of temperature inversions, introduce fine-scale changes in  $CO_2$  levels that might be difficult to reproduce even with the current 100 m resolution DALES setup. DALES does show a better daytime  $CO_2$  variability than LOTOS-EUROS, pointing to the importance of local processes.

To further evaluate the simulation results, we performed a comprehensive statistical analysis, using methods described in Sect. 7.3. The results of the statistical analysis are presented in Figure 9 and Table A2. The results of the MAE bootstrap analysis are presented in Figure B1 in the appendix.

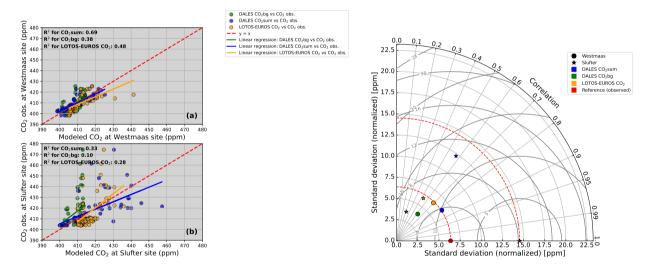

Figure 9. Left panel: Density plot comparing model predictions (DALES  $CO_{2sum}$ ,  $CO_{2bg}$ , and LOTOS-EUROS  $CO_2$ ) to observed  $CO_2$  concentrations for the daytime (7-22 UTC) during the 25-28 of June 2018 period at Westmaas (a) and at Slufter (b). The red dashed line represents the ideal relationship (y = x line). Linear regression lines are shown for  $CO_{2bg}$  (green),  $CO_{2sum}$  (blue) and LOTOS-EUROS  $CO_2$  (orange), along with the corresponding regression equations and  $R^2$  values. Right panel: Taylor diagram quantifying the model performance against observations. Circle: Westmaas, Star: Slufter. Blue: DALES  $CO_{2sum}$ , Green: DALES  $CO_{2bg}$ , Orange: LOTOS-EUROS  $CO_2$ , Red: reference (observed  $CO_2$ ). Grey circle lines are contours of equal RMSD.

In the urban background location of Westmaas (Figure 9a), the regression analysis indicates a significant improvement in daytime  $CO_2$  variability prediction using DALES  $CO_{2sum}$  compared to LOTOS-EUROS ( $R^2$ : 0.69 vs 0.48) for this location. This indicates that DALES  $CO_{2sum}$  provides a more accurate representation of  $CO_2$  variability, particularly in capturing local-scale influences than LOTOS-EUROS.

Furthermore, statistical metrics derived from the Taylor diagram also show an improvement in model predictions with DALES CO<sub>2sum</sub> compared to LOTOS-EUROS. This analysis shows a higher correlation (corr: 0.83 vs 0.69), a closer normalized standard deviation to the observed value (std: 6.46 vs 6.25; observed std: 6.38), and lower error metrics, such as RMSD (RMSD: 3.76 vs 4.93). Both MBE and RMSE are also lower for CO<sub>2sum</sub> than for LOTOS-EUROS (MBE: -0.19 vs 1.97 and RMSE: 3.77 vs 5.31), indicating lower overall errors and the highest accuracy of both variability and mean-level predictions in DALES at this location.

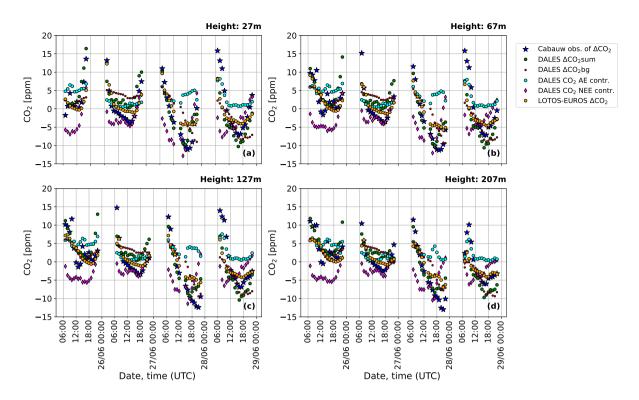

At the Slufter site (Figure 9b), both models exhibit low R<sup>2</sup> values (<0.5), indicating limited ability to explain observed variability. DALES CO<sub>2sum</sub> shows slightly better agreement with observations than LOTOS-EUROS, with a higher R<sup>2</sup> (0.33 vs. 0.28) and correlation coefficient (0.57 vs 0.53). The high RMSD values for both models further indicate substantial deviations from observed concentrations, with LOTOS-EUROS showing a slightly lower RMSD (12.52 vs. 12.43). Similarly, RMSE suggests a marginally lower total error in LOTOS-EUROS, while DALES provides a better estimate of the mean CO<sub>2</sub> level (MBE: 0.15 vs. 0.39; RMSE: 12.52 vs. 12.44). Importantly, DALES better captures the observed variability, with a normalized standard deviation (12.23) much closer to the observed value (14.52) compared to LOTOS-EUROS (5.93), which means DALES retains 85% of observed variability, while LOTOS-EUROS captures only 40%.

