

45 **Abstract**

46 Constraining dust models to understand and quantify the effect of dust upon climate and ecosystems  
47 requires comprehensive analyses of the physiochemical properties of dust-emitting sediments in arid  
48 regions. Building upon previous studies in the Moroccan Sahara and Iceland, we analyse a diverse set  
49 of crusts and aeolian ripples (n=55) from various potential dust-emitting basins within the Mojave  
50 Desert, California, USA. Our focus is on characterizing particle size distribution (PSD), mineralogy,  
51 aggregation/cohesion state and Fe mode of occurrence. Our results show differences in fully and  
52 minimally dispersed PSDs, with crusts exhibiting average median diameters of 92 and 37  $\mu\text{m}$ ,  
53 respectively, compared to aeolian ripples with 226 and 213  $\mu\text{m}$ , respectively. Mineralogical analyses  
54 unveiled strong variations between crusts and ripples, with crusts being enriched in phyllosilicates (24  
55 vs 7.8 %), carbonates (6.6 vs 1.1 %), Na-salts (7.3 vs 1.1 %) and zeolites (1.2 and 0.12 %), and ripples  
56 being enriched in feldspars (48 vs 37 %), quartz (32 vs 16 %), and gypsum (4.7 vs 3.1 %). The size  
57 fractions from crust sediments display a homogeneous mineralogy, whereas those of aeolian ripples  
58 more heterogeneity, mostly due to different particle aggregation. Bulk Fe content analyses indicate  
59 higher concentrations in crusts ( $3.0 \pm 1.3$  wt %) compared to ripples ( $1.9 \pm 1.1$  wt %), with similar  
60 proportions in their Fe mode of occurrence: nano Fe-oxides/readily exchangeable Fe represent  $\sim 1.6$   
61 %, hematite/goethite  $\sim 15$  %, magnetite/maghemite  $\sim 2.0$  % and structural Fe in silicates  $\sim 80$  % of the  
62 total Fe. We identified segregation patterns in PSD and mineralogy differences in Na-salts content  
63 within the Mojave basins, which can be explained by sediment transportation dynamics and  
64 precipitates due to groundwater table fluctuations described in previous studies in the region. Mojave  
65 Desert crusts show similarities with previously sampled crusts in the Moroccan Sahara in terms of PSD  
66 and readily exchangeable Fe, yet exhibit substantial differences in mineralogical composition, which  
67 should significantly influence the characteristic of the emitted dust particles.

68

70 mineralogy.

## 71 **1. Introduction**

72 Desert dust produced by wind erosion of arid and semi-arid surfaces has significant effects on climate,  
73 ecosystems and health (Weaver et al., 2002; Goudie & Middleton, 2006; Sullivan et al., 2007;  
74 Crumeyrolle et al., 2008; De Longeville et al., 2010; Karanasiou et al., 2012; Pérez García-Pando et al.,  
75 2014; among others). Dust affects the energy and water cycles through its absorption and scattering  
76 of both shortwave (SW) and longwave (LW) radiation (Perez et al., 2006; Miller et al., 2014), and exerts  
77 influence on cloud formation, precipitation patterns, and the associated indirect radiative forcing by  
78 serving as nuclei for liquid and ice clouds (e.g. Harrison et al., 2019). Dust also undergoes  
79 heterogeneous chemical reactions in the atmosphere that enhance their hygroscopicity and modify  
80 their optical properties (Bauer et al., 2005), and when deposited into ocean waters, its bioavailable  
81 iron content acts as a catalyst for photosynthesis by ocean phytoplankton, thereby increasing carbon  
82 dioxide uptake and influencing the global carbon cycle (Jickells et al., 2005). Dust primarily originates  
83 from arid inland basins, which include various sedimentary environments such as aeolian deposits,  
84 endorheic depressions, and fluvial- and alluvial-dominated systems (Bullard et al., 2011). Wind  
85 typically mobilizes loose sand from adjacent ripples or dunes, which then erodes more consolidated  
86 surfaces, typically paved sediments and crusts, to release dust (Stout and Lee, 2003; Shao et al., 2011).  
87 Atmospheric dust emission models have improved by identifying preferential dust sources using  
88 criteria like topography and hydrology (Ginoux et al., 2001). However, these models still struggle with  
89 capturing small-scale variability partly due to the lack of relevant soil measurements in arid regions,  
90 despite advancements in understanding the geomorphological and sedimentological factors  
91 influencing dust emissions (Bullard et al., 2011). For instance, the particle size distribution (PSD) and  
92 cohesion of the sediments affect saltation bombardment and aggregate disintegration processes  
93 involved in dust emission (Shao et al., 1993).

94 Understanding the mineral composition of dust is also crucial for assessing its climate impact. Dust  
95 contains various minerals such as quartz, clay minerals, feldspars, carbonates, salts, and iron oxides.  
96 The climate effects of dust are influenced by these minerals' relative abundances, sizes, shapes, and  
97 mixing states. For example, iron oxides control solar radiation absorption by dust (Formenti et al.,  
98 2014; Engelbrecht et al., 2016; Di Biagio et al., 2019; Zubko et al., 2019), nano Fe oxides and easily  
99 exchangeable Fe increase the fertilising effect of dust in ocean and terrestrial ecosystems  
100 (Hettiarachchi et al., 2019; Baldo et al., 2020, Hettiarachchi et al., 2020), K-feldspar and quartz impact  
101 ice nucleation in clouds (Atkinson et al., 2013; Harrison et al., 2019; Chatziparaschos et al., 2023), and  
102 calcite influences acid reactions on dust surfaces (Paulot et al., 2016). The mineralogical composition  
103 of dust can vary significantly across different regions due to geological and climatic factors (Claquin et  
104 al., 1999; Journet et al., 2014). However, most models assume a globally uniform dust composition  
105 due to limited global data on parent soil sources. Only a few models account for dust mineralogical  
106 composition variations (e.g., Scanza et al., 2015; Perlwitz et al., 2015; Li et al., 2021; Gonçalves Ageitos  
107 et al., 2023; Obiso et al., 2024) by using global soil type atlases that are based on the extrapolation of  
108 a limited number of soil analyses (Claquin et al., 1999; Journet et al., 2014). These atlases rely on  
109 assumptions about soil texture and colour, often base their data on soil samples taken from depths  
110 deeper than those relevant to wind erosion, and the method used to characterize particle size and  
111 associated mineralogy fully breaks down natural soil aggregates.

112 Since 2022, the EMIT mission has been acquiring comprehensive measurements of surface  
113 mineralogical composition for use in Earth System models (Green et al., 2020). EMIT employs imaging

114 spectroscopy across the visible to short wavelength infrared (VSWIR) spectral range from the  
115 International Space Station to map the occurrence and estimate the abundance of ten key dust source  
116 minerals. Additionally, EMIT has the potential to estimate surface soil texture. While identifying  
117 dominant surface minerals has traditionally been a strength of spectrometers, quantifying these  
118 minerals poses significant challenges. Factors such as mineral grain size and composition can affect  
119 spectral absorptions, certain dominant materials like quartz and feldspar exhibit minimal absorption  
120 features, and the presence of other materials can further complicate the analysis.

