**Abstract.** The chemical interaction between nitrogen oxides ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ) and  $\alpha$ -pinene plays a critical role in air quality  
25 and climate. However, uncertainties remain regarding their coupling in  $\text{NO}_x$  loss, renoxification, and oxidation chemistry. To address these gaps, we conducted controlled chamber experiments, analyzing nitric acid ( $\text{HNO}_3$ ),  $\text{NO}_2$ , and particulate nitrate ( $\text{pNO}_3$ ) for their oxygen and nitrogen stable isotope variations ( $\Delta^{17}\text{O}$ ,  $\delta^{18}\text{O}$ , and  $\delta^{15}\text{N}$ ). A strong linear relationship between  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$  across experiments revealed contributions of oxygen from ozone ( $\text{O}_3$ ) and atmospheric oxygen ( $\text{O}_2$ ) in forming reactive radicals. The  $\delta^{15}\text{N}$  values followed the order  $\delta^{15}\text{N}(\text{pNO}_3) < \text{NO}_2 < \text{HNO}_3$ , reflecting isotope fractionation during  $\text{NO}_x$   
30 oxidation. A new chemical mechanism accurately predicted aerosol precursor decay and simulated  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  values. Simulations showed  $\text{NO}_x$  photochemical cycling and  $\text{pNO}_3$  formation, primarily from organic nitrate, with  $\Delta^{17}\text{O}(\text{NO}_2)$  simulations achieving a root mean square error (RMSE) of 1.7%. Improved  $\delta^{15}\text{N}(\text{NO}_2)$  and  $\text{pNO}_3$  simulations used a nitrogen isotope fractionation factor ( $^{15}\alpha$ ) of 0.997 for  $\text{NO}_2 + \text{OH}$  reactions. However, modeling  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  of  $\text{HNO}_3$  proved challenging, likely due to sampling artifacts. This study provides insights into  $\Delta^{17}\text{O}$  transfer dynamics, nitrogen isotope

35 fractionation, and the role of  $\text{NO}_x$ -BVOC chemistry in air quality, highlighting the potential of  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  as tools for  
evaluating complex atmospheric processes.

## 1 Introduction

The oxidation of biogenic volatile organic compounds (BVOCs) in the presence of nitrogen oxides ( $\text{NO}_x = \text{NO} + \text{NO}_2$ )  
40 constitutes an important mechanism of coupled biogenic-anthropogenic interactions. This interplay bears significant  
consequences for air quality, climate, global reactive nitrogen budget, and secondary organic aerosols (SOA) (Hoyle et al.,  
2011; Ng et al., 2017; Romer et al., 2016; Sato et al., 2022; Takeuchi and Ng, 2019; Xu et al., 2015b, 2020; Zare et al., 2018).  
Monoterpenes ( $\text{C}_{10}\text{H}_{16}$ ) are a major class of BVOCs that, upon oxidation, can lead to significant organic nitrate and SOA  
formation both during daytime and nighttime (Aschmann et al., 2002; Bates et al., 2022; Bell et al., 2022; Fry et al., 2014;  
45 Hallquist et al., 1999; Nah et al., 2016; Nozière et al., 1999; Rindelaub et al., 2015). However, significant gaps exist in our  
comprehension of monoterpene and  $\text{NO}_x$  coupled chemistry, including the fate of organic nitrogen and its influence on  $\text{NO}_x$   
and oxidant budgets. Once formed, gas-phase organic nitrogen can either photolyze or oxidize, leading to the release of  $\text{NO}_x$   
("renoxification"), partition into the particle phase, resulting in particulate organic nitrogen production (Beaver et al., 2012;  
Browne et al., 2014; Browne and Cohen, 2012; Fisher et al., 2016; Wang et al., 2023), and/or undergo dry and wet deposition,  
50 leading to the removal of reactive nitrogen from the atmosphere. An important loss process for organic nitrate is hydrolysis in  
the particle phase, leading to the production of nitric acid ( $\text{HNO}_3$ ) (Day et al., 2010; Rindelaub et al., 2016; Russell et al., 2011;  
Takeuchi and Ng, 2019; Wang et al., 2021; Zare et al., 2018). Understanding the fates of organic nitrogen and the feedback in  
oxidation chemistry arising from BVOC/ $\text{NO}_x$  interactions is critical for accurately assessing their roles in  $\text{NO}_x$  loss and  
recycling,  $\text{O}_3$  formation, and SOA generation.

55 To address these fundamental uncertainties and advance our understanding, it is imperative to employ methodologies that can  
be used to deduce the reaction mechanisms governing the formation and fate of organic nitrogen. The natural variations of  
stable oxygen and nitrogen isotopes in various reactive nitrogen ( $\text{NO}_y = \text{NO}_x + \text{HNO}_3 + \text{alkyl nitrate (RONO}_2) + \text{peroxy nitrate (RO}_2\text{NO}_2) + \text{etc.}$ )  
molecules may be a promising analytical tool to enhance our insight into the intricate connections between  
60  $\text{NO}_x$  and BVOC chemistry and their implications for atmospheric composition (Michalski et al., 2012; Walters et al., 2018).  
Stable isotope approaches offer novel avenues to probe and refine our understanding of complex atmospheric processes,  
unravel the dynamics of BVOC/ $\text{NO}_x$  interactions, and ultimately contribute to formulating informed air quality management  
strategies.

65 Variations in oxygen (O) isotope ratios (i.e.,  $^{18}\text{O}/^{16}\text{O}$  and  $^{17}\text{O}/^{16}\text{O}$ ), commonly quantified using isotope delta notation ( $\Delta^{17}\text{O}$   
and  $\delta^{18}\text{O}$ ), offer a powerful proxy for assessing oxidation pathways involving  $\text{NO}_x$  photochemical cycling and nitrate formation

(Albertin et al., 2021; Alexander et al., 2020; Michalski et al., 2003; Morin et al., 2011; Walters et al., 2024b). This is owing to distinct  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  values exhibited by key atmospheric oxidants, which are proportionally transferred to  $\text{NO}_x$  during oxidation in the atmosphere (Hastings et al., 2003; Michalski et al., 2003). For instance, tropospheric  $\text{O}_3$  has an elevated  $\Delta^{17}\text{O}$  with a mean value near 26‰, and the transferable terminal oxygen atom of  $\text{O}_3$  ( $\text{O}_3^{\text{term}}$ ) exhibiting a  $\Delta^{17}\text{O}$  of  $39.3 \pm 2\text{‰}$  and elevated  $\delta^{18}\text{O}$  near  $126 \pm 12\text{‰}$  based on recent near-surface observations (Ishino et al., 2017; Vicars and Savarino, 2014). In contrast, other atmospheric oxidants such as  $\text{RO}_2/\text{HO}_2$  and  $\text{OH}$  have  $\Delta^{17}\text{O}$  values at or near 0‰ (Lyons, 2001; Walters et al., 2024a). The  $\delta^{18}\text{O}$  values of  $\text{RO}_2/\text{HO}_2$  and  $\text{OH}$  have not been directly determined but are anticipated to be lower than the  $\delta^{18}\text{O}(\text{O}_3^{\text{term}})$  (Michalski et al., 2012). The  $\Delta^{17}\text{O}$  isotopic differences provide quantitative measures to evaluate  $\text{NO}_x$  photochemical cycling and nitrate formation processes. Notably,  $\Delta^{17}\text{O}$  has been frequently utilized to assess atmospheric nitrate formation pathways, as different pathways yield distinct  $\Delta^{17}\text{O}$  values based on oxygen isotope mass-balance assumptions (Alexander et al., 2020; Michalski et al., 2003; Morin et al., 2011; Walters et al., 2024b). More recent advancements include the first reliable *in situ* measurements of  $\delta^{18}\text{O}(\text{NO}_2)$  and  $\Delta^{17}\text{O}(\text{NO}_2)$ , which enable an evaluation of  $\text{NO}_2$  formation pathways (i.e.,  $\text{NO} + \text{O}_3$  vs  $\text{NO} + \text{RO}_2/\text{HO}_2$ ) (Albertin et al., 2021; Walters et al., 2018, 2024b). Further, we have recently developed a chemical mechanism that can explicitly model  $\Delta^{17}\text{O}$  of numerous  $\text{NO}_y$  components, termed InCorporating Oxygen Isotopes of Oxidized Reactive Nitrogen (ICOIN) based on the Regional Atmospheric Chemistry Mechanism, Version 2 mechanism (RACM2) (Walters et al., 2024a). These new tools offer exciting opportunities for probing  $\text{NO}$  oxidation branching ratios, assessing organic nitrogen yields from  $\text{NO} + \text{RO}_2$  reactions under various  $\text{NO}_x/\text{BVOC}$  conditions, and evaluating nitric acid formation mechanisms including both inorganic and organic reaction pathways.

The stable nitrogen (N) isotope ratio variations ( $\delta^{15}\text{N}$ ) of  $\text{NO}_x$  and atmospheric nitrate have conventionally served as a valuable proxy for evaluating precursor emission sources, because of the preserved N mass between the precursor and oxidized end-products (Elliott et al., 2019; Hastings et al., 2013). However, it is essential to consider that  $\text{NO}_x$  photochemical cycling and atmospheric nitrate formation processes can also induce significant mass-dependent fractionation effects (Freyer et al., 1993; Li et al., 2020; Walters et al., 2016; Walters and Michalski, 2015, 2016). Field  $\delta^{15}\text{N}$  observations of  $\text{NO}_2$  and nitrate have demonstrated the potential of these fractionation effects to offer additional valuable information concerning  $\text{NO}_x$  photochemical cycling and atmospheric nitrate formation (Albertin et al., 2021; Bekker et al., 2023; Li et al., 2021; Walters et al., 2018). Recently, a novel chemical mechanism was devised to model the nitrogen isotope fractionation associated with  $\text{NO}_x$  chemistry, called incorporating  $^{15}\text{N}$  into the Regional Atmospheric Chemistry Mechanism ( $i_{\text{N}}\text{RACM}$ ) (Fang et al., 2021). Leveraging these advancements, we may utilize  $\delta^{15}\text{N}$  to gather supplementary quantitative insights into  $\text{BVOC}/\text{NO}_x$  interactions and their impact on organic nitrogen fates and contributions to  $\text{HNO}_3$  formation.

This study presents the first  $\Delta^{17}\text{O}$ ,  $\delta^{18}\text{O}$ , and  $\delta^{15}\text{N}$  values of several simultaneously collected  $\text{NO}_y$  species, including  $\text{NO}_2$ ,  $\text{HNO}_3$ , and  $\text{pNO}_3$ , from controlled laboratory experiments involving  $\alpha$ -pinene, the most abundant monoterpene. These experiments were conducted under diverse oxidant conditions to investigate distinct  $\text{RO}_2$  fates, enabling a comprehensive

105 evaluation of the impact of BVOC/NO<sub>x</sub> interactions on atmospheric oxidant budgets, organic nitrogen fates, and NO<sub>x</sub> loss and/or recycling. The  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  of the various NO<sub>y</sub> components were simulated utilizing recently developed isotope mechanism frameworks (Fang et al., 2021; Walters et al., 2024a), yielding invaluable insights into the formation mechanisms and fates of NO<sub>x</sub>, HNO<sub>3</sub>, and organic nitrogen under varying oxidant conditions. Additionally, this approach tremendously aids in our understanding of  $\Delta^{17}\text{O}$  transfer dynamics as well as  $\delta^{15}\text{N}$  fractionation patterns associated with NO<sub>x</sub> oxidation chemistry.