Overall, the results highlight the strengths and limitations of both models across different environments. At the urban background site of Westmaas, the representation of local-scale CO<sub>2</sub> variability and mean-level accuracy are significantly improved in DALES, in particular due to the integration of highly resolved AE and NEE. However, despite some improvements in DALES, even with high resolution LES and detailed local sources, both models face comparable challenges in reproducing CO<sub>2</sub> variability in the complex and dynamic coastal environment of Slufter.

# 8.3 The modelled CO<sub>2</sub> against rural Cabauw tower observations

570

Similar analysis has been performed for the Cabauw tower location. The time series of the atmospheric CO<sub>2</sub> mole fraction computed with DALES for the CO<sub>2bg</sub> and CO<sub>2sum</sub> tracers are compared to LOTOS-EUROS, as well as the CO<sub>2</sub> measurements of the Cabauw tower presented in Figure 10. To assess the capability of DALES to reproduce observed variability at various heights, modeling data was sampled at the Cabauw tower that were interpolated horizontally and vertically (using air density) to match the Cabauw measured CO<sub>2</sub> profile.

**Figure 10.** Time series of observed and modeled  $CO_2$  mole fraction anomalies (ppm) at different levels of the Cabauw tower: (a) at 27 m; (b) at 67m; (c) at 127m; (d) at 207m. Blue stars: the anomalies of observed  $CO_2$ ; green circles: the modeled  $CO_2$  anomalies from DALES  $CO_{2\text{sum}}$ ; red circles: the modeled  $CO_2$  anomalies from DALES  $CO_{2\text{bg}}$ ; light blue: contribution of all anthropogenic emissions (AE) to the  $CO_2$  mole fraction from DALES; purple diamonds: the modeled NEE contribution to  $CO_2$  mole fractions from DALES; orange circles: the modeled  $CO_2$  anomalies from LOTOS-EUROS. All presented values are calculated by subtracting the  $CO_2$  mean value (the average  $CO_2$  mole fraction over selected times (7-22 UTC) during the 25-28 of June 2018 period). The values are hourly-averaged, with time corresponding to the end of the averaging period.

During this period, the AE contribution to CO2 mole fractions was generally low, with a mean of  $\sim$ 2 ppm. Higher values of 5-7 ppm were observed during the early morning hours due to nighttime near-surface accumulation effects. A reduced anthropogenic contribution is expected due to rural location and wind direction, allowing for a comparison of biogenic and background variability in the models and observations for most of the selected period. A strong contribution from NEE in DALES  $CO_{2sum}$  was observed, reaching values below -10 ppm.

585

590

595

DALES CO<sub>2sum</sub> tends to follow daytime variations more closely than LOTOS-EUROS on June 25th, 27th and 28th, at lower levels (Figure 10 (a,b)), although showing comparable values during June 26, where the contribution from NEE is the lowest than during other days (>-5 ppm). The NEE contribution explains some of the daytime CO<sub>2</sub> declines due to photosynthesis, which is captured better in DALES than LOTOS-EUROS. However, an underestimation of this decline remains, with observed CO<sub>2</sub> values around 5 ppm lower than in DALES and 10 ppm in LOTOS-EUROS. This underestimation could be explained in part by an offset in the background level, especially at times when the local CO<sub>2</sub> loss due to photosynthesis is lower, such as

in the late evening (see red dots in Figure 10). Errors in background concentration could result from the coarse resolution of the original CAMS dataset, its 6-hour update frequency, which may not capture finer temporal variations, and also from the lack of CO<sub>2</sub> uptake by vegetation that could cause the overestimated background (Bennouna et al., 2024). The offset in vertical mixing may also contribute, especially in early morning/late evening hours.

600

610

At higher tower levels (Figure 10 (c,d)), the variability diminishes, which is consistent with the trapping of  $CO_2$  in a shallow surface layer during the early morning, although the biases relative to observations persist. The AE contribution remains small, whereas the loss through  $CO_2$  uptake over the day persists strongly, but with slightly lower values than at heights closer to the ground (by -2 ppm). The overestimation of  $CO_2$  molar fraction during daytime, particularly in the late evening when the local contributions of NEE and AE are small, could be partially explained by the poorly resolved background and its deviation from observations (Bennouna et al., 2024). Furthermore, biases in the modeled wind speed and direction compared to observations could also contribute to discrepancies in  $CO_2$  variability (Zheng et al., 2019).

To further evaluate the accuracy of the simulations and quantify the degree of correspondence to measurements at the Cabauw tower, we performed the statistical regression analysis as for Westmaas and Slufter. The results of this analysis are shown in Figure 11.