121 Overall, there is a notable lack of comprehensive measurements characterizing relevant properties of  
122 surface sediments in dust source regions. This gap hampers our ability to evaluate and constrain  
123 mineral abundance derived from reflectance spectroscopy and to improve dust emission modeling.  
124 Addressing this issue, the FRontiers in dust minerAloGical coMposition and its Effects upoN climaTe  
125 (FRAGMENT) project has, over recent years, conducted a series of coordinated and interdisciplinary  
126 field campaigns across remote dust source regions. The project's objectives include enhancing the  
127 understanding and quantification of dust-source properties, examining their relationship with emitted  
128 dust characteristics, refining spaceborne spectroscopy retrievals of surface minerals (Green et al.,  
129 2020, Clark et al., 2024), and improving the representation of dust mineralogy in Earth system models  
130 (Perlwitz et al., 2015; Li et al., 2021; Gonçalves et al., 2023; Obiso et al., 2023). The FRAGMENT field  
131 campaigns involved regional sediment sampling in several regions and detailed wind erosion and dust  
132 emission measurements at selected sites. Studies stemming from these activities include those by  
133 González-Romero et al. (2023), González-Flórez et al. (2022), and Panta et al. (2022), and González-  
134 Romero et al. (2024). These campaigns have been executed in various geographic locations, such as  
135 the Moroccan Sahara (2019), Iceland (2021), the Mojave Desert in the United States (2022), and  
136 Jordan (2022). Through these efforts, the FRAGMENT project contributes to filling critical knowledge  
137 gaps in dust-source characterization.

138 Following our previous studies in the Moroccan Sahara (González-Romero et al. 2023) and Iceland  
139 González-Romero et al. (2024), this study focuses on the characterization of dust-emitting sediments  
140 collected from the Mojave Desert in 2022. The Mojave Desert is a closed-basin wedge-shaped region  
141 located in the southwestern United States, between California and Nevada. The region is surrounded  
142 by mountain ranges and traversed by the Mojave river and other intermittent rivers for over 200 km  
143 from the San Bernardino mountains to the east (Dibblee, 1967, Reheis et al., 2012). Despite its limited  
144 global importance (dust emission from North America represents only ~3 % of the global dust  
145 emission; Kok et al., 2021), the Mojave Desert is an important regional dust source (Ginoux et al.,  
146 2012), with most emission occurring in the playa lakes and alluvium deposits near playa lakes (Reheis  
147 & Kihl, 1995; Reheis et al. 2009, Urban et al., 2018). Reynolds et al. (2009) observed 71 days with dust  
148 plumes during 37 months of camera recording at the Franklin Lake playa. According to remote sensing  
149 data (MODIS), aerosol optical depth (AOD) is higher in spring and summer and reaches a minimum in  
150 winter (Frank et al., 2007). However, from November to May, eastward flows of the jet-stream affect  
151 the Mojave Desert, which, in combination with topography, favour the development of northerly  
152 winds that can lead to dust emission (Urban et al., 2009). Up to 65 % of emission in the Mojave Desert  
153 is estimated to be due to natural factors, whereas 35 % to anthropogenic activities, including off-road  
154 recreation practices, mine operations, and military training and livestock grazing (Frank et al., 2007).  
155 The AOD in this region is also affected by dust transported from other regions (Tong et al., 2012) and  
156 pollution transported from the Los Angeles Basin (Frank et al., 2007, Urban et al., 2009). In the Mojave

157 Desert, Reynolds et al. (2009) noted an association between wet periods and dust emission, directly  
158 related to the generation of new thin crusts and salt crust removal.

159 The Mojave Desert includes several significant playa lakes, such as Rogers and Rosemond, Owens Lake,  
160 Death-Valley-Badwater, Panamint Valley, Bristol, Cadiz and Danby, Searles Lake, Soda Lake, and  
161 Mesquite Lake, among others (Reheis & Kihl, 1995; Reheis, 1997; Potter and Coppernoll-Houston,  
162 2019). Reynolds et al. (2007 and 2009) distinguished between two types of playa lakes: wet playas  
163 influenced by groundwater, and dry playas, unaffected by groundwater, though both can experience  
164 surface-water runoff. Goudie (2018) further delineated wet playas as having a groundwater table  
165 within 5 m of the surface, while dry playas have a groundwater table deeper than 5 m. Additionally,  
166 Goudie (2018), Buck et al. (2011), Nield et al. (2015) and Nield et al. (2016) observed that the  
167 interaction between salt minerals and the groundwater table on wet playas lead to the formation of  
168 fluffy surfaces through salt reworking by water during evapotranspiration.

169 In the Mojave Desert, three different Aridisols are present in the Rand mountains alluvial fan,  
170 corresponding to Xerillic soils or Aridisols according to Eghbal & Southard (1993), which are typical in  
171 arid and semi-arid regions, with low organic matter content and low structures. The uppermost layer  
172 of those Aridisols, ranging from 0 to 1 cm in depth exhibited a texture of 15-30% gravel, 69-74 % sand  
173 and 10-11 % clay. Reheis et al. (1995) described soils (<2 mm) primarily composed of silt (30-70 %) and  
174 clay (20-45 %). The mineralogy of those samples was dominated by quartz, feldspars, amphiboles, and  
175 clay minerals, including smectite, mica and kaolinite (Eghbal & Southard, 1993). The Cronese Lakes  
176 and Soda Lake playas are documented to contain salt precipitates, but mineralogy is not specified.  
177 Mesquite Lake playa is noted for its gypsum deposits (Reynolds et al., 2009). At Franklin Lake playa,  
178 surfaces are characterised by silt-clay size particles (Goldstein et al., 2017) with mineralogical  
179 descriptions provided in Reynolds et al. (2009) indicating fluffy surfaces comprised of halite,  
180 thenardite, trona, burkeite, calcite, illite, smectite, and kaolinite. Similar mineralogical results are  
181 described at Soda Lake by Reheis et al. (2009), with a higher proportion of Na-salts, quartz, gypsum  
182 and carbonates. Furthermore, Goldstein et al. (2017) identified a diverse array of minerals at Franklin  
183 Lake playa, including clays, zeolites, plagioclase, K-feldspar, quartz, calcite, dolomite and salt minerals  
184 such as trona, halite, burkeite and thenardite.

185 This study characterises the particle size distribution, mineralogy and modes of occurrence of Fe of  
186 selected potential dust-emitting sediment surfaces from the Mojave Desert. In addition, the  
187 mineralogy of different size fractions is analysed, based on a sieving protocol that minimally disturbs  
188 sediments. We further discuss the potential effect of sedimentary transport on the particle size and  
189 mineralogy across the sampled basins building upon previous studies in the literature. Finally, our  
190 results are broadly compared with current EMIT standard (semi-quantitative) products, and with those  
191 obtained using similar protocols in previous FRAGMENT campaigns in other regions (González-Romero  
192 et al., 2023; González-Romero et al., 2024).