## 2 Methods

### 2.1 Chamber Experiments

110 Photochemical and nighttime oxidation chamber experiments were conducted involving  $\alpha$ -pinene, NO<sub>x</sub>, and oxidant precursors at the Georgia Institute of Technology Environmental Chamber Facility that houses two 12 m<sup>3</sup> Teflon reactors (Boyd et al., 2015). A total of six different initial experimental conditions were targeted, including five photochemical and one nighttime condition as previously reported (Blum et al., 2023) (Table 1). The experiments varied in their precursor concentrations and oxidant types, which were utilized to probe different  $\alpha$ -pinene oxidation reactions involving OH, O<sub>3</sub>, and nitrate radical (NO<sub>3</sub>) and alkylperoxy radical (RO<sub>2</sub>) fates. Replicates were conducted in two of the targeted experimental conditions. The conducted 115 chamber experiments follow well-established laboratory protocols and experimental conditions (Boyd et al., 2015; Nah et al., 2016; Takeuchi and Ng, 2019; Tuet et al., 2017). Briefly, photochemical experiments were conducted by injecting dry ammonium sulfate seed aerosol and precursor (i.e.,  $\alpha$ -pinene (99% Sigma-Aldrich)), NO (Matheson), hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), or nitrous acid (HONO)) into the chamber, where either H<sub>2</sub>O<sub>2</sub> or HONO was used as an OH precursor to simulate different extents of RO<sub>2</sub>+NO pathway. Once the levels of precursors stabilized, the chamber lights were turned on, signifying 120 the start of the photochemical experiments. The procedure used to generate HONO (e.g., the reaction of sodium nitrite with sulfuric acid) also leads to the generation of significant NO and NO<sub>2</sub> as a reaction by-product (Kroll et al., 2005; Tuet et al., 2017). For simulated nighttime conditions, dry ammonium sulfate seed aerosol and  $\alpha$ -pinene were injected into the chamber, followed by flowing dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>) for fifteen minutes (Boyd et al., 2015; Takeuchi and Ng, 2019). The N<sub>2</sub>O<sub>5</sub> injection corresponded to the start of the nighttime experiments. The N<sub>2</sub>O<sub>5</sub> was generated by reacting NO<sub>2</sub> from a gas cylinder 125 (Matheson) with O<sub>3</sub> in a flow tube prior to the introduction to the chamber at a ratio of 2:1 to minimize O<sub>3</sub> concentrations in the chamber to avoid ozonolysis. All experiments were conducted at a relative humidity (RH) and temperature of 30 % and 22 °C, respectively. Before each experiment, the chamber was flushed with zero air and irradiated for at least 24 hours.

130

**Table 1. Summary of measured NO<sub>y</sub> precursor concentrations and targeted H<sub>2</sub>O<sub>2</sub> concentrations for the chamber experiments. All experiments were conducted using dry ammonium sulfate seed at a fixed temperature (22°C) and relative humidity (30%). The experiments were conducted using two different chambers designated as A and B.**

Experiment	$\alpha$ -pinene (ppb)	NO <sub>y</sub> (ppb)	Oxidant (ppb)
1	298	NO <sup>a</sup> = 55.3 HNO <sub>3</sub> <sup>d</sup> = 5.1	H <sub>2</sub> O <sub>2</sub> = 9,000
1R	297	NO <sup>a</sup> = 49.5 HNO <sub>3</sub> <sup>d</sup> = 3.5	H <sub>2</sub> O <sub>2</sub> = 9,000
2	290	NO <sup>a</sup> = 112 HNO <sub>3</sub> <sup>d</sup> = 3.18	H <sub>2</sub> O <sub>2</sub> = 6,000
3	286	NO <sup>a</sup> = 338 HNO <sub>3</sub> <sup>d</sup> = 4.77	H <sub>2</sub> O <sub>2</sub> = 6,000
4	293	NO <sup>a</sup> = 615 HNO <sub>3</sub> <sup>d</sup> = 5.74	H <sub>2</sub> O <sub>2</sub> = 4,500
4R	316	NO <sup>a</sup> = 655 HNO <sub>3</sub> <sup>d</sup> = 5.51	H <sub>2</sub> O <sub>2</sub> = 4,500
5	306	HONO <sup>b</sup> = 210 NO <sup>b</sup> = 320 NO <sub>2</sub> <sup>b</sup> = 460 HNO <sub>3</sub> <sup>d</sup> = 9.08	N/A
6	100	NO <sub>2</sub> , NO <sub>3</sub> , N <sub>2</sub> O <sub>5</sub> , HNO <sub>3</sub> , O <sub>3</sub> = d HNO <sub>3</sub> = 10.0	N/A

135 <sup>a</sup>The starting NO was assumed to have a  $\Delta^{17}\text{O} = 0\text{‰}$  and  $\delta^{15}\text{N} = -70.0\text{‰}$

<sup>b</sup>The starting HONO, NO, and NO<sub>2</sub> were assumed to have  $\Delta^{17}\text{O} = 0\text{‰}$  and  $\delta^{15}\text{N} = -5.9\text{‰}$

<sup>c</sup>The chamber HNO<sub>3</sub> “blank” was assumed to have  $\Delta^{17}\text{O} = 26\text{‰}$  and  $\delta^{15}\text{N} = -35\text{‰}$ .

<sup>d</sup>The emission rate of NO<sub>2</sub>, NO<sub>3</sub>, N<sub>2</sub>O<sub>5</sub>, HNO<sub>3</sub>, and O<sub>3</sub> into the chamber for a 20 minute injection period were modeled based on a flow tube simulation of the reaction of NO<sub>2</sub> with O<sub>3</sub> with a residence time of 70 s. The initial NO<sub>2</sub> was assumed to have  
 140 a  $\Delta^{17}\text{O} = 0\text{‰}$  and  $\delta^{15}\text{N} = -40.5\text{‰}$

Continuous online measurements of NO, NO<sub>2</sub>, and O<sub>3</sub> were conducted using chemiluminescence (Teledyne 200EU), cavity-attenuated phase shift (CAPS), and an O<sub>3</sub> monitor (Teledyne T400). A chemical ionization mass spectrometer (CIMS) was used for various NO<sub>y</sub> measurements including HONO and HNO<sub>3</sub> (Huey et al., 1998). The  $\alpha$ -pinene decay was monitored using  
 145 gas-chromatography flame ionization detector (GC-FID; Agilent 7890A). Organic nitrate were monitored using a filter inlet for gases and AEROSols (FIGAERO) coupled to a high-resolution time-of-flight iodide chemical ionization mass spectrometer (HR-ToF-I-CIMS) with particles collected on a Teflon filter (Lopez-Hilfiker et al., 2014; Nah et al., 2016; Takeuchi et al., 2022; Takeuchi and Ng, 2019; Wang et al., 2023). Aerosol composition was measured using a high-resolution time-of-flight  
 150 aerosol mass spectrometer (HR-ToF-AMS) that included measurement of non-refractory organics (Org), sulfate (SO<sub>4</sub>), nitrate

(NO<sub>3</sub>), and ammonium (NH<sub>4</sub>) (DeCarlo et al., 2006; Farmer et al., 2010). Water-soluble aerosol components were also measured using a particle-into-liquid sampler (PILS) coupled to ion chromatography (IC) (Orsini et al., 2003).

155 Collections of various NO<sub>y</sub> gaseous and aerosol components, including HNO<sub>3</sub>, NO<sub>2</sub>, and pNO<sub>3</sub> were conducted using a  
modified version of the ChemComb Speciation Cartridge (CCSC) with an extended denuder body for offline concentration  
and isotope composition analysis (Blum et al., 2020, 2023). Briefly, the CCSC collections began when the aerosol mass  
spectrometer data indicated the nitrate and secondary organic aerosol mass concentrations had peaked. The CCSC samples  
were collected at 8 L min<sup>-1</sup> for up to 4 h. To maintain the chamber integrity, zero-air was used to dilute at 25 L min<sup>-1</sup> once  
aerosol peak was reached and CCSC sample collection initiated. The CCSC denuder bodies were replaced one to four times  
160 depending on the concentration of NO<sub>x</sub> in the chamber. For each experiment, a single filter was used in the CCSC. In addition  
to the chamber experiments, samples were collected directly from the NO<sub>2</sub> tank (Matheson), which was used in the generation  
of N<sub>2</sub>O<sub>5</sub> for the nighttime oxidation experiments.

Honeycomb denuders were coated for the selective collection of HNO<sub>3</sub> (captured as nitrate (NO<sub>3</sub><sup>-</sup>)) and NO<sub>2</sub> (captured as nitrite  
165 (NO<sub>2</sub><sup>-</sup>)). A detailed description of the coating solutions, denuder preparation, and denuder extraction was previously described,  
and the pooled isotope reproducibility for both HNO<sub>3</sub> and NO<sub>2</sub> was ±1.7‰, ±1.8‰, and ±0.7‰, for δ<sup>15</sup>N, δ<sup>18</sup>O, and Δ<sup>17</sup>O  
(Blum et al., 2023) for these chamber experiments. The collection of PM<sub>2.5</sub> was conducted using a quartz filter (Cytiva  
Whatman, Grade QM-A; 47 mm diameter) that was housed in the ChemComb filter cartridge positioned downstream of the  
denuders. Before use, the quartz fiber filters were placed in a furnace at 550 °C overnight and stored in an airtight container.  
170 The filter samples were extracted in 20 mL of Milli-Q water (>18.2 MΩ) and allowed to leach for at least one week at room  
temperature. This method was conducted to enable hydrolysis of collected organic nitrate particles as previous studies have  
shown organic nitrate derived from α-pinene oxidation to hydrolyze to NO<sub>3</sub><sup>-</sup> in water with a lifetime of 8.8 h at pH = 6.9  
(Rindelaub et al., 2016) and 2.5 h at pH = 7.44 (Wang et al., 2021). Other types of organic nitrate, such as secondary nitrates,  
have been reported to be stable in water, especially at a neutral pH (Wang et al., 2021). The efficiency of our filter extraction  
175 technique for organic nitrate hydrolysis was evaluated using the online AMS and PILS data. After the filters were leached, the  
filters were removed, and the samples were shipped to Brown University where they were placed in a freezer until subsequent  
concentration and isotope analysis. For all sample media types, including denuders and filters, lab blanks were frequently  
taken. These blanks were prepared, handled, and analyzed the same way as all samples.

## 180 2.2 Concentration and Isotope Analysis

The denuder and filter extracts were analyzed for their NO<sub>2</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> content using a standardized colorimetric technique  
(e.g., EPA Methods 353.2) or ion chromatography, as previously described (Blum et al., 2020, 2023). The limits of detection  
(LOD) were approximately 0.1 μmol L<sup>-1</sup> and 0.3 μmol L<sup>-1</sup> for NO<sub>2</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> via colorimetric analysis and 3.0 μmol L<sup>-1</sup> for

NO<sub>2</sub><sup>-</sup> via ion chromatography. For all analyses, the average percent relative standard deviation was below 5%. The NO<sub>2</sub><sup>-</sup> and  
185 NO<sub>3</sub><sup>-</sup> concentrations from denuder blank extractions used for NO<sub>2</sub> ( $n = 5$ ) and HNO<sub>3</sub> ( $n = 5$ ) collection were below detection  
limits. Significant blanks were observed in the quartz filter extracts ( $1.5 \pm 0.2 \mu\text{mol L}^{-1}$ ;  $n = 5$ ).

The  $\delta^{15}\text{N}$ ,  $\delta^{18}\text{O}$ , and  $\Delta^{17}\text{O}$  isotope compositions were analyzed using the denitrifier method for NO<sub>3</sub><sup>-</sup> samples and the sodium  
azide in an acetic acid buffer method for NO<sub>2</sub><sup>-</sup> samples (Casciotti et al., 2002; McIlvin and Altabet, 2005; Sigman et al., 2001;  
190 Walters and Hastings, 2023). Briefly, these methods produce N<sub>2</sub>O from NO<sub>3</sub><sup>-</sup> and/or NO<sub>2</sub><sup>-</sup>, which is extracted, purified,  
concentrated, and injected into a continuous flow isotope ratio mass spectrometer for  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$  determination from  $m/z$   
measurement at 44, 45, and 46. In a separate batch analysis, the generated N<sub>2</sub>O is decomposed to O<sub>2</sub> and analyzed for  $\Delta^{17}\text{O}$   
determination from  $m/z$  measurement at 32, 33, and 34. The samples were calibrated with respect to internationally recognized  
NO<sub>3</sub><sup>-</sup> standards (IAEA-NO-3, USGS35, USGS34) or NO<sub>2</sub><sup>-</sup> reference materials (RSIL-N7373 and RSIL-10219) (Böhlke et al.,  
195 2003, 2007). The pooled standard deviations of the standards were  $\pm 0.1\%$  and  $\pm 0.6\%$  for  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$  of the NO<sub>3</sub><sup>-</sup> standards  
( $n = 78$ ) and  $\pm 0.3\%$  and  $\pm 0.3\%$  for  $\delta^{15}\text{N}$  and  $\delta^{18}\text{O}$  of the NO<sub>2</sub><sup>-</sup> reference materials ( $n = 15$ ), respectively. The  $\Delta^{17}\text{O}$  had a pooled  
standard deviation of  $\pm 0.6\%$  ( $n = 53$ ).