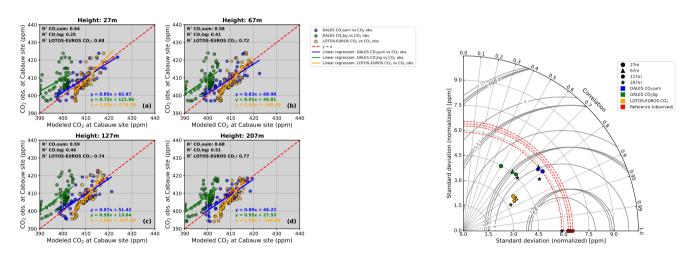

Figure 11. Left panel: Density plot comparing model predictions (DALES  $CO_{2sum}$ ,  $CO_{2bg}$ , and LOTOS-EUROS  $CO_2$ ) to observed  $CO_2$  mole fractions (ppm) at the Cabauw tower for the daytime (7-22 UTC) during the 25-28 of June 2018 at different heights: 27m (a), 67m (b), 127m (c), and 207m (d). The red dashed line represents the ideal relationship (y = x line). Linear regression lines are shown for  $CO_{2bg}$  (green),  $CO_{2sum}$  (blue), and LOTOS-EUROS  $CO_2$  (orange), along with the corresponding regression equations and  $R^2$  values. Right panel: Taylor diagram quantifying the model performance against observations. Circle: 27m, Triangle: 67m, Pentagon: 127m, Star: 207m. Blue: DALES  $CO_{2sum}$ , Green: DALES  $CO_{2bg}$ , Orange: LOTOS-EUROS  $CO_2$ , Red: reference (observed  $CO_2$ ). Grey circle lines represent values of RMSD.

The predictions of DALES and LOTOS-EUROS show moderate performance ( $R^2$  values higher than 0.5) in capturing the  $CO_2$  variability in the measurements during day hours, with  $R^2$  values slightly higher for LOTOS-EUROS compared to DALES

 $CO_{2sum}$  at 27 m ( $R^2$ :  $\sim$ 0.64 versus  $\sim$ 0.68). However, at mid-level heights, this difference increases, with DALES showing a greater offset ( $R^2$ : 0.58 vs. 0.72 at 67 m and 0.59 vs. 0.74 at 127 m). This may be in part due to background limitations, particularly on June 26 and 28, when the contributions of AE and NEE to  $CO_2$  mole fractions are minimal at the end of the day (see Figure 10). At 207 m height, the performance of both DALES  $CO_{2sum}$  and LOTOS-EUROS slightly increases, exhibiting lower biases against the observations, with  $R^2$  values of 0.68 and 0.77, respectively.

The statistical metrics presented in the Taylor diagram (right panel of Figure 11) illustrate the performance of different  $CO_2$  simulations (DALES  $CO_{2sum}$ , DALES  $CO_{2bg}$  and LOTOS-EUROS) compared to observations at various altitudes. The diagram shows that LOTOS-EUROS better captures the observed variability in terms of correlation coefficients (which are closely related to  $R^2$ ), exceeding those of DALES  $CO_{2sum}$  by approximately 5%-10%. However, some other metrics favor DALES  $CO_{2sum}$ . Specifically, its normalized standard deviation closely matches observations at all heights, reproducing 85%-90% of the observed variability on average, whereas LOTOS-EUROS shows weaker agreement, capturing only about 50% on average (see Figure 10).

In terms of MBE, DALES CO<sub>2sum</sub> exhibits lower errors compared to LOTOS-EUROS at all heights (MBE: 27 m: -0.65 vs 1.51; 67 m: 0.18 vs 1.93; 127 m: 0.32 vs 2.14; 207 m: 0.56 vs 2.56). This indicates a slightly higher performance of DALES CO<sub>2sum</sub> in predicting mean CO<sub>2</sub> levels for all heights during the day hours. Similarly, RMSE values are generally lower or comparable for DALES CO<sub>2sum</sub> than LOTOS-EUROS at all altitudes (RMSE: 27 m: 3.93 vs 4.16; 67 m: 4.25 vs 4.25; 127 m: 4.24 vs 4.47; 207 m: 3.42 vs 4.28), indicating a better general agreement with observed CO<sub>2</sub> concentrations and a reduced tendency for large deviations.