## 193 **2. Methodology**

### 194 **2.1 Study area**

195 The Mojave Desert, located between California and Nevada, has a diverse geological history spanning  
196 from the Cambrian and Precambrian eras to the Holocene (Figure 1). This geological complexity

197 encompasses volcanic, plutonic, metamorphic, and sedimentary units (Jennings et al., 1962; Miller et  
198 al., 2014). In areas once submerged during the last glacial maximum (LGM), we now find ephemeral  
199 playa lakes that have existed for thousands of years since the LGM, offering a glimpse into the region's  
200 dynamic past (Miller et al., 2018). These playa lakes together with alluvial fans, floodplains and other  
201 features are surrounded by a variety of source rocks, exhibit diverse particle sizes and compositions  
202 and can potentially emit dust under favourable wind conditions.

203 The regional distribution of the annual Frequency of Occurrence (FoO) of dust events with dust optical  
204 depth exceeding 0.1, derived from MODIS Deep Blue C6.1 Level 2 data following the methodology of  
205 Ginoux et al. (2012), is illustrated in Figure 2. The FoO provides an overall estimate of dust emission  
206 frequency above a certain threshold at a resolution of 0.1° by 0.1° over the region. Sediment samples  
207 were collected from various locations within the Mojave Desert region, including areas with relatively  
208 high FoO (see locations in Figures 1 and 2). Among these locations is Soda Lake and its surroundings,  
209 near Baker, CA, which is linked to Silver Lake to the north and is surrounded by igneous, volcanic, and  
210 carbonate rocks, as well as dune fields to the south (Figure 1). The area is influenced by aeolian,  
211 alluvial, and fluvial processes and experiences annual precipitation of 80-100 mm (Urban et al., 2018).  
212 This ephemeral lake contains salts resulting from the evaporation of groundwater sourced from an  
213 aquifer nestled in the Zzyzx Mountains (Honke et al., 2019). Dust emissions are a recurrent  
214 phenomenon, originating from fine sediments accumulated in the lake's central areas during sporadic  
215 floodings, from the white evaporite surfaces in the lake, and from the alluvial deposits to the south of  
216 the playa lake (Urban et al., 2018). According to the FoO, the areas with higher dust emissions are the  
217 southern part of the lake and the alluvial deposits to the southwest, extending up to Afton Canyon.

218 Samples were also collected from the Cronese lakes, Mesquite Lake, Ivanpah Lake and Coyote Lake  
219 (Figure 1), which lie in areas with significant FoO signals (Figure 2) and have been documented as dust  
220 sources in Reheis & Kihl (1995) and Reheis et al. (2009). The Cronese lakes are adjacent to the Soda  
221 Lake area to the west, sharing a similar geologic context (Figures 1 and 2). Mesquite Lake, located on  
222 the border between California and Nevada, is encircled by carbonate and igneous rocks, mirroring the  
223 geological setting of the nearby Ivanpah Lake. Notably, Mesquite Lake playa is the only playa affected  
224 by a gypsum mine pit, as documented by Reynolds et al. (2009). Further contributing to the diversity  
225 of the region's geological makeup is Coyote Lake, flanked by Miocene and Pleistocene sediments.  
226 These playa lakes, characterised as endorheic ephemeral lakes, receive groundwater inputs in some  
227 cases, enriching the lakes with salts that subsequently precipitate on the surfaces of their central  
228 regions (Whitney et al., 2015; Urban et al., 2018).

229 Other areas with relatively high FoO not sampled in our study include the Ashford Junction alluvial  
230 deposits and the Fort Irwin area, where the northern valley, including Nelson Lake, may be more prone  
231 to dust emission due to significant anthropogenic disturbance. It is important to note that the FoO  
232 may tend to highlight areas such as playas and their surroundings, where in some cases the most dust  
233 per unit area could be produced (Floyd and Gill, 2011; Baddock et al., 2016). However, some alluvial  
234 regions with lower emission rates not surpassing the FoO threshold may produce more dust overall  
235 due to their greater areal extent (Reheis and Kihl, 1995; Baddock et al., 2016). Additionally, many other  
236 types of dust-producing surfaces active in the Mojave Desert, such as gravel roads, agricultural lands,  
237 and recreational off-road tracks, are rarely observed by satellite retrievals (Urban et al., 2018).

238 The new EMIT sensor onboard the International Space Station offers a glimpse of the mineralogical  
239 diversity in the Mojave Desert (Green et al., 2020). Figure 3 displays standard Tetracorder RGB color  
240 composite semi-quantitative products for EMIT. Tetracorder is a software system that employs a set  
241 of algorithms within an expert system decision-making framework to identify and map compounds  
242 (Clark, 2024; Clark et al., 2024). Figure 3 shows a true color image, along with standard products for  
243 Fe<sup>2+</sup> and Fe<sup>3+</sup> bearing mineral electronic absorptions (including hematite and goethite) in the visible to  
244 very-near infrared spectral range. It also displays standard products for the EMIT-targeted minerals,  
245 excluding hematite and goethite: calcite, chlorite/serpentine, dolomite, gypsum, illite/muscovite,  
246 kaolinite-dioctahedral group, montmorillonite group, and vermiculite. These products highlight areas  
247 where the presence of each mineral or component is significant, measured in terms of band depth\*fit,  
248 where the fit represents the least squares correlation coefficient from a feature fit of observed and  
249 reference library spectra. These analyses reveal the widespread presence of phyllosilicates such as  
250 kaolinite, smectite, montmorillonite, and illite across the area. The northeastern sector, particularly  
251 around Mesquite Lake, exhibits notable concentrations of carbonates and gypsum. Additionally,  
252 goethite and hematite are detected, with a more pronounced presence of goethite in the northern  
253 portion and hematite in the southern part of the region. The detection of mixtures of Fe<sup>2+</sup> and Fe<sup>3+</sup>  
254 within various minerals enriches our understanding of the region's mineralogical diversity.

255 Quantitative surface mineralogy (mineral mass abundances of the 10 EMIT-targeted minerals) and soil  
256 texture products are currently being developed by the EMIT team for use in Earth System Models.  
257 Their publication and evaluation will be the focus of forthcoming publications. Thus, it is beyond the  
258 scope of this study to perform a detailed quantitative comparison between our analyses and  
259 comparable EMIT products. However, in the results section, we broadly compare these standard  
260 products with the results of our in-situ analyses.

## 261 **2.2 Sampling**

262 Representative surfaces of dust-emitting sediments were sampled in May 2022, with depths of up to  
263 3 cm, using a 5 cm<sup>2</sup> inox shovel. Samples were stored in a plastic bag, labelled, and documented with  
264 photographs, descriptions, and coordinates, and transported to the laboratories for subsequent  
265 analyses. The type of samples considered are crusts (semi-cohesive fine sediments accumulated  
266 during floodings in depressions) and ripples (aeolian ripples that are built up under favorable winds  
267 and supply sand for saltation) (Figure 4). A total of 55 surface sediments and ripples (32 from Soda  
268 Lake, 9 from Mesquite Lake, 1 from Ivanpah Lake, 11 from the Cronese Lakes, and 2 from Coyote Lake)  
269 were sampled for laboratory analysis. Once in the laboratory, the samples were dried for 24-48 h at  
270 40-50 °C, sieved to pass through a 2 mm mesh.