All isotope measurements were reported relative to reference standards using delta ( $\delta$ ) notation (Eq. 1):

$$200 \quad \delta = \left( \frac{x_{R_{\text{sample}}}}{x_{R_{\text{reference}}}} - 1 \right) \quad (\text{Eq. 1})$$

where  $x$  refers to the heavy isotope (i.e., <sup>15</sup>N, <sup>18</sup>O, or <sup>17</sup>O) and  $R$  refers to the ratio of the heavy to the light isotope (i.e., <sup>15</sup>N/<sup>14</sup>N,  
<sup>18</sup>O/<sup>16</sup>O, or <sup>17</sup>O/<sup>16</sup>O), for the sample or the reference material. The nitrogen and oxygen reference material includes atmospheric  
air and Vienna Standard Mean Ocean Water (VSMOW), respectively. Oxygen isotope mass-independence ( $\Delta^{17}\text{O}$ ) was  
quantified using the linear definition with a mass-dependent coefficient of 0.52, which is approximately representative of  
205 oxygen mass-dependent coefficients expected and observed in nature (Young et al., 2002) (Eq. 2):

$$\Delta^{17}\text{O} = \delta^{17}\text{O} - 0.52 \times \delta^{18}\text{O} \quad (\text{Eq. 2})$$

The linear  $\Delta^{17}\text{O}$  approximation is commonly used to describe large mass-independent effects such as those related to O<sub>3</sub>  
reactions, and this definition is commonly used in the atmospheric chemistry community to track the influence of O<sub>3</sub> oxidation  
and  $\Delta^{17}\text{O}$  propagation into reactive components (Alexander et al., 2020; Kim et al., 2022; Michalski et al., 2003; Savarino et  
210 al., 2013).

### 2.3 Data Reduction and Corrections

Due to significant NO<sub>3</sub><sup>-</sup> blanks found in the pNO<sub>3</sub> filter extracts, the measured  $\delta^{15}\text{N}$ ,  $\delta^{18}\text{O}$ , and  $\Delta^{17}\text{O}$  were corrected based on  
mass-balance (Eq. 3-4):

$$215 \quad \delta(\text{corrected, pNO}_3) = \frac{\delta(\text{measure}) - (f(\text{blank}) \times \delta(\text{blank}))}{1 - f(\text{blank})} \quad (\text{Eq. 3})$$

$$f(\text{blank, pNO}_3) = \frac{[\text{NO}_3^-(\text{blank})]}{([\text{NO}_3^-(\text{blank})] + [\text{NO}_3^-(\text{sample})])} \quad (\text{Eq. 4})$$

where  $[\text{NO}_3^-]$ , corresponds to the concentration of  $\text{NO}_3^-$  in either the blank or sample, and  $f(\text{blank})$  corresponds to the fraction of  $\text{NO}_3^-$  that corresponds to the blank. The quartz filter extracts had  $\delta^{15}\text{N}$ ,  $\delta^{18}\text{O}$ , and  $\Delta^{17}\text{O}$  values of  $1.6 \pm 1.1\text{‰}$ ,  $16.6 \pm 1.4\text{‰}$ , and  $3.4 \pm 0.5\text{‰}$ , respectively ( $n = 3$ ). Blank corrections were made for all samples when  $f(\text{blank})$  was less than 30%. Samples with  $f(\text{blank})$  that exceeded 30% were not reported for their isotope compositions, which included 1 out of 8 quartz filter extracts. The uncertainty in the blank corrected isotope deltas was calculated using a Monte-Carlo simulation for 10,000 iterations and assuming a normal distribution using Matlab. For the quality assurance criterion of an  $f(\text{blank}) < 30\%$ , the uncertainties were calculated to be less than 4.1‰, 1.4‰, and 0.9‰ for  $\delta^{15}\text{N}$ ,  $\delta^{18}\text{O}$ , and  $\Delta^{17}\text{O}$ , respectively.

## 2.4 Aerosol Nitrate Composition

The relative contribution of organic aerosol nitrate ( $\text{pNO}_3(\text{Org})$ ) to the total  $\text{pNO}_3$  was determined from two approaches. First, the relative proportion of  $\text{pNO}_3(\text{Org})$ , was calculated based on  $\text{NO}^+$  and  $\text{NO}_2^+$  HR-ToF-AMS fragmentation as previously described (Farmer et al., 2010; Fry et al., 2009; Kiendler-Scharr et al., 2016; Xu et al., 2015a) (Eq. 5):

$$f(\text{pNO}_3, \text{Org}) = \frac{(R_{\text{obs}} - R_{\text{AN}})(1 + R_{\text{ON}})}{(R_{\text{ON}} - R_{\text{AN}})(1 + R_{\text{obs}})} \quad (\text{Eq. 5})$$

where  $f(\text{pNO}_3, \text{Org})$  refers to the fraction of  $\text{pNO}_3(\text{Org})$  to the total  $\text{pNO}_3$ ,  $R$  refers to  $\text{NO}^+/\text{NO}_2^+$  fragments, and obs, AN, and ON refers to the observed, ammonium nitrate, and organic nitrate, respectively. The  $R_{\text{AN}}$  was obtained from routine ionization efficiency calibration of the HR-ToF-AMS using 300 nm ammonium nitrate aerosols and was 1.37. The  $R_{\text{ON}}$  was calculated based on the measured  $R_{\text{AN}}$  and the ratio of  $R_{\text{ON}}/R_{\text{AN}}$  previously reported for similar conducted experiments (Takeuchi and Ng, 2019), resulting in an  $R_{\text{ON}}$  of  $2.70 \pm 0.29$  and  $3.86 \pm 0.34$  for photochemical and nighttime oxidation experiments, respectively. The second method for qualitatively determining  $f(\text{pNO}_3, \text{Org})$  involved evaluating the relative change in the molar ratio of  $\text{NH}_4/\text{SO}_4$ , as an increase in  $\text{NH}_4/\text{SO}_4$  has been observed to be associated with inorganic  $\text{pNO}_3$  formation (Takeuchi and Ng, 2019).

## 2.5 Box Model Simulations

The chamber experiments were simulated using the Framework for 0-D Atmospheric Modeling (FOAM) box model (Wolfe et al., 2016). The model was initiated for each experiment using the measured precursor concentrations for  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HONO}$ , and  $\alpha$ -pinene before chamber lights were turned on or  $\text{N}_2\text{O}_5$  was injected and using the targeted  $\text{H}_2\text{O}_2$  concentrations. Additionally, a "chamber blank" of  $\text{HNO}_3$ , based on the CIMS measurements, was present before the start of the experiment (Fig. S1). To accurately reflect this condition in the model, an initial concentration of  $\text{HNO}_3$  was included in the experimental simulations based on the observed CIMS measurements (Table 1). The pressure, temperature, and relative humidity were fixed at 1013 mbar, 295 K, and 30%, respectively. The measured chamber light flux data was used. The model was run in two parts for the photochemical reactions, including from lights on to peak SOA mass concentration (part 1) and from aerosol decay and chamber dilution to the end of  $\text{NO}_y$  collections (part 2). For the nighttime experiments, the model simulations were conducted

in three parts, including from the start of N<sub>2</sub>O<sub>5</sub> injection to the end of N<sub>2</sub>O<sub>5</sub> injection (part 1), from the end of N<sub>2</sub>O<sub>5</sub> injection to peak SOA mass concentrations (part 2) and from the decay of organic aerosol and chamber dilution to the end of NO<sub>y</sub> collection (part 3). The N<sub>2</sub>O<sub>5</sub> injection was simulated by first modeling the NO<sub>2</sub> reaction with O<sub>3</sub> in the flow tube, considering a flow tube residence time of 70 s. The nighttime experiment was then simulated by allowing the flow tube products (i.e., NO<sub>2</sub>, O<sub>3</sub>, NO<sub>3</sub>, HNO<sub>3</sub>, and N<sub>2</sub>O<sub>5</sub>) to emit into the chamber for 20 minutes (part 1). Next, the experiment was modeled without the flow tube emission to the start of aerosol decay and chamber dilution (part 2) and from aerosol decay and chamber dilution to the end of NO<sub>y</sub> collections (part 3). For both photochemical and nighttime experiments, the model simulations from the decay of organic aerosol to the end of NO<sub>y</sub> collection included a chamber dilution rate of  $k_{\text{dil}} = 8.00 \times 10^{-5} \text{ s}^{-1}$ , which was determined based on accurately matching the decay of NO for the photochemical experiments with the highest levels of initial starting NO<sub>y</sub> (i.e., Exp. 4, and 5).

A new chemical mechanism was developed, termed University of South Carolina  $\alpha$ -pinene (USC-API), to accurately model the oxidation of NO<sub>x</sub> and  $\alpha$ -pinene (Table S1-S2). This mechanism was developed due to difficulties in simulating the initial decay of the aerosol precursors including  $\alpha$ -pinene, NO, NO<sub>2</sub>, and HONO for the various experiment conditions using either the Regional Atmospheric Chemical Mechanism, v2 (RACM2; (Goliff et al., 2013) or the Master Chemical Mechanism v3.3.1 (Jenkin et al., 1997; Saunders et al., 2003). The USC-API mechanism focuses on simulating  $\alpha$ -pinene and NO decay along with NO<sub>x</sub> oxidation but does not intend to accurately simulate SOA production and later-generation chemistry. The mechanism includes the inorganic reactions included in RACM2, including 16 species and 45 reactions. It also incorporates 29 organic species and 61 reactions to detail organic chemistry up to one generation past pinonaldehyde formation as well as the formation of pinonaldehyde derived peroxyacetyl nitrate formation, with subsequent chemistry represented by a lumped approach. The  $\alpha$ -pinene oxidation pathways involving OH, O<sub>3</sub>, and NO<sub>3</sub>, along with specific reactions of the resulting RO<sub>2</sub> with HO<sub>2</sub>, NO, NO<sub>3</sub>, and other RO<sub>2</sub> radicals, are included. The photochemical oxidation of  $\alpha$ -pinene largely follows the MCMv3.3.1 (Saunders et al., 2003), incorporating two hydroxyl-nitrate isomers from OH/O<sub>2</sub>/NO, including one tertiary (ONITa) and one secondary (ONITb) and the formation of a tertiary pinene carbonyl nitrate (ONITc). Nighttime oxidation chemistry integrates a recent mechanism for organic nitrate formation, producing pinene nitrate hydroperoxide, including one tertiary (ONITOOHa) and one secondary (ONITOOHb) via HO<sub>2</sub> reactions and dimer/pinene dinitrate (PDN) through RO<sub>2</sub> interactions (Bates et al., 2022). Product yields for organic nitrate were adjusted based on experimental isotope data, accounting for OH/O<sub>2</sub>/NO and NO<sub>3</sub> pathways, which can be elucidated based on a comparison to  $\Delta^{17}\text{O}$  (Walters et al., 2024b).

275

The  $\Delta^{17}\text{O}$  of NO<sub>y</sub> compounds were simulated using the newly developed USC-API mechanism modified using the InCorporating Oxygen Isotopes of oxidized reactive Nitrogen in the Regional Atmospheric Chemistry Mechanism, Version 2 (ICOIN-RACM2) model framework (Walters et al., 2024a). Briefly, the model framework tracks the transfer and propagation of  $\Delta^{17}\text{O}$  from O<sub>3</sub> into NO<sub>y</sub> and O<sub>x</sub> species. This mechanism tags the oxygen atoms transferred from O<sub>3</sub> into NO<sub>y</sub> and O<sub>x</sub>

280

considering mass-balance and reaction stoichiometry and enables the offline calculation of  $\Delta^{17}\text{O}$  based on the output of concentrations of various  $\text{NO}_y$  and  $\text{HO}_x$  isotopologues (Eq. 6):

$$\Delta^{17}\text{O}(X) = f(Q) \times \Delta^{17}\text{O}(\text{O}_3^{\text{term}}) \quad (\text{Eq. 6})$$

where  $X$  refers to the various  $\text{NO}_y$  and  $\text{O}_x$  molecules and  $f(Q)$  is the fractional number of oxygen-atoms deriving from  $\text{O}_3$  for a particular molecule. The  $\Delta^{17}\text{O}(\text{O}_3^{\text{term}})$  represents the  $\Delta^{17}\text{O}$  value of the terminal and transferrable O atom of  $\text{O}_3$ , which was assumed to be  $39 \pm 2\%$  based on recent near-surface collections of  $\text{O}_3$  (Ishino et al., 2017; Vicars and Savarino, 2014) and  $\text{O}_3$  generated from  $\text{O}_2/\text{NO}_x$  photochemical experiments conducted under normal temperature and pressure conditions (Michalski et al., 2014). The initial  $\Delta^{17}\text{O}(\text{NO})$  and  $\Delta^{17}\text{O}(\text{NO}_2)$  was set to  $0\%$ , while the initial  $\Delta^{17}\text{O}(\text{HNO}_3)$  from the “chamber blank” was set to  $26\%$ , representing  $2/3$  O-atoms derived from  $\text{O}_3$ . This value was not measured but assumed based on the measured  $\Delta^{17}\text{O}(\text{HNO}_3)$  for Exp. 1 and 2, in which the  $\text{HNO}_3$  “chamber blank” significantly contributed to the total produced experimental  $\text{HNO}_3$ , up to approximately 20% (Fig. S1).