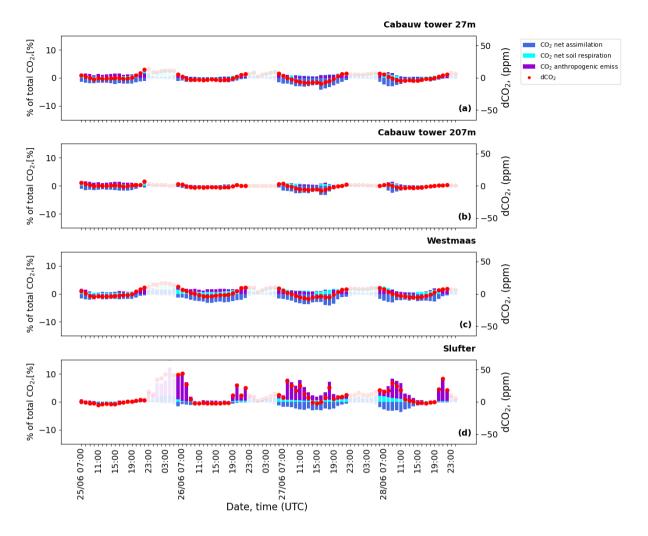

Despite this, the RMSD values for DALES CO<sub>2sum</sub> are higher than those for LOTOS-EUROS at 67 m and 127 m, whereas at 27 m and 207 m, DALES CO<sub>2sum</sub> shows comparable or slightly better agreement (RMSD: 27 m: 3.87 vs 3.87; 67 m: 4.25 vs 3.78; 127 m: 4.23 vs 3.92; 207 m: 3.37 vs 3.43). This suggests that DALES CO<sub>2sum</sub> captures the observed variability slightly less accurately at mid-level heights, while at the lowest and highest measurement levels, it performs similarly or marginally better than LOTOS-EUROS.

Nevertheless, while there are subtle differences between the two models, statistical metrics indicate that DALES CO<sub>2sum</sub> and LOTOS-EUROS exhibit a good performance at the rural Cabauw site. During the considered period, both the local anthropogenic signal and the spatial variations in CO<sub>2</sub> molar fractions remain relatively weak, and the precision of the simulations is largely determined by the background concentrations and the representation of local biospheric contributions.

#### 8.4 Contribution of modeled local CO<sub>2</sub> components to regional CO<sub>2</sub> enhancement

620

One of the objectives of this study is to examine the individual contributions of simulating individual flux components of atmospheric CO<sub>2</sub> to the total CO<sub>2</sub> that is observed at the measurement sites used in our study. To do this, we use the scalar CO<sub>2</sub> tracers in DALES from which the components of atmospheric CO<sub>2</sub> can be easily determined (see Sect. 6.1). Figure 12 presents all these components for each measurement site separately.

**Figure 12.** The hourly-averaged percentage contribution of various modeled local CO<sub>2</sub> components to the overall atmospheric CO<sub>2</sub> mole fraction [% of full CO<sub>2</sub> mole fraction] at three different measurement locations over the period from June 25 to June 28, 2018. Cabauw tower at two heights: (a) 27m and (b) 207m, and near-surface (10 m) at (c) Westmaas and (b) Slufter. The colored bars represent the contributions from three components of atmospheric CO<sub>2</sub>: anthropogenic emissions (violet), CO<sub>2</sub> soil respiration (cyan), as well as CO<sub>2</sub> net assimilation (blue). The red dots represent dCO<sub>2</sub>, which is the deviation of total CO<sub>2</sub> from the background [in ppm]. Each bar in the plots starts from 0, and to avoid overlap, the position of positive bars is adjusted such that bars with lower values are displayed in front. The values are hourly-averaged, with time corresponding to the end of the averaging period.

At the Cabauw tower location, a clear diurnal pattern in atmospheric  $CO_2$  is observed at 27 m height (Figure 12a) and diminished at 207 m (Figure 12b) height. Here,  $CO_2$  net assimilation has the largest contribution during daytime and soil respiration during early morning/late evening ( $\sim$ 5% in total), reflecting the contribution of biogenic activity. At a higher altitude of 207 m, the diurnal pattern in both  $CO_2$  biogenic components become smoother ( $\sim$ 2%), due to the increased distance from the surface. The contribution from anthropogenic emissions is visible but in general remains tiny, especially at higher altitude

(within 5 ppm). As discussed above, the absence of large urban areas nearby and the north-west wind direction during this period (see Figure 6) explain the low contribution of anthropogenic emissions to the  $CO_2$  variability during this period. Thus, in this area the contribution of local agricultural emissions prevails, especially at the lowest tower level (see Figure 4).

At the Westmaas site (Figure 12c), we anticipated a higher local  $CO_2$  signal from anthropogenic emissions due to nearby urban areas. However,  $CO_2$  levels are only slightly above those measured at the lowest height at Cabauw (by 1-2%). This smaller difference may be due to the lower elevation at Westmaas (10 m vs. 27 m at Cabauw), combined with plume dilution and vertical mixing, which could significantly reduce the anthropogenic  $CO_2$  reaching Westmaas during this period. The predicted variability in soil respiration contributes significantly to total  $CO_2$  concentrations, particularly at early morning/late evening (up to  $\sim$ 5%). Besides, as indicated in the  $CO_2$  NEE time series in Figure 8, the negative contribution from the daytime photosynthesis  $CO_2$  sink offsets the positive contributions from both anthropogenic and soil respiration emissions, resulting in a net negative local contribution to the  $CO_2$  concentration at day time throughout the studied period (by - 3%).