271 Our rationale for selecting crusts and ripples is two-fold. On the one side, dust emission is primarily  
272 driven by two mechanisms: saltation bombardment and aggregate disintegration. In saltation  
273 bombardment, dust is ejected from soil aggregates (typically crusts and paved sediments rich in clay  
274 and silt particles) when impacted by saltating sand particles. In aggregate disintegration, dust is  
275 released from saltating soil aggregates (Shao et al., 1993; Alfaro et al., 1997; Shao, 2001). By  
276 characterizing the PSD (both dry and wet sieved) and mineralogy of ripples (concentrating sand  
277 particles) and crusts (concentrating clay and silt particles), we provide comprehensive and valuable  
278 information for developing and refining dust emission models. On the other side, in arid regions,  
279 quartz and feldspar typically dominate sediment mass. However, current spaceborne hyperspectral

280 instruments (such as EMIT) cannot directly identify feldspar and quartz because their absorption  
281 features lie outside the instrument's spectral range. This poses a significant challenge in quantifying  
282 surface mineral abundances from remote spectroscopy. At all FRAGMENT sampling locations  
283 (Morocco, Iceland, US-Mojave, and Jordan), we measured reflectance spectra using an ASD Fieldspec  
284 3. By characterizing and contrasting ripples (with high quartz and feldspar content and larger particle  
285 sizes) and crusts, we aim to provide information to enhance understanding and improve modelling  
286 assumptions for estimating surface mineral abundances and soil texture from remote spectroscopy in  
287 subsequent studies.

288 We acknowledge that the limited number of samples collected may not fully represent the potential  
289 variability among crusts and ripples within the studied locations due to varying conditions (Buck et al.,  
290 2011). However, our samples broadly represent the composition and particle size distributions (PSDs)  
291 of this type of sediments in these areas, allowing for meaningful comparisons with sediments from  
292 other locations.

## 293 **2.3 Analyses**

### 294 2.3.1 Particle size distribution

295 Particle size distributions (PSD) of bulk samples (<2 mm) were analysed as described in González-  
296 Romero et al. (2023) for the evaluation of the aggregation state. First, we conducted a minimally  
297 dispersed PSD (MDPSD) analysis, which minimizes the breaking of the aggregates that are  
298 encountered in natural conditions. Second, we conducted a fully dispersed PSD (FDPSD) analysis,  
299 which breaks the aggregates. Wet dispersion was done according to Sperazza et al. (2004), using water  
300 and sodium hexametaphosphate dispersion for 24 h. Both PSDs (MDPSD and FDPSD) were obtained  
301 by a laser diffractometer with the Malvern Mastersizer 2000 Hydro G and Scirocco for the fully and  
302 minimally dispersed conditions, respectively. We note that under wet dispersion, at least some salt  
303 minerals may dissolve.

304 In addition, we separated 20 selected samples from different sources, including 16 crusts and 4 aeolian  
305 ripples, into different size ranges to understand how mineral composition changes with size. We used  
306 a series of sieves with mesh sizes of 2 mm, 1 mm, 500  $\mu\text{m}$ , 250  $\mu\text{m}$ , 80  $\mu\text{m}$ , 63  $\mu\text{m}$ , 40  $\mu\text{m}$ , and 20  $\mu\text{m}$ .  
307 The sieving process involved hand shaking the full column for 1 minute, followed by ultrasound  
308 sonication for 1 minute at the 500  $\mu\text{m}$ , 80  $\mu\text{m}$ , 40  $\mu\text{m}$ , and 20  $\mu\text{m}$  size fractions. This method ensured  
309 the effective separation of the size fractions for subsequent mineralogical analysis.

### 310 2.3.2 Mineralogical composition

311 To quantify the different contents of crystalline minerals and amorphous components, X-Ray  
312 Diffraction (XRD) coupled with a Rietveld quantitative method were used (Rietveld, 1969; Cheary and  
313 Coelho, 1992; Young, 1995 and Topas, 2018). Adding a known amount of an internal standard material  
314 allowed, via the Rietveld method, the quantification of a mixture of minerals and any non-crystalline  
315 material in the mixture not included in the Rietveld method (De la Torre et al., 2001; Madsen, 2001,  
316 Scarlett and Madsen, 2006; Machiels et al., 2010; Ibañez et al., 2013). For the analysis, a measured  
317 amount of dry ground sample was mixed and dry ground again with 10-20 % of fluorite ( $\text{CaF}_2$  powder,  
318 Merck), used here as an internal standard for quantitative purposes. The XRD patterns of the samples

319 were analysed by a Bruker D8 A25 Advanced Powder X-ray diffractometer operated at 40kV and 40  
320 mA with monochromatic Cu K $\alpha$  radiation ( $\approx 1.5405 \text{ \AA}$ ). This device uses a Bragg-Brentano geometry  
321 and a sensitive detector LynxEye 1D. Diffractograms were recorded from 4 to 120 $^\circ$  of 2 $\theta$  and steps of  
322 0.015 $^\circ$  in 1s and maintained rotation (15/min). For the clay identification, samples were analysed using  
323 the oriented aggregate method by XRD, decanting clay fractions from samples and smearing the  
324 slurries in glass slides. After, three treatments were applied including air drying (AO), glycolation with  
325 ethylene glycol (AG) and heating at 550  $^\circ\text{C}$  for 2h (AC) with its three different diffractograms. Finally,  
326 the three diffractograms allows to corroborate the presence of Illite, Chlorite, Palygorskite and  
327 Montmorillonite through Thorez (1976) and USGS Open File procedures. Data collected were  
328 evaluated using the Bruker AXS DIFFRAC.EVA software package (Bruker AXS, Karlsruhe, Germany,  
329 2000) and the Rietveld analyses performed with TOPAS 4.2 program (Bruker AXS, 2003-2009). A  
330 Chebyshev function of level 5 was used to fit the background and abundances of crystalline and  
331 amorphous phases were normalised to 100 %. Fits were evaluated by visual comparison,  $R_{wp}$  (R-  
332 weighted pattern),  $R_{exp}$  (R-expected), and Goodness of Fit (GOF).