Additionally,  $\delta^{15}\text{N}$  of  $\text{NO}_y$  molecules were also simulated by adapting the framework from the recently developed isotope variant of the RACM2 mechanism, termed  $i_{\text{N}}\text{RACM}$ : incorporating  $^{15}\text{N}$  into the Regional Atmospheric Chemistry Mechanism (Fang et al., 2021). The model framework explicitly tracks the  $^{15}\text{N}$  and  $^{14}\text{N}$  abundance of various  $\text{NO}_y$  molecules and includes nitrogen isotope fractionation associated with  $\text{NO}_x$  oxidation. The  $\delta^{15}\text{N}$  of various  $\text{NO}_y$  components is then calculated using a  $^{15}\text{N}/^{14}\text{N}$  ratio of 0.003677 for air. The  $\delta^{15}\text{N}$  chamber simulations were initiated with starting concentrations for the nitrogen isotopologues depending on the initial  $\text{NO}_y$  source. For the nighttime oxidation experiments that used  $\text{NO}_2$  as the initial  $\text{NO}_y$  source (Exp. 6), the starting  $\delta^{15}\text{N}(\text{NO}_2)$  was set to  $-40.5\%$ , which was the measured value from the  $\text{NO}_2$  source (Matheson  $\text{NO}_2$  tank) ( $-40.5 \pm 0.5\%$ ;  $n = 3$ ). For the experiments that initialize experiments using  $\text{NO}$  (Exp. 1-4), a  $\delta^{15}\text{N}(\text{NO})$  value of  $-70.0 \pm 1.4\%$  was assumed based on previous measurements from a commercially available tank of  $\text{NO}$  (Fibiger et al., 2014). Finally, for the HONO experiments (Exp. 5), a  $\delta^{15}\text{N}(\text{HONO})$  value of  $-5.9 \pm 0.5\%$  was assumed based on the lab generation of HONO in a previous study, following a similar methodology as utilized in this study (Chai and Hastings, 2018). Additionally, the “chamber blank”  $\delta^{15}\text{N}(\text{HNO}_3)$  was set to  $-35\%$ , which was the average of the photochemical experiments using  $\text{H}_2\text{O}_2$  and a high initial  $\text{NO}$  concentration (Exp. 4).

The base chemistry in all of the model simulations is identical and the tagging of the isotope tracers does not impact the model chemistry (Fang et al., 2021; Walters et al., 2024a). All model simulations were conducted without considering chamber wall-loss. Additionally, these are gas-phase mechanisms and do not explicitly model heterogeneous reactions or aerosol chemistry. Further, given the low relative humidity conditions and dry aerosol seed conditions, organic nitrate hydrolysis was not included in the initial model. The chemical mechanism performance in simulating  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  values and thus oxidation chemistry was evaluated using the RMSE metric (Eq. 7):

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (\delta_o - \delta_m)^2} \quad (\text{Eq. 7})$$

where  $\delta_o$  are the isotope observations,  $\delta_m$  are the model simulated values, and  $n$  is the number of observations. Adjustments to  
315 the model chemistry were conducted to reduce the RMSE values.

### 3. Results and Discussion

#### 3.1 Isotope Observations

##### 3.1.1 $\Delta^{17}\text{O}$ and $\delta^{18}\text{O}$ of $\text{NO}_y$

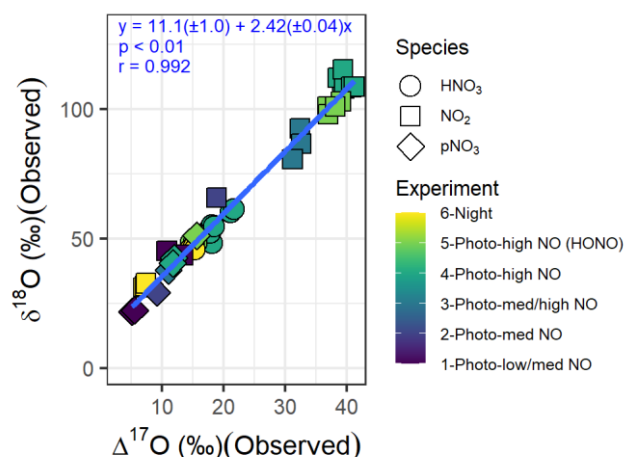

There was a significant relationship between  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$  across  $\text{NO}_y$  species ( $\delta^{18}\text{O} = (11.1 \pm 1.0) + (2.42 \pm 0.04) \times \Delta^{17}\text{O}$ ;  $r =$   
320  $0.992$ ;  $p < 0.01$ ) (Fig. 1). The strong linear relationship between  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$  indicates that the oxygen isotopes of the  
various collected  $\text{NO}_y$  compounds derived between two dominant pools of O-sources, with high and low  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$  values  
that were consistent across all experimental conditions. The high-end member  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$  source can reasonably be assumed  
to derive from  $\text{O}_3^{\text{term}}$ . Assuming a  $\Delta^{17}\text{O}(\text{O}_3^{\text{term}})$  value of  $39.3 \pm 2.0$  ‰ (Ishino et al., 2017; Michalski et al., 2014; Vicars and  
Savarino, 2014), would indicate a  $\delta^{18}\text{O}$  transferred from  $\text{O}_3^{\text{term}}$  to the  $\text{NO}_y$  products of  $106 \pm 5.0$ ‰. Assuming the low-end  
325 member O-source to have a  $\Delta^{17}\text{O}$  of 0‰, indicates a  $\delta^{18}\text{O}$  value of  $11.1 \pm 1.0$ ‰ transferred into the  $\text{NO}_y$  products that could be  
reasonably be expected to derive from  $\text{RO}_2$ ,  $\text{HO}_2$ , and  $\text{OH}$  radicals. The  $\delta^{18}\text{O}$  of  $\text{RO}_2/\text{HO}_2$  radicals has previously been  
suggested to be near  $\delta^{18}\text{O}(\text{O}_2)$  (Michalski et al., 2012). Indeed, the derived  $\delta^{18}\text{O}$  value of  $11.8 \pm 1.0$ ‰ is near the atmospheric  
 $\delta^{18}\text{O}(\text{O}_2)$  value of  $23.2$  ‰ (Craig, 1957), which should be near the  $\text{O}_2$  in the chamber that was from a zero-air generator. Slight  
differences between these values could be due to kinetic isotope effects associated  $\text{RO}_2/\text{HO}_2$  reactions. In addition to  $\text{RO}_2/\text{HO}_2$   
330 radicals, the  $\text{OH}$  radical plays an important role in the photochemical formation of  $\text{HNO}_3$  and would be expected to  
proportionally transfer its O atom to the  $\text{HNO}_3$  product.

The  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  values increased in the order  $\text{pNO}_3 < \text{HNO}_3 < \text{NO}_2$ . The  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  of  $\text{NO}_2$ ,  $\text{HNO}_3$ , and  $\text{pNO}_3$  were  
sensitive to the types of experiments and their oxidant conditions. For example,  $\text{NO}_2$  samples collected during the  
335 photochemical experiments (i.e., Exp. 1-5) indicated that  $\delta^{18}\text{O}(\text{NO}_2)$  and  $\Delta^{17}\text{O}(\text{NO}_2)$  increased with the initial  $[\text{NO}_y]$ , the ratio  
of initial  $[\text{NO}_y]:[\text{BVOC}]$ , and with decreasing initial  $[\text{H}_2\text{O}_2]$ . These sensitivities to  $\delta^{18}\text{O}(\text{NO}_2)$  and  $\Delta^{17}\text{O}(\text{NO}_2)$  reflect the  
balance between NO branching ratios involving  $\text{O}_3$  vs  $\text{RO}_2/\text{HO}_2$  (Albertin et al., 2021; Walters et al., 2018). Thus, the relative  
branching ratios of  $\text{NO}+\text{O}_3$  and  $\text{NO}+\text{RO}_2/\text{HO}_2$  changed with experimental photochemical conditions, favoring a greater  
proportion of  $\text{NO}+\text{O}_3$  reactions for higher initial  $\text{NO}_y$  and lower  $[\text{H}_2\text{O}_2]$  conditions. For the nighttime oxidation experiment  
340 (Exp. 6), the  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  reflected the initial production of  $\text{N}_2\text{O}_5$  from the oxidation of  $\text{NO}_2$  (from a gas cylinder) with  $\text{O}_3$ .  
The expected  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  values can be calculated assuming  $\text{N}_2\text{O}_5$  equilibrium between  $\text{NO}_3$  and  $\text{NO}_2$  (i.e.,  $\text{N}_2\text{O}_5 \rightleftharpoons \text{NO}_2 + \text{NO}_3$ ) and using O isotope mass balance (Eq. 8):

$$\delta(\text{NO}_2) = \frac{1}{5}(\delta(\text{O}_3^{\text{term}})) + \frac{4}{5}(\delta(\text{NO}_2^{\text{tank}})) \quad (\text{Eq. 8})$$

where  $\delta$  refers to either  $\Delta^{17}\text{O}$  or  $\delta^{18}\text{O}$ ,  $\text{O}_3^{\text{term}}$  refers to the O-atom at the terminal end of  $\text{O}_3$  and  $\text{NO}_2^{\text{tank}}$  refers to the  $\text{NO}_2$  from  
345 the tank source with measured  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  values of  $-0.1 \pm 0.1 \text{ ‰}$  ( $n=3$ ) and  $13.1 \pm 0.2 \text{ ‰}$  ( $n=3$ ), respectively. Using the  
assumed  $\Delta^{17}\text{O}(\text{O}_3^{\text{term}})$  of  $39.3 \pm 2.0 \text{ ‰}$ , and the calculated  $\delta^{18}\text{O}(\text{O}_3^{\text{term}})$  incorporated into  $\text{NO}_y$  ( $106 \pm 5.0 \text{ ‰}$ ) we would estimate  
the  $\Delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  of  $\text{NO}_2$  for the nighttime oxidation experiment to be  $7.7 \pm 0.4 \text{ ‰}$  and  $31.7 \pm 1.0 \text{ ‰}$ , respectively, which was  
near their measured values from the nighttime chamber experiments of  $(7.2 \pm 0.2 \text{ ‰})$  and  $(31.9 \pm 0.7 \text{ ‰})$  ( $n = 3$ ), respectively.

350 **Fig. 1.** The observed oxygen isotope delta values of various  $\text{NO}_y$  species (i.e.,  $\text{HNO}_3$ ,  $\text{NO}_2$ , and  $\text{pNO}_3$ ) from the  $\alpha$ -pinene/ $\text{NO}_y$  oxidation experiments. A strong linear correlation (blue line) was observed between  $\delta^{18}\text{O}$  and  $\Delta^{17}\text{O}$ .

### 3.1.2 $\delta^{15}\text{N}$ of $\text{NO}_y$

The  $\delta^{15}\text{N}$  of all  $\text{NO}_y$  species exhibited a large range from  $-90.3$  to  $-4.0 \text{ ‰}$  ( $n = 47$ ) (Fig. 2). This large range of  $\delta^{15}\text{N}$  values  
355 were significantly influenced by the  $\delta^{15}\text{N}$  values of the various initial  $\text{NO}_y$  sources that included tank NO (Exp. 1-4), HONO  
(Exp. 5), and tank  $\text{NO}_2$  (Exp. 6) ( $p < 0.01$ ). The experiments using tank-NO had the lowest  $\delta^{15}\text{N}$  ( $\bar{x} \pm s$ ) of  $(-56.1 \pm 21.3 \text{ ‰}; n = 32)$ ,  
followed by tank- $\text{NO}_2$  of  $(-34.7 \pm 12.2 \text{ ‰}; n = 6)$ , and the highest average was for the HONO experiments of  $(-7.8 \pm 5.7 \text{ ‰}; n = 9)$ .  
This trend of  $\delta^{15}\text{N}$  values tracks with the initial measured or assumed  $\delta^{15}\text{N}$  source value, in which  $\delta^{15}\text{N}$  of the generated  
HONO (assumed to be  $-5.9 \pm 0.5 \text{ ‰}$ ) (Chai and Hastings, 2018) was higher than the measured  $\text{NO}_2$  tank ( $-40.9 \pm 0.2 \text{ ‰}; n = 3$ ),  
360 and the NO tank (assumed to be  $-70.0 \pm 1.4 \text{ ‰}$ ) (Fibiger et al., 2014). This finding provides evidence that  $\delta^{15}\text{N}$  can be used as  
a qualitative tracer to track  $\text{NO}_x$  emissions for sources with large differences in their emission  $\delta^{15}\text{N}$  signatures. However, the  
experiments also demonstrate large  $\delta^{15}\text{N}$  fractionation between the various  $\text{NO}_y$  species for each experiment and initial  $\text{NO}_y$   
source.