The Slufter site (Figure 12d) displays a distinct pattern in which anthropogenic emissions play a dominant role in the local  $CO_2$  variability. When plumes from nearby facilities reach the measurement site, the anthropogenic contribution exceeds 10% of the total  $CO_2$  mole fraction. The influence of net  $CO_2$  assimilation is also pronounced, though it is lower compared to the Westmaas site. The  $CO_2$  sink at Slufter is considerably weaker than at Westmaas, and it is insufficient to counterbalance the strong positive contributions of local anthropogenic activity, resulting in a strongly positive overall local contribution to the  $CO_2$  variability at this location throughout the simulation period.

These results demonstrate the ability of the new DALES framework to support the evaluation of local CO<sub>2</sub> sources and their contributions to atmospheric CO<sub>2</sub> concentrations. The weak signal of anthropogenic emissions at the Cabauw tower, particularly at higher tower levels, contrasts sharply with the more urban or industrially influenced sites such as Slufter, where anthropogenic sources dominate. Besides, we show that biogenic CO<sub>2</sub> fluxes contribute significantly to diurnal variability. Even in Westmaas, a short distance from the port and center of Rotterdam, the biogenic component contributes significantly to the simulated diurnal CO<sub>2</sub> variability (see also Figure 8). This highlights the importance of an accurate representation of biogenic sources in the high-resolution modeling of urban CO<sub>2</sub> variability.

# 9 Perspectives of LES development towards the simulation of CO<sub>2</sub> emissions

650

655

660

665

670

675

680

Despite significant progress in integrating CO<sub>2</sub> emissions into the LES model presented in this study, it is essential to address existing limitations and challenges to enable further improvements and more accurate future implementations.

In our work, we mentioned the limitations in LES in reproducing the observed variability, particularly under stable boundary layer conditions as well as in the coastal environment, as revealed in observations at Slufter. Although LES models still face challenges in accurately simulating nocturnal stable ABL conditions, proposed solutions have been developed to better resolve turbulence in stable boundary layers at coarser horizontal resolutions (>10 m) (de Roode et al., 2017; Dai et al., 2021). However, the verification of these methods is still ongoing and the corresponding routines have yet to be implemented in the community version of DALES. The coastal environment is also an area for further improvement in LES,

especially the integration of a more accurate marine atmosphere in high-resolution models, which is planned to be done in the next few years within Ruisdael observatory. Achieving this will require an even finer spatial resolution to resolve the complex processes in the coastal environment. Yet, while DALES has the potential to operate at horizontal resolutions as fine as 1 m, the current 100 m resolution used in our setup is a compromise, balancing computational feasibility and domain size. These constraints are partly introduced by the meteorological data resolution from the HARMONIE-AROME model, which currently operates at ~2.5 km resolution (N25 grid). However, from 2024 on, HARMONIE-AROME switches to the N20 grid, featuring a finer horizontal resolution ( $\sim$ 1.3 km), which could enhance LES accuracy, particularly in regions with strong local CO<sub>2</sub> sources. The 6-hour temporal resolution of the  $0.125^{\circ} \times 0.125^{\circ}$  CAMS EGG4 reanalysis data used in our study limits its ability to reproduce observed diurnal CO2 variability. However, recent CAMS data sets, offering 3-hour data and higher horizontal resolution  $(0.1^{\circ} \times 0.1^{\circ})$ , may improve CO<sub>2</sub> background representation in future simulations (https://ads.atmosphere.copernicus.eu/datasets/cams-global-greenhouse-gas-forecasts?tab=overview, last access: 27 November 2024). Despite bias correction applied in CAMS EGG4 (Bennouna et al., 2024), it does not employ flux inversion techniques to optimize CO<sub>2</sub> surface fluxes, unlike optimized CAMS products with lower spatiotemporal resolution (e.g. https://ads.atmosphere.copernicus.eu/datasets/cams-global-greenhouse-gas-inversion?tab=overview, last access: 11 March 2025). However, the spaciotemporal resolution of optimized CAMS is still a limitation. An alternative approach is to use, for example, the LOTOS-EUROS output, with its finer horizontal and temporal resolution (up to 1 km and hourly output), coupled with DALES, which could enhance the representation of background variability of chemical compounds. To increase the accuracy of LES simulated CO<sub>2</sub> variability, it is planned to switch from nudged to open boundary conditions. This has been shown to enhance the accuracy and applicability of the LES framework across diverse atmospheric conditions (Liqui Lung et al., 2024).