### 333 2.3.3 Mode of occurrence of Fe

334 As XRD is not precise enough for Fe-oxide quantification, wet chemistry and sequential extractions of  
335 Fe are needed for quantification of the mode of occurrence of Fe (González-Romero et al., 2023;  
336 2024). Samples were analysed with a two-step acid digestion for the total Fe (FeT) content following  
337 Querol et al. (1993, 1997). A reference material (NIST-1633b, coal fly ash) was used for quality control  
338 in every batch. The sequential extraction presented in Shi et al. (2009), Baldo et al. (2020) and  
339 González-Romero et al. (2024) were used to quantify readily exchangeable Fe ions and nano Fe oxides  
340 (FeA), the amount of crystalline Fe oxides as goethite and hematite (FeD), and crystalline magnetite  
341 (FeM). For the first extraction, 30 mg sample were leached with 10 ml of an ascorbate solution  
342 (extractant solution) and shaken in dark conditions for 24 h and filtered. Another 30 mg were leached  
343 with 10 ml of a dithionite solution (extractant solution), shaken for 2 h in dark conditions and filtered  
344 for the second extraction. The solid residue was then leached again in 10 ml of an oxalate solution for  
345 6 h in dark conditions and filtered for the third extraction. The extracted solution of each phase (FeT,  
346 FeA, FeD and FeM) was analysed to quantify dissolved Fe by Inductively Coupled Plasma Atomic  
347 Emission Spectrometry (ICP-AES). FeA is obtained with the first extraction, FeD is obtained subtracting  
348 from the second extraction the amount of Fe from the first extraction. Finally, the FeM is related to  
349 the third extraction. At the end, the equivalent to the Fe as structural Fe was obtained:  $FeS = FeT - FeA$   
350  $- FeD - FeM$  which is included in other minerals and amorphous phases. To test accuracy, 30 mg of  
351 Arizona Test Dust (ATD; ISO 12103-1, A1 Ultrafine Test Dust; Powder Technology Inc.) was subjected  
352 to the same extraction procedure in every batch and extraction.

353 The averaged Fe content of the reference material 1633b was  $7.6 \pm 0.5 \%$  (certified 7.8%).  
354 Furthermore, the average values of the sequential Fe extraction of the ATD reference material were  
355  $0.073 \pm 0.012$ ,  $0.47 \pm 0.01$ , and  $0.042 \pm 0.002 \%$  for FeA, FeA+FeD and FeM, respectively, while the  
356 certified contents are 0.067, 0.48, and 0.047 %, respectively.

## 357 **3. Results**

### 358 **3.1. Particle size distribution**

359 The PSD and median particle diameter of fully and minimally disturbed samples are key parameters  
360 for understanding the cohesion and aggregation state of sediments (González-Romero et al., 2024).  
361 We note that in the Mojave Desert some basins are enriched in salts, which can cause some artefacts  
362 in the FDPD. The dissolution of salts during wet dispersion for bulk PSD analysis (<2 mm) can remove  
363 aggregating agents. These salt cementation of the crusts might reduce the dust emission potential of  
364 the surface.

365 The average PSDs of crusts across different basins exhibit remarkable similarity, yet disparities  
366 between FDPDs and MDPSDs are pronounced, indicating varying degrees of particle cohesion and  
367 aggregation at Cronese, Mesquite, Ivanpah and Coyote lakes. In these locations, FDPDs feature a  
368 dominant mode at 8-10  $\mu\text{m}$  alongside a coarser mode at 100  $\mu\text{m}$ , while MDPSDs are characterised by  
369 a dominant coarser mode (Figure 5). In contrast, Soda Lake crusts exhibit similarity between FDPDs  
370 and MDPSDs. Averaged FDPDs and MDPSDs of aeolian ripples from the Mojave Desert are found to  
371 be similar, typically featuring a major size mode between 100-300  $\mu\text{m}$ . However, distinctions arise  
372 when analysing specific lakes. Aeolian ripples from Soda, Cronese, and Coyote lakes showcase a  
373 dominant coarse mode at 200-300  $\mu\text{m}$ , whereas those from Mesquite Lake show a dominant mode at  
374 a finer scale, approximately at 100  $\mu\text{m}$  (Figure 5).

375 The crusts' mean of all median particle diameters (mean median) in the analysed Mojave Desert dust  
376 source sediments reveal a coarser MDPSD compared to FDPD, with values of 92 and 37  $\mu\text{m}$ ,  
377 respectively. In contrast, the mean median particle diameter is similar for aeolian ripples (226 and 213  
378  $\mu\text{m}$ , respectively) (Table S1). Analysing specific locations, the mean median particle diameter from the  
379 MDPSD of crusts varies, with the finest crust observed at Ivanpah Lake (35  $\mu\text{m}$ ) and the coarsest at  
380 Mesquite Lake (141  $\mu\text{m}$ ). For FDPD, the finest crust originates from Coyote Lake (8.4  $\mu\text{m}$ ), while the  
381 coarsest is from Soda Lake (52  $\mu\text{m}$ ) (Table S1). Similarly, for aeolian ripples, the mean median particle  
382 diameters for both MDPSD and FDPD are finer at Mesquite Lake (167 and 67  $\mu\text{m}$ , respectively) and  
383 coarser at Cronese lakes (264 and 234  $\mu\text{m}$ , respectively) (Table S1). The high degree of particle  
384 aggregation observed in crusts, contrasting with the lower aggregation state in ripples, aligns with  
385 findings reported for dust-emitting sediments from Morocco by González-Romero et al. (2023).

386 The mean median particle diameters of crusts collected in the Mojave Desert are similar to those from  
387 Morocco described by González-Romero et al. (2023). Specifically, the mean median MDPSD diameter  
388 for the Mojave Desert ( $92 \pm 74 \mu\text{m}$ ) closely resembles that of the Morocco Draâ Lower basin ( $113 \pm 79$   
389  $\mu\text{m}$ ), albeit slightly finer, and is notably coarser than that of Iceland ( $55 \pm 62 \mu\text{m}$ ) (González-Romero  
390 et al., 2023, 2024). Furthermore, the finest crust sampled in the Mojave Desert (Ivanpah with 35  $\mu\text{m}$ )  
391 is almost twice as coarse as the finest from Morocco (L'Bour with 20  $\mu\text{m}$ ). For FDPD, the Icelandic top  
392 sediment surface is the coarsest ( $56 \pm 69 \mu\text{m}$ ), followed by both Morocco and Mojave crusts ( $37 \pm 77$   
393 and  $37 \pm 48 \mu\text{m}$ , respectively). Additionally, average MDPSD median diameters of aeolian ripples from  
394 the Mojave Desert sources samples closely resemble those from Morocco (226 and 221  $\mu\text{m}$ ,  
395 respectively), while those from Iceland are slightly coarser (280  $\mu\text{m}$ ).

396 Dry sieved size fractions of dust-emitting sediments show the highest percentage of mass in the 250-  
397 500 and 80-250  $\mu\text{m}$  fractions, with minimal mass within 500-1000  $\mu\text{m}$ , 1-2 mm and the finer fractions  
398 (20-40 and  $<20 \mu\text{m}$ ) (Figure 6, Table S2). In both cases, the size fractions from 80 to 500  $\mu\text{m}$   
399 accumulated a total of 75 to 90 % of the total mass fraction (Table S2).