365 Overall, there were significant differences in the  $\delta^{15}\text{N}$  of the various  $\text{NO}_y$  species ( $p < 0.01$ ). Overall,  $\delta^{15}\text{N}(\text{HNO}_3)$  that averaged  $-25.9 \pm 13.0\%$  ( $n = 20$ ) were higher than  $\delta^{15}\text{N}(\text{NO}_2)$  that averaged  $-52.5 \pm 25.2\%$  ( $n = 20$ ), which were higher than  $\delta^{15}\text{N}(\text{pNO}_3)$  that averaged  $-72.6 \pm 22.9\%$  ( $n = 7$ ). This trend suggests that the produced  $\text{HNO}_3$  was associated with a positive isotope fractionation ( $\epsilon$ ) that favored the preferential formation of  $^{15}\text{N}$  into  $\text{HNO}_3$  relative to  $\text{NO}_2$ . The isotope fractionation ( $^{15}\alpha$ ) associated with  $\text{NO}_2 + \text{OH}$  has yet to be directly measured but has been predicted in the literature with large differences in the suggested value. For example,  $^{15}\alpha(\text{NO}_2 + \text{OH})$  has been suggested to be 0.997 based on the reduced mass of the transition complex (Freyer, 1991), while it has been predicted to be 1.040 in the  $i_N\text{RACM}$  mechanism (Fang et al., 2021). The higher predicted  $^{15}\alpha(\text{NO}_2 + \text{OH})$  value of 1.040 would be consistent with the trend of elevated  $^{15}\text{N}$  in  $\text{HNO}_3$  relative to  $\text{NO}_2$ . The  $\delta^{15}\text{N}(\text{pNO}_3)$  values were lower than  $\delta^{15}\text{N}(\text{NO}_2)$ . This difference compared to  $\text{HNO}_3$  provides support that the generated  $\text{pNO}_3$  did not derive from  $\text{HNO}_3$  and instead derived from another source such as organic nitrate. Conversely, the hydrolysis of  $\text{pNO}_3$  is likely not a main contributor to  $\text{HNO}_3$  due to their large  $\delta^{15}\text{N}$  differences. The low  $\delta^{15}\text{N}(\text{pNO}_3)$  values would reflect the influence of  $\text{NO}_x$  isotope exchange, which depletes  $\text{NO}$  in  $^{15}\text{N}$  relative to  $\text{NO}_2$  (Freyer et al., 1993; Li et al., 2020; Walters et al., 2016). The  $^{15}\text{N}$  depleted  $\text{NO}$  can then react with  $\alpha$ -pinene derived peroxy radicals leading to organic nitrate production with a low  $\delta^{15}\text{N}$  value relative to  $\delta^{15}\text{N}(\text{NO}_2)$ . This trend in  $\delta^{15}\text{N}(\text{NO}_y)$  followed all experiments except for the HONO experiments (Exp. 5), in which  $\delta^{15}\text{N}(\text{NO}_2)$  ( $-5.8 \pm 1.8\%$ ;  $n = 4$ ) were insignificantly different from the  $\delta^{15}\text{N}(\text{HNO}_3)$  ( $-6.2 \pm 0.7\%$ ;  $n = 4$ ) ( $p > 0.05$ ).

Fig. 2. The observed  $\delta^{15}\text{N}$  of various  $\text{NO}_y$  species (i.e.,  $\text{HNO}_3$ ,  $\text{NO}_2$ , and  $\text{pNO}_3$ ) collected during the various conducted  $\alpha$ -pinene/ $\text{NO}_y$  oxidation experiments. The measured  $\delta^{15}\text{N}$  were sorted by the various starting  $\text{NO}_y$  sources, including HONO ( $\delta^{15}\text{N} = -5.9 \pm 0.5\%$ ), tank-NO ( $\delta^{15}\text{N} = -70.0 \pm 1.4\%$ ), and tank- $\text{NO}_2$  ( $\delta^{15}\text{N} = -40.9 \pm 0.2\%$ ).

385

### 3.2 Particle Nitrate Composition

The generated pNO<sub>3</sub> could have both inorganic (i.e., HNO<sub>3</sub> condensation) and organic (i.e., organic nitrate condensation) contributions. The δ<sup>15</sup>N data would indicate that the pNO<sub>3</sub> appeared to derive from a separate source than HNO<sub>3</sub> due to their large δ<sup>15</sup>N differences, suggesting that pNO<sub>3</sub> was derived primarily from organic nitrate. We also utilized the HR-ToF-AMS NO<sup>+</sup> and NO<sub>2</sub><sup>+</sup> data to evaluate the contributions of pNO<sub>3</sub> for the experiments. The  $f(\text{pNO}_3, \text{Org})$  was calculated according to Eq. 5 for each of the conducted experiments (Table 2). Overall,  $f(\text{pNO}_3, \text{Org})$  was calculated to have a mean of (1.25 ± 0.04;  $n=8$ ), indicating that the generated pNO<sub>3</sub> derived from organic nitrate. The calculated  $f(\text{pNO}_3, \text{Org})$  was higher than 1 even when considering uncertainty estimates. This could be due to deriving  $R_{\text{ON}}$  values from previously reported  $R_{\text{ON}}/R_{\text{AN}}$  ratios from previously conducted α-pinene oxidation experimental conditions conducted utilizing substantially lower initial precursor concentrations by approximately a factor of 10 (Takeuchi and Ng, 2019). Thus, due to the potential uncertainty in our approach in estimating  $f(\text{pNO}_3, \text{Org})$ , the composition of the generated pNO<sub>3</sub> was also investigated using a qualitative approach involving evaluating the relative change in the molar ratio of NH<sub>4</sub>/SO<sub>4</sub> from the HR-ToF-AMS (Fig. S2). For each type of experiment, we found the NH<sub>4</sub>/SO<sub>4</sub> molar ratio to be consistently near 1.5. This type of NH<sub>4</sub>/SO<sub>4</sub> profile is consistent with the generated pNO<sub>3</sub> deriving from organic nitrate, as the dissolution of HNO<sub>3</sub> into aqueous aerosol followed by neutralization with available NH<sub>3</sub> would be expected to lead to an abrupt increase in the molar ratio of NH<sub>4</sub>/SO<sub>4</sub> (Takeuchi and Ng, 2019). Overall, both the quantitative and qualitative analysis of pNO<sub>3</sub> composition utilizing the AMS data as well as our δ<sup>15</sup>N data indicates that pNO<sub>3</sub> was mainly derived from organic nitrate. Hereinafter, we will assume that the NO<sub>3</sub><sup>-</sup> extracted from the filter collections derived from organic nitrate.

Table 2. Summary of the HR-ToF-AMS data including NO<sup>+</sup>/NO<sub>2</sub><sup>+</sup> fragmentation data ( $R_{\text{obs}}$ ), calculated  $f(\text{pNO}_3, \text{Org})$ , maximum pNO<sub>3</sub> ( $\text{Max}(\text{pNO}_3)$ ). Additionally, we quantified the amount of pNO<sub>3</sub> from the PILS (PILS/AMS) and the filter collection relative to the HR-ToF-AMS (Filter/AMS).

Exp.	$R_{\text{obs}} (\bar{x} \pm \sigma)$	$f(\text{pNO}_3, \text{Org}) (\bar{x} \pm \sigma)$	Max(pNO <sub>3</sub> ) (μg m <sup>-3</sup> )	PILS/AMS (%)	Filter/AMS (%)
1	3.36±0.30	1.26±0.10	13.8	41.8	97.8
1R	3.16±0.21	1.19±0.08	13.3	37.8	83.5
2	3.36±0.13	1.27±0.05	25.9	33.2	105.3
3	3.32±0.21	1.25±0.09	27.4	NA	80.5
4	3.18±0.32	1.20±0.13	25.5	42.1	75.8
4R	3.40±0.33	1.27±0.14	15.0	NA	76.1
5	3.49±0.25	1.31±0.11	24.7	NA	59.5
6	5.63±0.49	1.25±0.11	38.6	NA	7.6

The pNO<sub>3</sub> measured by the HR-ToF-AMS indicated similar profiles for the various types of conducted experiments, in which  
410 pNO<sub>3</sub> concentrations peaked and subsequently decayed due to wall loss and chamber dilution (Fig. 3). Overall, the maximum  
pNO<sub>3</sub> concentrations ranged from 13.3 to 38.6 μg m<sup>-3</sup> across the various experiments (Table 2). The lowest maximum pNO<sub>3</sub>  
corresponded to the experimental conditions with low initial NO<sub>x</sub> relative to H<sub>2</sub>O<sub>2</sub> and BVOC conditions (i.e., Exp 1). In  
contrast, the highest maximum pNO<sub>3</sub> occurred during the nighttime oxidation experiments (i.e., Exp 6). The pNO<sub>3</sub>  
concentrations determined from the HR-ToF-AMS were compared with additional measurement techniques, including the  
415 PILS and the filter collections for offline analysis (Fig. 3; Table 2). The PILS pNO<sub>3</sub> measurements were available for 4 out of  
the 8 conducted experiments and indicated a similar time profile as the HR-ToF-AMS; however, the PILS pNO<sub>3</sub> observations  
were always lower than the HR-TOF-AMS with the amount of pNO<sub>3</sub> determined from PILS relative to the HR-ToF-AMS  
(PILS/AMS) ranging between 33.2% to 53.8%. The pNO<sub>3</sub> quantified using filter collection and extraction technique was higher  
than the PILS and in closer agreement with the HR-ToF-AMS for most of the photochemical experiments. For the  
420 photochemical experiments (Exp. 1-5), the pNO<sub>3</sub> determined using the filter collection relative to the HR-ToF-AMS  
(Filter/AMS) for the photochemical experiments ranged between 59.5 to 105.3% and averaged 86.5±12.35 (n=7). However,  
the filter collection resulted in nearly negligible pNO<sub>3</sub> for the nighttime oxidation experiments (i.e., Exp. 6).

The pNO<sub>3</sub> concentrations determined using the PILS were always lower than that determined by the HR-ToF-AMS and the  
425 offline filter collection technique, which would indicate that that not all the collected pNO<sub>3</sub>, which were shown to mainly  
derive from organic nitrate, were hydrolyzed to NO<sub>3</sub><sup>-</sup>(aq) within the PILS chamber before quantification via Ion  
Chromatography. The filter collection and extraction method (i.e., leach in MQ water for 1 week), enabled the successful  
hydrolysis of the collected pNO<sub>3</sub> to NO<sub>3</sub><sup>-</sup>(aq) from the photochemical experiments, an important pre-requisite for subsequent  
isotope analysis. The filter collection technique, however, resulted in near negligible pNO<sub>3</sub> for the nighttime oxidation  
430 experiments, limiting our ability to measure the isotope composition of pNO<sub>3</sub> from this experiment. This difference in the  
efficacy of the offline filter collection technique for pNO<sub>3</sub> characterization between the photochemical and nighttime oxidation  
experiments could be related to the type of organic nitrate formed during the conducted experiments. The photochemical α-  
pinene oxidation experiments have been suggested to result in higher relative production of tertiary organic nitrate, while  
nighttime oxidation leads to a relatively lower fraction of tertiary organic nitrate with estimated values of 62% and 15%,  
435 respectively (Zare et al., 2018). Recent work has suggested a hydrolysis lifetime of no more than 30 minutes and a hydrolyzable  
portion of particulate organic nitrate from α-pinene oxidation experiments between 23-32% and 9-17% for α-pinene + OH and  
α-pinene + NO<sub>3</sub> reactions, respectively (Takeuchi and Ng, 2019). The offline filter collection and extraction technique matches  
the trend in which more pNO<sub>3</sub> hydrolyzed for the photochemical experiments compared to the nighttime; however, the filter  
technique would indicate a higher proportion of potential hydrolysable pNO<sub>3</sub> from photochemical experiment than these  
440 previous estimates, though with a different timescale. From these results and comparisons, we speculate that the pNO<sub>3</sub> offline  
filter measurements to encompass the hydrolysable portion of pNO<sub>3</sub> within a week (as the filter samples were extracted and  
leached in MQ for at least one week), while the HR-ToF-AMS measurements represent the total pNO<sub>3</sub>, and the PILS

measurements correspond to the readily hydrolysable portion of pNO<sub>3</sub>. Further, the box model simulations of organic nitrate speciation indicate that the nighttime organic nitrate was dominated by the formation of dimer, pinene dinitrate, as well as secondary hydroxyl-nitrate (Fig. S3). If this speciation is correct, the results would suggest that these types of organic nitrate were not readily hydrolysable.