685

690

695

700

710

715

Besides, attention should be paid to the further improvement of anthropogenic emissions input. The national emission inventory for the Netherlands is constantly updated and data are expected to be more accurate in the future (Van der Net et al., 2024). In the meantime, ensemble experiments incorporating perturbations in anthropogenic emissions will be performed to address this uncertainty in the modeling. The need for high-resolution activity and proxy data to advance the downscaling workflow and improve the emission input preparation for LES is also an important area for further work. Additional refinement could be achieved through the use of high-resolution monitoring data, such as ship traffic and waterway data, as well as detailed agricultural land use information across the Netherlands (van der Woude et al. (2023), https://www.clo.nl/en/indicators/en006111-land-use-in-the-netherlands-2015, last access: 27 November 2024).

Moreover, the vertical allocation of emissions and plume rise are important to be further improved. In the setup used in this study (with 100 m horizontal resolution), plume rise is a subgrid process; therefore, using a parameterization is an appropriate approach. An alternative to the approach adopted here could be to address plume rise in LES by prescribing a heat source in the potential temperature equation at the location of the chimney top. This method enables LES to compute the heating tendency, which in turn modifies the vertical velocity through its effect on buoyancy. A key challenge is to accurately estimate the heat production at the stack, which represents the energy added by the emission of heated air per unit time. This would also help represent the interaction of the emission plume with the ambient meteorological conditions. Note that this works if the model

grid is very fine (<50m), and that if the plume is narrow compared to the grid. Furthermore, our plume rise algorithm does not yet consider the influence of the emitting plume on local meteorology, such as thermal and radiative effects on atmospheric stability (Lohmann and Feichter, 2005).

In DALES the vertical profiles are not source-specific, but rather a simplified even distribution of the emissions between the calculated bottom and top of the plume for SNAP categories, which include vertical component. As pointed out by Brunner et al. (2019), there are benefits of applying accurate category-specific emission initial vertical distribution.

In addition, LES can optimize emissions for specific SNAP categories by integrating top-down atmospheric observations with bottom-up inventories. This approach refines the spatial and temporal distribution of emissions, providing a high-resolution benchmark for validating and adjusting reported estimates. However, the use of LES in atmospheric transport inversions poses several challenges. This includes the limited spatial and temporal extent of LES domains that restricts inversion to local or short-term events. This requires careful nesting within larger-scale models to capture background conditions accurately (see, e.g., Barlow et al. (2011); Lauvaux et al. (2016)). Besides, high computational costs also constrain the ensemble size and averaging periods required for robust inversions. Although analytical inversions may be feasible for a limited number of tracers or emission parameters, the high dimensionality and inherent nonlinear dynamics of LES simulations generally require ensemble-based methods (e.g., Brunner et al. (2019)). Despite these challenges, LES-based inversions offer a valuable framework for process-level understanding and can serve as a benchmark for evaluating bottom-up inventories under well-constrained conditions.

As this study shows, the results are sensitive to the representation of biogenic CO<sub>2</sub> fluxes, even at short distances from urban centers. Hence, future efforts should also improve the representation of these fluxes at the resolution of the model, moving beyond our highly simplified split between grasslands and forests. In the case of intensive agriculture in the Netherlands, this is complicated by a significant role of management. The measurement from the Loobos observation station made within Ruisdael Observatory can be helpful in this context, as this station is in the forested area at distance from important anthropogenic emissions, but with a region of intensive agriculture to the west. Thus, validating the biogenic fluxes from LES at the Loobos location would be beneficial. In addition, the incorporation of forested land may be upgraded to consider the vertical height of the forest, which also influences the simulated atmospheric dynamics. It may require a large upgrade of the model code, including the possible implementation of flexibility of trees representation if the model resolution changes. However, even much less sophisticated solutions could bring about important improvements. The same holds for the representation of urban landscapes. Currently, three-dimensional city maps for The Netherlands are under construction at TU Delft (https://3d.bk. tudelft.nl/projects/, last access: 27 November 2024).

# 10 Conclusions

725

730

735

745

We present a new atmospheric modeling platform for simulating the spatiotemporal CO<sub>2</sub> concentration at the hectometer resolution. The main novelty is to calculate the turbulent mixing and transport of CO<sub>2</sub> in the Dutch environment explicitly by

means of the Dutch atmospheric LES. In this work, we present and discuss a workflow for downscaling the km-scale national emission inventory, consisting of point and area diffuse sources, into 100 m scale DALES input.