400 Close to the centre of the Soda Lake, where numerous crust samples were collected, before reaching  
401 massive crust cementation by evaporite minerals, the FDPD median diameter reaches very fine sizes  
402 (8-15  $\mu\text{m}$ ) (Figure S1). In contrast, towards the edges of the basin (closer to the mountains surrounding  
403 this endorheic lake), the size markedly increases, ranging from 22 to 87  $\mu\text{m}$  (Figure S1). Similar  
404 patterns, yet with coarser sizes, are observed for the MDPSD. As described in previous studies, the  
405 fluctuation of the groundwater table in the centre of the basin can lead to a massive precipitation of  
406 salts, resulting in the formation of compact crusts (Figure 4) (Reynolds et al., 2007; Nield et al., 2016a;  
407 Nield et al., 2016b; Urban et al., 2018) that should effectively reduce dust emission. However, at the  
408 edges, where the precipitation of salts is less frequent, and reworking of the crusts by fluctuations in  
409 the groundwater table occurs, salty and spongy crusts are formed (Figure 4) (Nield et al., 2016a and  
410 Nield et al., 2016b). These spongy crusts, being less compact, are more easily broken by saltating  
411 particles, potentially leading to high-salt dust emissions.

412 The slight particle size segregation, with finer particles accumulating towards the center of the lake,  
413 can be attributed to the transport of sediments from the surrounding mountains to the lake's center  
414 by runoff waters during rain episodes. Initially, the coarser particles are deposited, followed by the  
415 finer particles that remain suspended in the water for a longer duration. Nevertheless, the crusts in  
416 the surroundings alluvial fans of the Soda Lake are fine enough (22-87  $\mu\text{m}$  in the edges compared to  
417 8-15  $\mu\text{m}$  in the centre, Figure S1) and surrounded by dunes (availability of saltators for saltation  
418 bombardment) to have a high potential dust emission under favourable conditions (Reynolds et al.,  
419 2006; Reheis et al., 2009; Urban et al., 2018).

## 420 **3.2. Mineralogy**

421 Dust-emitting sediments from the Mojave Desert primarily consist of feldspars ( $41 \pm 12 \%$ , including  
422 albite/anorthite and microcline), quartz ( $22 \pm 11 \%$ ) and clay minerals ( $18 \pm 12 \%$ , such as kaolinite,  
423 montmorillonite and illite). Additionally, minor contents of carbonate minerals ( $6.6 \pm 6.6 \%$ ),  
424 amphibole (pargasite)  $4.1 \pm 1.5 \%$ , and iron oxides (maghemite/magnetite) ( $0.77 \pm 0.54 \%$ ) are  
425 observed (Figure 7, Tables 2 and S3). At Soda, Mesquite and Cronese lakes, Na-salts such as halite,  
426 thenardite, trona, and burkeite are also present, with an average salt content of  $5.0 \pm 11 \%$ .  
427 Additionally, zeolites ( $0.77 \pm 1.1\%$  to  $8.5\%$ ) including laumontite and analcime are detected at Soda,  
428 Cronese, and Coyote lakes (the southern sites), with the highest content observed at Coyote Lake.  
429 High amounts of gypsum are found at Mesquite Lake ( $15 \pm 29 \%$ ) (Figure 7, Tables 2 and S3). Moreover,  
430 Mesquite Lake crusts exhibit high contents of dolomite and calcite ( $15 \pm 11\%$ ) compared to other  
431 basins ( $3.6 \pm 2.6\%$  to  $7.2\%$ ) (Table 2).

432 The overall mineral composition of the dust-emitting sediments originates primarily from the source  
433 rocks prevalent in the region. These include dominant of Mesozoic granitic rocks, as well as pre-  
434 Tertiary, Tertiary and Quaternary volcanic rocks, and Pre-Cambrian and Mesozoic metamorphic rocks  
435 (Figure 1). In the northern, northeastern, and eastern areas of Mesquite Lake, an important limestone  
436 and dolostone massif from the Palaeozoic era contributes notably to the high content of calcite and

437 dolomite in the sediments of this lake (Figure 1). Zeolite content in the sediments may be attributed  
438 to the weathering of volcanic outcrops in the region or to precipitation in alkaline lakes. This diverse  
439 bedrock mineralogy results in a wide variety of minerals in the dust-emitting sediments. The form of  
440 iron oxide detected in the samples, identified via XRD, is maghemite. However, distinguishing between  
441 maghemite and magnetite using XRD is challenging (Vandenberghe et al., 2000), and magnetite has  
442 been found to be ubiquitous in Mojave dust (Reheis et al., 2009; Reynolds et al., 2006). Therefore, we  
443 refer to maghemite/magnetite to account for the potential presence of both minerals in the samples.  
444 In comparison to aeolian ripples, the average composition of the crusts shows enrichment in clay  
445 minerals ( $24 \pm 11$  versus  $7.8 \pm 2.3$  % in crust and ripples, respectively), carbonates ( $6.6 \pm 6.6$  versus  $1.1$   
446  $\pm 2.2$  %), Na-salts ( $7.3 \pm 13$  versus  $1.1 \pm 3.7$  %), zeolites ( $1.2 \pm 1.9$  versus  $0.12 \pm 0.52$  %) and  
447 maghemite/magnetite ( $0.92 \pm 0.59$  versus  $0.49 \pm 0.28$  %), while being depleted in quartz ( $16 \pm 7.2$   
448 versus  $32 \pm 9.5$  %), feldspars ( $37 \pm 9.7$  versus  $48 \pm 13$  %) and gypsum ( $3.1 \pm 14$  versus  $4.7 \pm 20$  %), and  
449 showing a similar amphibole content ( $4.1 \pm 1.5$  versus  $4.1 \pm 1.6$  %) (Figure 7, Tables 2 and S3). These  
450 mineral enrichment and depletion trends in crusts are observed in all the playa lakes, except for  
451 Mesquite Lake, which is discussed below.

452 In Soda Lake, the concentration of Na-salts in crusts increases towards the inner part of the lake,  
453 ranging from 5-10 % at the margins to 45-50 % in the centre, where compact and fully salt-cemented  
454 crusts form. This phenomenon is illustrated in Figure 8, which presents a geological and mineralogical  
455 cross-section of Soda Lake. In addition to the water transport to this central part of the basin during  
456 the rain episodes, groundwater discharge from the Zzyzx mountains occurs. There, the groundwater  
457 table is close to the surface, and its interaction with the surface causes the massive mobilisation of  
458 Na-salts that consolidate the crusts (Figure 4) (Nield et al., 2016b). Cycles of precipitation and  
459 dissolution of the salts yield salty spongy crusts (Figure 4) at the edges of these massive crusts, with  
460 higher dust emission potential in the degraded salty crusts (Nield et al., 2016a). The very high content  
461 of Na-salts content in Soda Lake is attributed to the continuous high Na-S-Cl groundwater interaction  
462 in the vicinity of Zzyzx, defining Soda Lake as a wet playa lake according to Reynolds et al. (2009) and  
463 Urban et al. (2018). On the other hand, Cronese, Coyote, and Ivanpah are categorised as dry lakes.

464 Mesquite Lake features extensive gypsum deposits at the surface, which are a major component of  
465 both dunes and crusts. A small gypsum mine operates in Mesquite Lake. The gypsum content in crusts  
466 is notably higher at the center (80%) compared to the margins (3-11%). In contrast, the contents of  
467 Na-salts and carbonates are greater at the margins (30% and 12-18%, respectively) than at the center  
468 (7.5-14% and <0.1-6.9%, respectively). Aeolian ripples at the center of Mesquite Lake exhibit a very  
469 high gypsum content, whereas at the margins, these ripples contain higher amounts of quartz,  
470 feldspars, and clays than at the center. Despite the presence of the disturbed mine area, most large  
471 dust events at Mesquite Lake have been observed to originate from natural (undisturbed) playa  
472 surfaces near the margins (Reynolds R., personal communication).