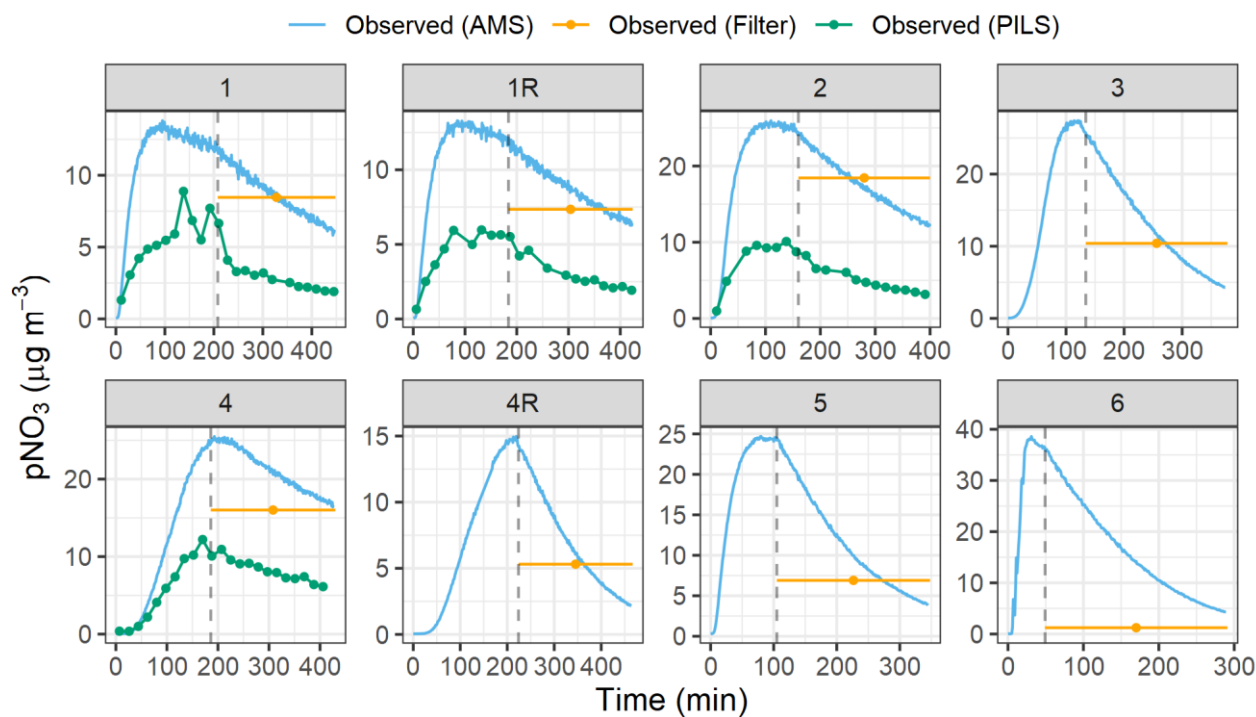

Fig. 3. The observed pNO<sub>3</sub> concentrations are faceted by the various experiments conducted. The concentrations were determined using the High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS), particle-into-liquid sampler (PILS), and filter collection (Filter). The start of the chamber dilution is indicated by the dashed vertical lines, corresponding to the abrupt decrease in pNO<sub>3</sub>.

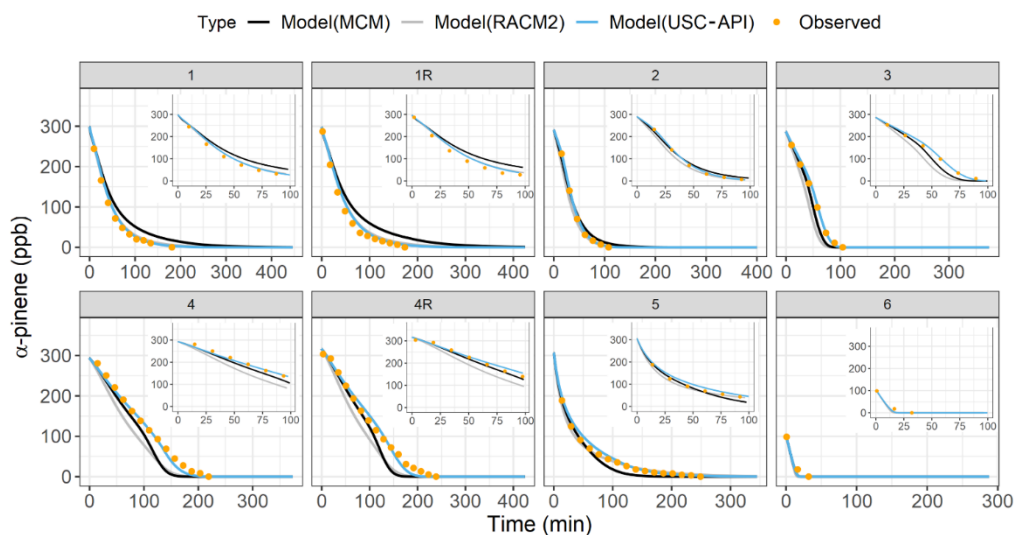

### 3.3 Model Simulations

#### 3.3.1 Precursor Decay

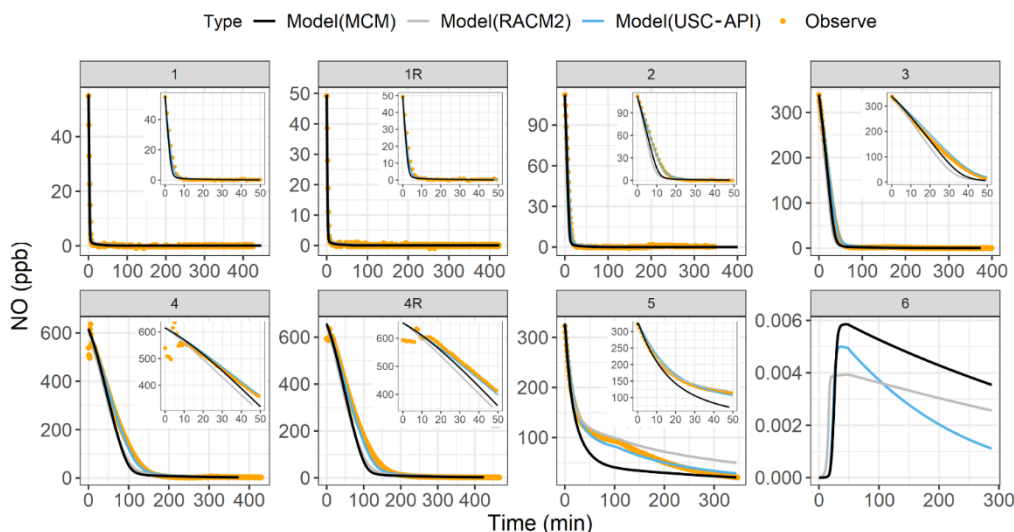

Box model simulations were conducted to evaluate the oxidation and decay of precursors used in the experiments, ensuring that the correct amount of oxidant was accurately simulated. For all the photochemical experiments, the box model utilizing the USC-API mechanism was able to well-simulate the decay of  $\alpha$ -pinene and NO for all experiments (Fig. 4-5). This comparison indicates that the developed mechanism well represents the oxidation of  $\alpha$ -pinene and formation of oxidants under

a wide range of experimental conditions. The simulations using the USC-API mechanism was a vast improvement compared to using the RACM2 or the MCM subset for  $\alpha$ -pinene chemistry for simulating NO and  $\alpha$ -pinene decay for the photochemical experiments (Exp. 1-5).

465 **Fig. 4.** The observed (orange data points) and the modeled (lines)  $\alpha$ -pinene decay for the various conducted experiments. The modeled results are based on three chemical mechanisms: MCM (black), RACM2 (grey), and USC-API (light blue). Insets highlight the initial decay period from 0 to 100 minutes.

470 **Fig. 5.** The observed (orange data points) and the modeled (lines) NO decay for the various conducted experiments. The NO observations for Experiment 6 were not available. The modeled results are based on three chemical mechanisms: MCM (black), RACM2 (grey), and USC\_API (light blue). Insets highlight the initial decay period from 0 to 50 minutes.

### 3.3.2 $\Delta^{17}\text{O}$ Simulation

The model simulations for the photochemical experiments indicate a substantial temporal change in  $\Delta^{17}\text{O}(\text{NO}_2)$  (Fig. 6). The  $\Delta^{17}\text{O}(\text{NO}_2)$  initially starts at 0‰ and begins to increase due to the production of  $\text{O}_3$  that elevate  $\Delta^{17}\text{O}(\text{NO}_2)$  as  $\text{NO}$  is oxidized by  $\text{O}_3$ . For the nighttime experiment, the box model predicts  $\Delta^{17}\text{O}(\text{NO}_2)$  to remain steady with a value near 7.6‰, due to  $\text{N}_2\text{O}_5$  thermal equilibrium with  $\text{NO}_2$  and  $\text{NO}_3$  resulting in the  $\Delta^{17}\text{O}(\text{NO}_2) = \Delta^{17}\text{O}(\text{N}_2\text{O}_5)$ . Generally, the  $\Delta^{17}\text{O}$  simulation of  $\text{NO}_2$  were in excellent agreement with the observations, as indicated by an RMSE of 1.7‰ (Table 3). Considering the range of observed  $\Delta^{17}\text{O}(\text{NO}_2)$  values that spanned 34.2‰, the model RMSE value is quite exceptional. This strong agreement indicates that the box model and employed chemical mechanism well-represented the  $\text{NO}_x$  photochemical cycling and  $\text{NO}_2/\text{NO}_3/\text{N}_2\text{O}_5$  thermal equilibrium. Further, our model analysis would indicate that an assumed  $\Delta^{17}\text{O}(\text{O}_3^{\text{term}})$  value of 39‰, well-simulated the  $\Delta^{17}\text{O}(\text{NO}_2)$  values across a range of experimental conditions. The strong agreement between the model and observations supports the robustness of our chemical mechanism in representing the critical oxidation processes and isotope transfer within the  $\text{NO}_x$  system. Additionally, the model's capability to simulate  $\Delta^{17}\text{O}(\text{NO}_2)$  under both photochemical and nighttime conditions highlights its effectiveness in capturing the transition between photochemical and thermal equilibrium pathways in  $\text{NO}_x$  chemistry. For the nighttime experiment, the steady  $\Delta^{17}\text{O}(\text{NO}_2)$  further confirms the model's accurate depiction of the equilibrium between  $\text{NO}_2$ ,  $\text{NO}_3$ , and  $\text{N}_2\text{O}_5$ , an essential aspect of nighttime  $\text{NO}_x$  processing. This result indicates that the model is well-suited to describe isotope dynamics in environments with varying  $\text{NO}_x$  levels and oxidant influences.

The simulated  $\Delta^{17}\text{O}(\text{pNO}_3)$  using the base mechanism closely matched the observations with an average RMSE of 1.2‰, indicating that the relative production routes of organic nitrate ( $+\text{OH}/\text{O}_2/\text{NO}$  vs  $+\text{NO}_3$ ) were correctly simulated for the various experimental conditions (Fig. 7). Oxygen isotope mass-balance indicates that the  $\alpha$ -pinene-derived peroxy radicals +  $\text{NO}$  pathway would be the expected pathway led to a low  $\Delta^{17}\text{O}(\text{pNO}_3)$  value as only one oxygen atom in the nitro group of the generated  $\text{RONO}_2$  could derive from  $\text{O}_3$ . In contrast, the  $\alpha$ -pinene oxidation involving  $\text{NO}_3$  leading to organic nitrate would be the pathway leading to a high  $\Delta^{17}\text{O}(\text{pNO}_3)$  value as all of the oxygen atoms in the  $\text{NO}_3$  group could derive from  $\text{O}_3$  (Walters et al., 2024a). The excellent agreement between model and observation indicates that the developed chemical mechanism generally well-reproduced organic nitrate formation pathways involving  $\alpha$ -pinene for the conducted photochemical experiments. Overall, the excellent agreement between model and observation for  $\Delta^{17}\text{O}(\text{pNO}_3)$  provides confidence in the model's representation of organic nitrate formation involving  $\alpha$ -pinene across diverse photochemical conditions. It suggests that the model's parameterization of  $\alpha$ -pinene oxidation pathways and the resulting isotope fractionation effects on  $\text{pNO}_3$  is well-calibrated, supporting its utility for simulating organic nitrate formation and its impact on aerosol chemistry.