We extended DALES with methodology to account for the vertical distribution of emissions from elevated point sources, including the modeling of plume rise. This is done using an online algorithm that considers the interaction between the plume properties and ambient atmospheric conditions. To represent biogenic CO<sub>2</sub> fluxes from respiration and photosynthesis, DALES has been extended with a simplified land surface model that differentiates between grasslands and forests. The performance of DALES has been evaluated using the LOTOS-EUROS model and the available in-situ observations for daytime (7-22 UTC) during a four-day test period in June 2018. A rigorous statistical analysis quantifies the benefits of the high-resolution modeling approach, particularly near urban and industrial areas. This is evident in the standard deviations, which are closer to the observed values across all measurement sites and generally lower RMSD. For instance, DALES CO<sub>2sum</sub> in Slufter has a std of 15.27 ppm, closely matching the observed std of 12.23 ppm, compared to 5.93 ppm in LOTOS-EUROS. A similar trend is observed at the Cabauw tower, where DALES explains more than 85% of the variability in terms of standard deviation at all heights, compared to less than 50% in LOTOS-EUROS. Additionally, DALES CO<sub>2sum</sub> in Westmaas shows better performance with R<sup>2</sup> and correlation values of 0.69 and 0.83, respectively, along with a lower RMSD of 3.76 ppm, compared to the LOTOS-EUROS values of 0.48, 0.69, and 4.93 ppm, respectively (see Table A2 for more details). Besides, we identified limitations in the current framework, such as larger deviations from observations at the Cabauw rural location and challenges in simulating coastal environments, which will require further improvement in future developments.

A multi-tracer approach is used to keep track of the contribution of anthropogenic and biogenic fluxes to the simulated  $CO_2$  concentrations. This analysis enhanced our understanding of the relative importance of their contributions in explaining the  $CO_2$  variability in the measurements that have been used. The significant variations in  $CO_2$  concentration observed in Slufter on the Maasvlakte at the Western tip of the Rotterdam harbor are largely explained by anthropogenic activity (up to 10% of total  $CO_2$  for the period considered). The importance of ecosystem fluxes of  $CO_2$  has been demonstrated, even in close proximity to urban and industrial  $CO_2$  emissions. These fluxes contribute largely to the  $CO_2$  concentration variability during daytime when they may even cancel out local anthropogenic concentration enhancements (as seen in Cabauw and Westmaas, where the daytime contribution of local  $CO_2$  is negative, reaching -3%), emphasizing the importance of an accurate representation of biogenic processes in modelling of urban  $CO_2$ .

The DALES framework has significant potential to advance atmospheric CO<sub>2</sub> concentration modeling and support the independent evaluation of national emission inventories at the urban scale. This framework is expected to facilitate the quantification of local emission hotspots in combination with inversion techniques, while also reinforcing air quality monitoring efforts. Furthermore, by delivering detailed information on subgrid processes, such as turbulence, boundary layer dynamics, and localized emission dispersion, DALES can enhance parameterizations in larger-scale models through nesting, contributing to more accurate regional climate predictions (Sun, 2016). Ultimately, these advances will support more informed decision-making (e.g., by using LES output to refine long-term forecasts with mesoscale models, incorporating AI) and the formulation of effective policies aimed at mitigating climate change and its associated impacts, both in the Netherlands and beyond.

Code and data availability. The emission inventory used in this study were obtained from the Emission Registration (ER) portal, processed by the National Institute of Public Health and the Environment (RIVM) and are accessible at https://data.emissieregistratie.nl/export, last access: 27 November 2024. The Dutch Atmospheric Large-Eddy Simulation (DALES) 4.4 with emission module, developed in this study, is an open-source code available under the GNU GPL version 3. This specific version of the DALES model is available in the Zenodo repository (Karagodin-Doyennel , 2024a). HARMONIE-AROMA model data on a rectilinear grid, specifically the "Winds of the North Sea in 2050" (WINS50) dataset covering the Netherlands with a 1-hour temporal resolution, are available at https://dataplatform.knmi.nl/dataset/wins50-wfp-nl-ts-singlepoint-3, last access: 27 November 2024. CAMS (Copernicus Atmosphere Monitoring Service) data can be freely accessed at https://ads.atmosphere.copernicus.eu/, last access: 27 November 2024. The complete "offline" emission downscaling workflow program, developed and utilized in this study, is open-source and freely accessible code available at Karagodin-Doyennel (2024b). The CBS Vierkant  $100 \times 100$  m and ESRI Shapefile datasets, which were used within the downacaling procedure, are available on the CBS website: https://www.cbs.nl/nl-nl/dossier/nederland-regionaal/geografische-data/kaart-van-100-meter-bij-100-meter-met-statistieken, last access: 27 November 2024. The annual  $NO_x$  emission traffic shape file can be accessed in the Zenodo repository: (Karagodin-Doyennel, 2025). Data from the Cabauw measurement site, used for validation, are accessible via the ICOS Carbon Portal: https://data.icos-cp.eu/portal/, last access: 27 November 2024.