473 Amphiboles in the Mojave Desert, sourced from metamorphic rocks in the area, are homogeneous  
474 and can serve as a marker for emitted desert dust in the region. Comparing mineralogy from Mojave  
475 Desert crusts to Moroccan surface samples (González-Romero et al., 2023), the former are largely  
476 enriched in feldspars, clay minerals, Na-salts, and gypsum, and depleted in quartz and carbonates,  
477 with trace proportions of amphibole, zeolites, and maghemite/magnetite. Ripples in the Mojave  
478 Desert are depleted in quartz and carbonates, enriched in feldspars, clay minerals, Na-salts, and  
479 gypsum, with traces of amphibole, maghemite/magnetite, and zeolites compared to Moroccan

480 ripples. The mineralogy of the Mojave Desert is markedly different from that of Iceland, due to  
481 differences in bedrock geology, although both contain feldspars, zeolites, and maghemite/magnetite  
482 (González-Romero et al., 2024).

483 Particle aggregation of the dust-emitting sediments from the Mojave Desert samples is similar to those  
484 described by González-Romero et al. (2023) for Moroccan samples, likely due to the presence of clays,  
485 Na-salts and precipitated carbonates. This aggregation inhibits aerodynamic entrainment and dust  
486 emission should be primarily controlled by saltation bombardment (Shao et al., 1993). According to  
487 the XRD analysis, the occurrence of crystalline Fe oxides is limited to maghemite/magnetite in contrast  
488 to the hematite/goethite content found in Moroccan crusts (González-Romero et al., 2023). However,  
489 due to the XRD low precision on the detection of low contents of minerals such as hematite and  
490 goethite, their presence in the samples cannot be ruled out. In fact, both the EMIT standard products  
491 (Figure 3), and the Fe mode of occurrence analysis discussed in the next section suggest the presence  
492 of hematite and goethite.

493 The EMIT standard products (Figure 3) indicate the presence of phyllosilicates such as kaolinite,  
494 smectite, montmorillonite, and illite, broadly consistent with our results. Specifically, around Mesquite  
495 Lake, where elevated levels of gypsum and carbonates were detected, the EMIT results corroborate  
496 the significance of these minerals in the same vicinity. Similarly, in Coyote, Ivanpah, and Cronese Lakes,  
497 there is agreement regarding the prevalence of illite and muscovite as the major clay minerals,  
498 alongside kaolinite. However, discrepancies arise in Soda Lake, where EMIT identifies a dominant  
499 presence of montmorillonite, contrasting with our XRD results indicating a predominance of illite,  
500 muscovite, and kaolinite. While Tetracorder identified predominant montmorillonite, illite, muscovite  
501 and kaolinite could be on the order of 30% of the montmorillonite abundance and not show in the  
502 EMIT spectra without a more sophisticated non-linear radiative transfer model to find the relative  
503 abundances of these two minerals. This is due to the relative absorption strengths of the spectral  
504 features of these minerals relative to those in montmorillonite. While our XRD analyses highlight the  
505 presence of maghemite/magnetite, these minerals do not present clear absorbing features in the  
506 spectral range of the EMIT instrument and are not considered within the 10 EMIT standard minerals.  
507 In contrast to the XRD results, EMIT highlights the significant presence of goethite in the northern  
508 sources (Mesquite and Ivanpah Lakes). Conversely, in the southern sources (Soda, Cronese, and  
509 Coyote Lakes), EMIT highlights a major mixture of Fe<sup>2+</sup> and Fe<sup>3+</sup> species. The limited precision of XRD  
510 for low proportions of Fe oxides, underscores the need for complementary techniques and analyses  
511 to bolster our findings.

512 The mineralogical composition of the dry size-segregated fractions of the dust-emitting sediments is  
513 outlined in Table S4. The findings indicate that there is no significant size enrichment process in crusts;  
514 rather, there exists a relatively uniform distribution of quartz, feldspars, zeolites, and Fe oxides across  
515 all size fractions (Figure 6). A slight, albeit not significant, enrichment of carbonates and clays is  
516 observed, along with a slight depletion of Na-salts and gypsum in the finer fractions (<20 µm).  
517 Additionally, pargasite shows a slight enrichment in the 40-80 µm fraction. In contrast, for aeolian  
518 ripples, quartz exhibits significant enrichment in the coarser fraction (250-500 µm) and depletion in  
519 the finer ones (<80 µm). Regarding carbonates, clays, and Fe oxides, there is an enrichment towards  
520 the finer fractions (<20 µm), while the content of feldspars remains relatively homogeneous. Pargasite  
521 content increases in the 40-80 µm fraction, and Na-salts and gypsum are either not detected or  
522 present in trace amounts (Figure 6). The notable disparity in the enrichment factor between crusts

523 and aeolian ripples is partly attributed to the reduced amount of sand in crusts and the differing  
524 cohesion states: crusts exhibit high cohesion, resulting in a homogenised mineralogy across size  
525 fractions (as aggregates form a homogeneous concretion of minerals), while aeolian ripples display  
526 lower or negligible aggregation, leading to a slightly more heterogeneous mineralogy across size  
527 fractions compared to crusts.

### 528 **3.3. Mode of occurrence of Fe**

529 The average content of FeT in the crusts is  $3.0 \pm 1.3$  wt %, while for aeolian ripples is  $1.9 \pm 1.1$  wt %.  
530 Among these crusts,  $1.8 \pm 0.92$  % of the FeT occurs as FeA,  $17 \pm 7.2$  % as FeD,  $2.1 \pm 1.2$  as FeM and  $79$   
531  $\pm 8.5$  % as FeS (Tables 3 and S5). Aeolian ripples have very similar contents and modes of occurrence  
532 of Fe in the analysed samples of the Mojave Desert.

533 Among the crusts, Ivanpah has the highest FeT content at 4.9 %, followed by Cronese and Coyote lakes  
534 ( $3.7 \pm 1.2$  % and 3.5 %, respectively), with Soda Lake showing a similar content ( $3.1 \pm 1.2$  %). Mesquite  
535 has the lowest FeT ( $1.6 \pm 0.53$  %), probably due to dilution of detrital Fe-bearing minerals with salts  
536 and gypsum. FeS is the dominant mode of occurrence in most lakes, ranging from 68 % (1 sample) at  
537 Ivanpah, to  $74 \pm 3.5$  and  $74 \pm 13$  % at Mesquite and Cronese, and to  $83 \pm 2.8$  and  $82$  % at Soda and  
538 Coyote lakes. The FeD is higher at Ivanpah (29 %), Cronese Lakes ( $21 \pm 11$  %) and Mesquite Lake ( $20 \pm$   
539  $2.7$  %) than at Soda and Coyote lakes ( $14 \pm 2.5$  and 14 %). FeM is higher at Mesquite Lake ( $3.7 \pm 1.2$   
540 %), followed by Cronese and Coyote lakes ( $2.3 \pm 1.1$  and 2.4 %), and Soda ( $1.5 \pm 0.49$  %) and Ivanpah  
541 Lakes (0.82 %). Finally, FeA is higher at Cronese Lake ( $2.4 \pm 0.99$  %), compared to Coyote, Mesquite,  
542 Soda and Ivanpah lakes (1.8,  $1.8 \pm 0.93$ ,  $1.5 \pm 0.81$  and 1.4 %) (Tables 3 and S5). Crusts are enriched in  
543 FeT, FeD and FeA compared to ripples, while ripples are enriched in FeM and FeS (Tables 3 and S5).