The simulated  $\Delta^{17}\text{O}$  of  $\text{HNO}_3$  (Fig. 8) begins at 26‰, reflecting the assumed  $\Delta^{17}\text{O}$  value of an  $\text{HNO}_3$  chamber blank. This initial value was not directly measured but was estimated to achieve agreement with the measured  $\Delta^{17}\text{O}$  of  $\text{HNO}_3$  in Exp. 1 and Exp. 2, where  $\text{HNO}_3$  production was relatively low (Fig. S1). At the onset of the experiment,  $\Delta^{17}\text{O}(\text{HNO}_3)$  decreases as

newly formed HNO<sub>3</sub>, which has a  $\Delta^{17}\text{O}$  lower than the chamber blank value, begins to dominate. For Exp. 1, 2, and 6,  $\Delta^{17}\text{O}(\text{HNO}_3)$  continues to decrease over time, eventually reaching a plateau as HNO<sub>3</sub> production ceases. In contrast, for Exp. 3, 4, and 5, after an initial decline in  $\Delta^{17}\text{O}(\text{HNO}_3)$ , the values begin to rise. This increase is driven by the production of HNO<sub>3</sub> with higher  $\Delta^{17}\text{O}$  values, resulting from elevated  $\Delta^{17}\text{O}(\text{NO}_2)$  associated with the buildup of O<sub>3</sub>. Overall, the simulated  $\Delta^{17}\text{O}(\text{HNO}_3)$  is proportional to the maximum  $\Delta^{17}\text{O}(\text{NO}_2)$ , reflecting the dilution of  $\Delta^{17}\text{O}(\text{NO}_2)$  in additional NO<sub>y</sub> products due to the incorporation of O atoms from oxidants other than O<sub>3</sub>. Overall, the model does a poor job of capturing  $\Delta^{17}\text{O}(\text{HNO}_3)$  relative to observations, with an average RMSE of 4.6‰ compared to an observed range of 8.2‰. The model reasonably aligns with observations for the Exp. 1 and 2, where measurements were influenced by a chamber blank or HNO<sub>3</sub> carry-over effect, assumed to have a  $\Delta^{17}\text{O}(\text{HNO}_3)$  value of 26‰. However, for the high initial NO<sub>x</sub> concentration experiments (Exp. 3, 4, and 5), the simulated  $\Delta^{17}\text{O}(\text{HNO}_3)$  was consistently too high. In the high HNO<sub>3</sub> production experiments (Exp. 4 and 5), the influence of a potential chamber HNO<sub>3</sub> blank was negligible due to the large amount of HNO<sub>3</sub> produced (Fig. S1). Here, the discrepancies between measured and modeled  $\Delta^{17}\text{O}(\text{HNO}_3)$  suggest a missing or under-accounted HNO<sub>3</sub> production pathway. Based on oxygen isotope mass-balance expectations, we identified two potential pathways that could yield a lower  $\Delta^{17}\text{O}(\text{HNO}_3)$  than the dominant NO<sub>2</sub>+OH channel, which has a  $\Delta^{17}\text{O}$  transfer factor of  $(2/3)(\Delta^{17}\text{O}(\text{NO}_2))$  (Alexander et al., 2020). First, the NO + HO<sub>2</sub> reaction was considered as a possible source of low- $\Delta^{17}\text{O}(\text{HNO}_3)$ , with a  $\Delta^{17}\text{O}$  transfer factor of  $(1/3)(\Delta^{17}\text{O}(\text{NO}))$  (Alexander et al., 2020). However, this reaction is unlikely to explain the model mismatch since HO<sub>2</sub> levels were low in Exp 5. Second, organic nitrate hydrolysis could be a possible source of low- $\Delta^{17}\text{O}$  HNO<sub>3</sub>, especially if derived from +OH/NO reactions with a  $\Delta^{17}\text{O}$  transfer factor of  $(1/3)(\Delta^{17}\text{O}(\text{NO}))$  (Walters et al., 2024a). This source of HNO<sub>3</sub> would not be consistent with the  $\delta^{15}\text{N}$  data of HNO<sub>3</sub> and pNO<sub>3</sub>, which indicated large differences suggesting that these molecules were not related (Fig. 2). Still, to test this hypothesis, we conducted a sensitivity analysis allowing pinene hydroxyl-nitrate, pinene carbonyl nitrate, and pinene nitrooxy-hydroperoxide to hydrolyze with a lifetime of 2 hours (Table S3). We did not enable the dimer or pinene dinitrate to hydrolyze since these were dominant organic nitrate formed during nighttime oxidation, which we found minimal hydrolysis to occur from the filter extracts (Fig. 3). This modified simulation, "USC\_API\_Hydro," slightly improved the  $\Delta^{17}\text{O}(\text{HNO}_3)$  agreement for Exp. 3, 4, and 5, reducing the average RMSE from 5.5‰ in the base model to 3.8‰ in the updated model (Table 3). However, for experiments with low-medium initial NO<sub>x</sub> concentration (Exp. 1 and 2), organic nitrate hydrolysis resulted in a higher RMSE (6.3‰) compared to the base model (1.9‰). Organic nitrate hydrolysis had minimal impact on  $\Delta^{17}\text{O}(\text{NO}_2)$  but did affect  $\Delta^{17}\text{O}(\text{pNO}_3)$ , particularly in high initial NO<sub>x</sub> concentration experiments. Specifically, including this pathway decreased model performance for  $\Delta^{17}\text{O}(\text{pNO}_3)$  in Exp. 3 and 4, though it improved the fit for Exp. 5. Overall, despite considering hydrolysis of organic nitrate to HNO<sub>3</sub>, the simulated  $\Delta^{17}\text{O}(\text{HNO}_3)$  for Exp. 4 and 5 remained too high to match observations and was not improved by decreasing the hydrolysis lifetime.

Therefore, based on our oxygen-isotope mass-balance framework, we were unable to identify a suitable missing or under-constrained HNO<sub>3</sub> production source in the model to explain the relatively low observed  $\Delta^{17}\text{O}(\text{HNO}_3)$  in high-NO<sub>y</sub> experiments. Thus, we speculate that the collected HNO<sub>3</sub> in high initial NO<sub>x</sub> experiments (Exp. 4 and 5) may not fully represent

540 HNO<sub>3</sub> produced under experimental conditions. While we would not expect  $\Delta^{17}\text{O}$  fractionation if HNO<sub>3</sub> were incompletely  
 collected by the denuder system, our results may be biased toward HNO<sub>3</sub> produced earlier in the experiments when  
 $\Delta^{17}\text{O}(\text{HNO}_3)$  is expected to be lower (Fig. 8). Although our collection method yielded consistent and precise  $\Delta^{17}\text{O}(\text{HNO}_3)$   
 values across repeat experiments (Blum et al., 2023), the accuracy of these values remains uncertain. These findings suggest  
 that an alternative HNO<sub>3</sub> collection method may be necessary to more accurately characterize  $\Delta^{17}\text{O}(\text{HNO}_3)$  in chamber  
 545 experiments.

Overall, the results of the  $\Delta^{17}\text{O}$  model simulations offer detailed insights into the oxidation chemistry dynamics associated  
 with NO<sub>x</sub> and  $\alpha$ -pinene under varied photochemical and nighttime conditions. The model effectively captured the oxidation  
 dynamics associated with NO<sub>2</sub> photochemical cycling and nighttime equilibrium as well as captured the chemistry associated  
 550 with organic nitrate formation. However, the model displayed limitations in simulating  $\Delta^{17}\text{O}(\text{HNO}_3)$ , particularly for  
 experiments with high initial NO<sub>x</sub> conditions where the observed values were lower than predicted. Sensitivity analyses  
 suggested that inclusion of additional HNO<sub>3</sub> formation pathways such as organic nitrate hydrolysis could partially improve the  
 model's accuracy though further refinement is necessary and suggesting a potential artifact associated with HNO<sub>3</sub> collection.

555

**Table 3. Summary of the calculated average RMSE for the  $\Delta^{17}\text{O}$  model simulations using the USC-API chemistry and inclusion of organic nitrate hydrolysis (USC-API-Hydro) mechanism.**

Exp	$\Delta^{17}\text{O}(\text{NO}_2)$ (‰)			$\Delta^{17}\text{O}(\text{pNO}_3)$ (‰)			$\Delta^{17}\text{O}(\text{HNO}_3)$ (‰)

575 **Fig. 8. Comparison between the modeled and observed  $\Delta^{17}\text{O}(\text{HNO}_3)$  values sorted by the various conducted experiments. The data points represent the average experiment time for each denuder collection, with the black line span the collection time range (from start to stop). The measurement uncertainty ( $\pm\sigma$ ) is included as the lighter grey shaded region. The model simulations include both the base model (USC-API) and considering the potential role of organic nitrate hydrolysis (USC-API-Hydro). The  $\Delta^{17}\text{O}(\text{HNO}_3)$  is initially set at 26%, based on the assumption that the  $\text{HNO}_3$  “chamber blank” had this value.**

### 580 3.3.3 $\delta^{15}\text{N}$ Simulation

The  $\delta^{15}\text{N}$  simulations using the base chemistry mechanism indicate intriguing isotope dynamics (Fig. 9). Generally, the simulated  $\delta^{15}\text{N}(\text{NO}_2)$  quickly increases at the start of the experiment due to the  $\text{NO}/\text{NO}_2$  isotope exchange with a large isotope fractionation factor which preferentially favors the partitioning of  $^{15}\text{N}$  into  $\text{NO}_2$  relative to  $\text{NO}$ . For the photochemical experiments, as  $\text{NO}_2$  is converted to  $\text{HNO}_3$ , the  $\delta^{15}\text{N}(\text{NO}_2)$  decreases due to the assumed isotope fractionation associated with the  $\text{NO}_2 + \text{OH}$  reaction of 1.040 (Fang et al., 2021), favoring the preferential transfer of  $^{15}\text{N}$  into the  $\text{HNO}_3$  product. This also leads to the model predicting higher  $\delta^{15}\text{N}(\text{HNO}_3)$  relative to  $\text{NO}_2$ , as the  $\text{NO}_2 + \text{OH}$  was the dominant reaction pathway for  $\text{HNO}_3$  production in the photochemical experiments. The  $\delta^{15}\text{N}(\text{pNO}_3)$  initially starts near the starting  $\delta^{15}\text{N}(\text{NO})$  value as  $\alpha$ -pinene-derived peroxy radicals +  $\text{NO}$  was the main simulated formation pathway for the photochemical experiments. Due to the  $\text{NO}/\text{NO}_2$  isotope equilibrium reaction, the  $\delta^{15}\text{N}(\text{NO})$  decreases relative to  $\delta^{15}\text{N}(\text{NO}_x)$  as  $^{15}\text{N}$  preferentially partitions into  $\text{NO}_2$ . This causes the low  $\delta^{15}\text{N}$  of the formed  $\text{pNO}_3$ , which was derived from organic nitrate, relative to the other measured  $\text{NO}_y$  components.

Overall, the  $\delta^{15}\text{N}(\text{NO}_2)$  simulation using the base chemistry model had decent agreement with the observations with an RMSE of 8.9%; however, large disagreements were observed for photochemical experiments with elevated initial  $\text{NO}_y$  (Fig. 9; Table 4). For these experiments (Exp. 3-5), the simulated  $\delta^{15}\text{N}(\text{NO}_2)$  were much lower than observed and the model predicted a

substantial decrease in  $\delta^{15}\text{N}(\text{NO}_2)$  as the experiment progresses which was not observed. The photochemical cycling involving  $\text{NO}_x$  was well-simulated using the model chemistry as evidenced by a strong concentration and  $\Delta^{17}\text{O}$  agreement between observations and model. It is inherently more challenging to model  $\delta^{15}\text{N}$  compared to  $\Delta^{17}\text{O}$  of  $\text{NO}_y$  compounds. This is due to mass-dependent fractionation that can have a significant impact on  $\delta^{15}\text{N}$  values, which is largely assumed in the adapted  $i_{\text{N}}\text{RACM}$  mechanism (Fang et al., 2021). Therefore, we speculate that the  $\delta^{15}\text{N}(\text{NO}_2)$  model disagreement could be due to inaccurate nitrogen fractionation utilized within  $i_{\text{N}}\text{RACM}$ . The model simulation predicted a substantial decrease in  $\delta^{15}\text{N}(\text{NO}_2)$  as the experiments progressed due to the large nitrogen isotope fractionation factor or KIE associated with the  $\text{NO}_2 + \text{OH}$  reaction assumed in the  $i_{\text{N}}\text{RACM}$  mechanism to be 1.040 (Fang et al., 2021), defined as (Eq. 9):

$$605 \quad KIE = {}^{15}\alpha = \frac{{}^{15}\text{NO}_2 + \text{OH}}{{}^{14}\text{NO}_2 + \text{OH}} \quad (\text{Eq. 9})$$

Previously, the KIE associated with this reaction has been estimated to be 0.997 based on the reduced masses in the transition complex (Freyer, 1991). Therefore, we also conducted additional  $\delta^{15}\text{N}$  simulations using a KIE (or  ${}^{15}\alpha$ ) for the  $\text{NO}_2 + \text{OH}$  reaction of 0.997 (Fig. 6), noted as the USC-API-KIE. The modified  $\delta^{15}\text{N}(\text{NO}_2)$  simulations, using the adjusted  $\text{NO}_2 + \text{OH}$  KIE, resulted in a better agreement with the observations decreasing the RMSE from 8.9 to 2.6 ‰ (Table 4). Considering the large range of  $\delta^{15}\text{N}(\text{NO}_2)$  observations that spanned 72.2‰, the modified  $\delta^{15}\text{N}(\text{NO}_2)$  simulations are in close agreement (within 4%) of the observations. Further, the modified simulations indicated that  $\delta^{15}\text{N}(\text{NO}_2)$  temporal simulation better matched the observations for the photochemical experiments with high initial  $\text{NO}$  concentrations (Exp 3-5) (Fig. 9). Overall, based on a comparison of measured to simulated  $\delta^{15}\text{N}(\text{NO}_2)$ , the  $\text{NO}_2 + \text{OH}$  KIE was best approximated using a value of 0.997, enabling the accurate simulation of  $\delta^{15}\text{N}(\text{NO}_2)$ .