# Appendix A

**Table A1.** Parameters of the A- $g_{\rm s}$  model used in DALES

Symbol	Parameter	Value (grassland)	Value (forest)
$Q_{10,\mathrm{gm}}$	Temperature response coefficient to calculate gm [-]	2.0	2.0
$Q_{10,\mathrm{amax}}$	Temperature response coefficient to calculate Ammax [-]	2.0	2.0
$Q_{10,\cos 2}$	Temperature response coefficient to calculate the ${\rm CO}_2$	1.5	1.5
	compensation concentration [-]		
$T_{1,\mathrm{gm}}$	Low reference temperature to calculate gm [K]	278	278
$T_{2,\mathrm{gm}}$	High reference temperature to calculate gm [K]	301	305
$T_{1,\mathrm{Ammax}}$	Low reference temperature to calculate Ammax [K]	286	281
$T_{2,\mathrm{Ammax}}$	High reference temperature to calculate Ammax [K]	311	311
$g_{min}$	Cuticular (minimum) conductance to water vapor $[m s^{-1}]$	2.5e-4	2.5e-4
$a_d$	Regression coefficient to calculate Cfrac [kPa <sup>-1</sup> ]	0.07	0.07
$K_x$	Extinction coefficient of PAR inside the canopy [m	0.7	0.7
	ground m <sup>-1</sup> leaf]		
$\alpha_0$	Light use efficiency at low light conditions [mg $J^{-1}$ ]	0.014	0.017
$R_{10}$	Respiration at 10°C	0.23	0.1
$g_{ m m,298}$	Mesophyll conductance at 298 K [mm s <sup>-1</sup> ]	7.0	3.0
A <sub>mmax, 298</sub>	CO <sub>2</sub> maximal primary productivity at 298 K [m <sup>2</sup> leaf	1.7	2.2
	$s^{-1}$ ]		
$f_0$	Maximum value of Cfrac [-]	0.85	0.89
CO <sub>2comp298</sub>	CO <sub>2</sub> compensation concentration at 298 K [ppm]	68.5	68.5

**Table A2.** Statistical metrics to evaluate the robustness of model performance against measurements at Cabauw, Westmaas, and Slufter locations

Dataset	Location	Height	$\mathbf{R}^2$	Correlation	Std	RMSD	MBE	RMSE
		( <b>m</b> )			(ppm)	(ppm)	(ppm)	(ppm)

# Appendix B

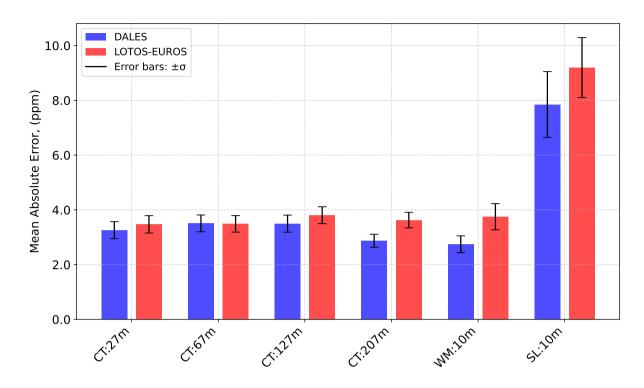

Figure B1. Bootstrap analysis (1000 iterations) of Mean Absolute Error (MAE) between model predictions (DALES  $CO_{2sum}$  and LOTOS-EUROS  $CO_2$ ) and  $CO_2$  observations at multiple heights and locations. The bars represent the mean MAE, with error bars indicating  $\pm \sigma$  based on bootstrap sampling. Locations and specific heights are labeled below the bars: CT:27m - Cabauw Tower at 27m; CT:67m - Cabauw Tower at 67m; CT:127m - Cabauw Tower at 127m; CT:207m - Cabauw Tower at 207m; WM:10m - Westmaas at 10m; SL:10m - Slufter at 10m.

Author contributions. A.-K.D. developed the emission downscaling workflow and DALES extentions, performed all simulations, handled the visualization and wrote the original draft with formal analysis. J.V.G.d.A. and B.v.S. assisted with the integration of forest components into the A-gs scheme and contributed to the results analysis. H.D.v.d.G. was responsible for the TNO observational data description and assisted with the analysis. F.J. supported the software implementation, initial process of data for assimilation, and assisted in the model development. S.H. conceptualized the research work, developed the methodology, and contributed to the writing and analysis of the results. All the authors participated in editing the paper and discussing the results.

805 Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We are grateful to the Dutch Research Council (NWO) for financial support of this research as part of the Ruisdael Observatory scientific research infrastructure (grant no. 184.034.015). We also extend our thanks to RIVM, especially to Margreet van Zanten, Romuald te Molder, and Jolien van Huystee, for providing comprehensive emissions datasets, plume thermal properties, and assistance in their description and fruitful discussion. We thank Arjo Segers from TNO for providing LOTOS-EUROS simulation data and discussion on the setup. Additionally, we thank DAT.MOBILITY, particularly Eric Pijnappels, for granting access to the NO<sub>x</sub> traffic emission data used in this research. We are also grateful to ICOS for the opportunity to use CO<sub>2</sub> measurements from the Cabauw tower. Finally, we acknowledge SURFSARA for providing the computational resources to conduct the simulations for this study, and NWO for supporting the project budget through the National Roadmap for Large-Scale Research Facilities (https://www.nwo.nl/en/researchprogrammes/national-roadmap-for-large-scale-research-facilities, last access: 27 November 2024).