615 Generally, the simulated  $\delta^{15}\text{N}(\text{pNO}_3)$  values were in close agreement with the observations with an RMSE of 5.0‰ for the base simulations (Fig. 10; Table 4), especially considered the measurement uncertainty that was as high as 4.1‰ due to a significant filter  $\text{NO}_3^-$  blank. The modified  $\delta^{15}\text{N}$  simulations using the adjusted  $\text{NO}_2 + \text{OH}$   ${}^{15}\alpha$  of 0.997 slightly decreased the RMSE of  $\delta^{15}\text{N}(\text{pNO}_3)$  to 4.5%. The simulated  $\delta^{15}\text{N}(\text{pNO}_3)$  were insensitive to the adjustments for  $\text{NO}_2 + \text{OH}$  KIE because the organic nitrate formed relatively quickly under the experimental conditions before significant influence of the  $\text{NO}_2 + \text{OH}$  isotope effect on the residual  $\delta^{15}\text{N}(\text{NO}_x)$ . Overall, this excellent  $\delta^{15}\text{N}$  comparison indicates that the adapted  $i_{\text{N}}\text{RACM}$  mechanism well-describes the fractionation associated with  $\text{NO} + \alpha$ -pinene derived peroxy radicals. This result validates the mechanism's utility for modeling  $\delta^{15}\text{N}$  values in similar organic-influenced photochemical environments.

625 In contrast to  $\delta^{15}\text{N}(\text{NO}_2)$  and  $\delta^{15}\text{N}(\text{pNO}_3)$ , the model struggled to accurately simulate the  $\delta^{15}\text{N}(\text{HNO}_3)$  observations with an RMSE of 12.5‰ for the base model simulation (Fig. 11; Table 4). The modified  $\delta^{15}\text{N}$  simulations that included an update to  $\text{NO}_2 + \text{OH}$   ${}^{15}\alpha$  to 0.997, led to worse agreement between the model and observed  $\delta^{15}\text{N}(\text{HNO}_3)$  values with an RMSE of 24.1‰. Notably, the modified  $\delta^{15}\text{N}$  model mechanism simulations significantly improved the model  $\delta^{15}\text{N}(\text{HNO}_3)$  agreement with observations for the HONO experiments, which were too high in the base model simulations (Fig. 11). However, the modified

630 mechanism led to a worse agreement between the simulated  $\delta^{15}\text{N}(\text{HNO}_3)$  and observations for the photochemical experiments involving  $\text{H}_2\text{O}_2$  and  $\text{NO}$  (Exp 1-4). We speculate that these differences could be due to sampling artifacts or  $\text{HNO}_3$  loss on the chamber wall and/or sampling inlets, consistent with our findings for the  $\Delta^{17}\text{O}(\text{HNO}_3)$  simulations. These artifacts highlight the challenges associated with accurately capturing  $\delta^{15}\text{N}(\text{HNO}_3)$  in chamber studies, where wall effects and sampling techniques may interfere with precise isotopic measurements.

635

Our model comparison highlights the complexity of simulating nitrogen isotope dynamics in atmospheric chamber experiments. The improved  $\delta^{15}\text{N}(\text{NO}_2)$  agreement with an adjusted KIE value for  $\text{NO}_2 + \text{OH}$  highlights the sensitivity of nitrogen isotopes to specific fractionation processes. While  $\delta^{15}\text{N}(\text{pNO}_3)$  simulations were robust to changes in KIE, indicating the stability of iNRACM's treatment of  $\text{NO} + \text{organic peroxy radical}$  interactions, the  $\delta^{15}\text{N}(\text{HNO}_3)$  simulations revealed 640 limitations in both base and modified models. The findings suggest that additional factors, such as chamber wall interactions, may need to be considered to improve  $\delta^{15}\text{N}(\text{HNO}_3)$  model performance. Future studies should prioritize refining isotopic fractionation factors, especially for reactions involving reactive nitrogen oxides and hydroxyl radicals, to better capture nitrogen isotope variability in photochemical environments. Additionally, advancements in experimental setups to mitigate sampling artifacts could enhance the reliability of  $\delta^{15}\text{N}$  measurements, thereby improving model accuracy for nitrogen isotopic 645 compositions in complex photochemical systems.

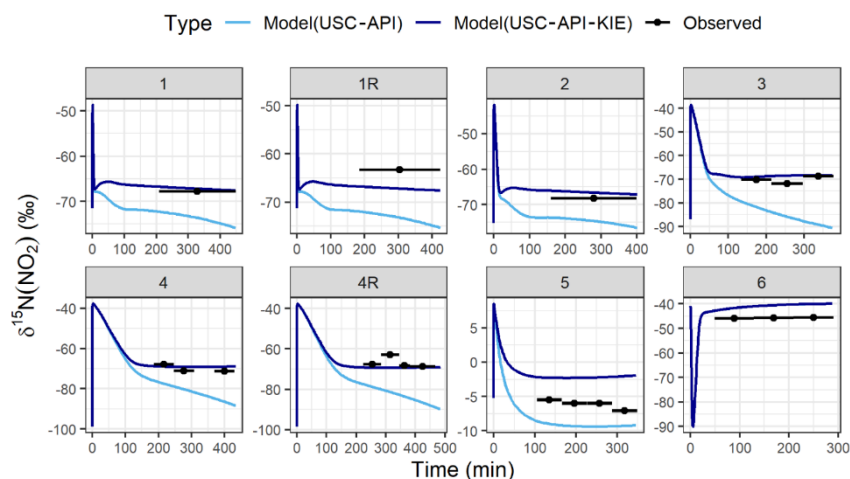

**Table 4. Summary of the calculated average RMSE for the  $\delta^{15}\text{N}$  model simulations using the base chemistry (USC-API) and the KIE mechanism (USC-API-KIE), which includes an updated  $^{15}\alpha$  for the  $\text{NO}_2+\text{OH}$  reaction of 0.997.**

## 5. Conclusion

This study provides a comprehensive investigation of  $\text{NO}_x$  and BVOC oxidation chemistry using stable isotope analyses and chemical modeling. Through  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  observations compared to model simulation, we gained critical insights into  $\Delta^{17}\text{O}$  transfer dynamics involved  $\text{NO}_x$  oxidation chemistry and nitrogen isotope fractionation. By adopting a  $\Delta^{17}\text{O}$  value for  $\text{O}_3^{\text{term}}$  of 39%, our model utilizing a recently developed  $\Delta^{17}\text{O}$  transfer framework successfully reproduced  $\Delta^{17}\text{O}$  values for  $\text{NO}_2$  across diverse environmental conditions, affirming the robustness of the photochemical understanding of  $\Delta^{17}\text{O}$  transfer dynamics. Furthermore, under the experimental conditions, we derived a  $\delta^{18}\text{O}$  value of  $106 \pm 5\%$  for oxygen atoms transferred into  $\text{NO}_y$  from the  $\text{O}_3^{\text{term}}$ , and a value of  $11.8 \pm 1.0\%$  for oxygen atoms transferred from other oxidants, such as  $\text{RO}_2$ ,  $\text{HO}_2$ , and  $\text{OH}$ . Moreover, we found that the recently developed  $\text{INRACM}$  model framework for simulating  $\delta^{15}\text{N}$  was significantly improved by adopting a  $^{15}\alpha = 0.997$  for the  $\text{NO}_2 + \text{OH}$  reaction, leading to better agreement with  $\delta^{15}\text{N}(\text{NO}_2)$ . This result highlights the importance of refining fractionation assumptions in isotope-based chemical mechanisms. However, the updated fractionation factor introduced challenges in accurately simulating  $\delta^{15}\text{N}$  values for  $\text{HNO}_3$ , highlighting persistent uncertainties in the sampling and modeling of  $\text{HNO}_3$  under the experimental conditions.

Our development of the USC-API mechanism marked a substantial advancement over existing frameworks such as RACM2 and MCM for describing  $\text{NO}_x$  and BVOC oxidation. This mechanism not only captured  $\text{NO}_x$  photochemical cycling and  $\alpha$ -pinene decay dynamics but also provided accurate simulations of organic nitrate production. One of the major implications of this mechanism is that the weighted branching ratio of  $\alpha$ -pinene+OH+NO leading to organic nitrate versus  $\text{NO}_2$  production was set to 0.222 based on the MCM, which led to the correct photochemical dynamics involving  $\text{NO}_x$ , which was evaluated using  $\Delta^{17}\text{O}$ . The mechanism further clarified the roles of daytime  $\alpha$ -pinene+OH+NO reactions versus nighttime  $\alpha$ -pinene+ $\text{NO}_3$  reactions contributing to organic nitrate production. Our model and result comparisons indicate instances where the  $\alpha$ -pinene+ $\text{NO}_3$ +  $\text{HO}_2$  pathway significantly contributed to organic nitrate production during photochemical experiments. This nuanced understanding of organic nitrate formation has implications for atmospheric  $\text{NO}_x$  budgets and SOA production.

Isotope observations and model simulation revealed stark differences between  $\text{HNO}_3$  (medium-high  $\Delta^{17}\text{O}$  and high  $\delta^{15}\text{N}$ ) and particulate nitrate ( $\text{pNO}_3$ ; low  $\Delta^{17}\text{O}$  and low  $\delta^{15}\text{N}$ ), indicating distinct formation pathways. Our findings strongly suggest that  $\text{pNO}_3$  in these experiments originated exclusively from organic nitrate, a conclusion supported by online AMS data. Furthermore, the  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  evidence demonstrated that organic nitrate hydrolysis was not a major source of  $\text{HNO}_3$  under the studied conditions, which predominantly involved low relative humidity. These insights offer new opportunities to probe  $\text{pNO}_3$  hydrolysis and its implications for nitrate chemistry under varying environmental conditions. Despite these advances, limitations in accurately modeling  $\Delta^{17}\text{O}$  and  $\delta^{15}\text{N}$  values for  $\text{HNO}_3$  highlighting the need for improved collection methodologies. Experimental artifacts, potentially linked to the use of long sampling lines and  $\text{HNO}_3$  losses in chamber experiments, may have biased the collected data. These methodological challenges indicate the importance of refining sampling techniques for  $\text{HNO}_3$  in chamber experiments to ensure representative measurements in future studies.

The implications of this work extend beyond the laboratory setting. Stable isotope techniques demonstrated their potential as powerful tools for probing complex  $\text{NO}_x$  and BVOC interactions and atmospheric oxidation chemistry. Future research should aim to expand these methodologies to other BVOC systems under a wider array of conditions, including variations in relative humidity, aerosol seed composition, and oxidant availability. Furthermore, integrating isotope techniques into field campaigns could provide invaluable constraints on  $\text{NO}_x$  oxidation and organic nitrate formation processes in real-world atmospheric environments. Overall, this study not only advances our understanding of the oxygen and nitrogen stable isotope dynamics involved in  $\text{NO}_x$  oxidation chemistry, but also provide insights into  $\text{NO}_x$  and BVOC chemistry. Addressing the limitations identified here and applying these techniques across broader contexts will enhance the predictive power of atmospheric chemistry models, aiding in the development of more effective air quality management strategies and climate policies.

*Code and Data availability.* The box model simulations, including model mechanisms, input files, and output files have been made publicly available at: <https://zenodo.org/records/14241585>. The experimental data and figure codes have been made

publicly available at: <https://zenodo.org/records/14241591>. The chemical mechanism and isotope data are provided in the Supplementary Material.

725 *Author contributions.* WWW, MT, NLN, MGH designed the conducted experiments. WWW, MT, DEB, GE, PT, WX, JR, FL, GH, JBM conducted the experiments. WWW and DEB conducted the offline data analysis. WWW conducted the chamber simulations with input from MGH, MT and NLN. WWW wrote the manuscript with input from all authors. WWW and MGH secured funding.