544 Overall, the bulk Fe content in crusts is driven by structural Fe from clays and amphiboles (as deduced  
545 from the high correlation shown in Figure 9a), followed by small proportions of hematite and goethite  
546 (not detected by XRD), which are clearly higher at the northern lakes Ivanpah and Mesquite lakes  
547 (consistent with the highlighted presence of goethite in the EMIT standard products), probably due to  
548 the Precambrian and Cambrian metamorphic rocks that supply sediments. Furthermore, the easily  
549 exchangeable Fe is also driven by clay minerals (Figure 9b).

550 Compared to crusts in other arid regions analysed by González-Romero et al. (2023, 2024), the  
551 analysed Mojave Desert crusts have similar FeT content than Moroccan crusts but are much lower  
552 than the Iceland top sediments (loose surface sediments in Iceland according to González-Romero et  
553 al. (2024)) ( $3.0 \pm 1.3$ ,  $3.6 \pm 0.71$  and  $9.5 \pm 0.39$  %, for Mojave, Morocco, and Iceland respectively). The  
554 proportion of FeS in FeT is similar to the Icelandic sediments but higher than in Moroccan samples ( $79$   
555  $\pm 8.5$  and  $79 \pm 6.5$  %, and  $67 \pm 2.4$ , respectively). The proportion of FeM is clearly lower than that of  
556 Iceland, but higher than that of Morocco ( $2.1 \pm 1.2$  and  $16 \pm 5.4$  %, for Mojave and Iceland; Morocco  
557 proportion is negligible). The FeD proportion is intermediate between Morocco and Iceland ( $17 \pm 7.2$ ,  
558  $31 \pm 2.3$ ,  $3.5 \pm 1.5$  %, respectively), while the FeA proportion is similar to both Morocco and Iceland  
559 crusts ( $1.8 \pm 0.92$ ,  $1.3 \pm 0.39$  and  $1.9 \pm 0.55$  %, respectively) (Figure 10).

### 560 **4. Discussion and conclusions**

561 The playa lakes sampled within the Mojave Desert can serve as significant dust-emitting sources in the  
562 region. Descriptions provided by Urban et al. (2018) and satellite imagery (Figure 2) confirm the

563 presence of desert dust emissions originated from these areas. The lithology, geological/tectonic  
564 evolution, and past and current climate conditions collectively contribute to the formation of these  
565 dust sources in the Mojave Desert.

566 Dust-emitting sediments in this region predominantly stem from substratum rocks, comprising mainly  
567 granitic and volcanic formations, along with metamorphic Pre-Cambrian, Cambrian, Paleozoic, and  
568 Mesozoic rocks. Endorheic basins, shaped by faulting during the Tertiary-Quaternary period,  
569 accumulated fine sediments through erosion, transportation, and deposition processes. Wetter  
570 conditions prevailing during the Pleistocene epoch led to the formation of deep lakes within the  
571 basins, which gradually desiccated as the climate evolved. These arid conditions rendered the playa  
572 lakes susceptible to dust emission under specific atmospheric conditions. Notably, a particle size  
573 segregation is observed, transitioning from coarser sediments in the proximal alluvial areas towards  
574 finer particle crusts within the central regions of the lakes. In the playa lakes, finer sediments  
575 accumulate towards the centre of the lakes due to flood events inundating the central areas and  
576 ponding, which facilitates the deposition of coarser particles followed by top finer sediment sizes.

577 As represented in the conceptual model depicted in Figure 11, the finer dust particle size distributions  
578 range from 8.4 to 99  $\mu\text{m}$  inside Soda Lake and 46 to 111  $\mu\text{m}$  outside Soda Lake, underscoring this  
579 sedimentation process. Comparisons with conceptual models proposed for other regions, such as  
580 those by González-Romero et al. (2023, 2024) for locations in Morocco and Iceland, reveal a similar  
581 transport fractionation phenomenon occurring in the Mojave Desert. These crusts, observed within  
582 Soda Lake, show enrichment in clay minerals, carbonate minerals, salts, and iron oxides, while  
583 experiencing depletion in coarser constituents such as feldspars and quartz.

584 In the Mojave Desert, there are two distinct types of playa lakes, characterised as wet and dry,  
585 depending on the regime of the groundwater table and its relationship with the surface, as described  
586 by Reynolds et al. (2007 and 2009), Buck et al. (2011), Nield et al. (2016a and b), Urban et al. (2018)  
587 and Goudie (2018). Understanding the groundwater table regime is fundamental in this region due to  
588 its profound relation on the porosity of the crust and its consequential impact on mineralogy, including  
589 the precipitation and enrichment of salts (Figure 11). This dynamic contrasts sharply with other  
590 conceptual models, where the relationship between crust formation and the groundwater table is  
591 either minimal or absent entirely. For instance, there is no or little relation between crusts and  
592 groundwater table in Morocco, and in Iceland, where the water regime is largely influenced by  
593 floodings from glaciers (González-Romero et al., 2023, 2024). In wet playa lakes like Soda Lake, the  
594 presence of salty crusts, whether massive or spongy, is significantly pronounced. Conversely, in dry  
595 playa lakes such as Ivanpah, Coyote, and Cronese, the relationship of salt crusts is notably less  
596 prominent as the proportion of Na-salts is lower (see Figure 11).

597 At Soda Lake, a hard crust, measuring up to 0.5 meters in thickness (Figure 3), forms through the  
598 extensive precipitation of Na-salts, particularly near the Zzyzx area, where a relatively constant  
599 mobilisation of salts is due to the water table evaporation or vapour discharge from deeper parts of  
600 the sediment towards the surface (Nield et al., 2015, 2016a and b). Along the edges of this massive  
601 crusty area, the frequent oscillation of the water table may result in the precipitation and dissolution  
602 of salts in lower quantities compared to the centre, leading to the formation of weaker crusts  
603 characterised by high porosity. These porous crusts may contribute to an increased dust emission rate  
604 compared to the hard salt crusts found in the centre. Dry lakes such as Ivanpah, Cronese, and Coyote

605 do not exhibit the formation of spongy crusts due to the low concentrations of salts. In wet playas,  
606 strong dust emission may happen when very strong winds rip off thin crusts exposing the fine-grained  
607 sediment beneath including lithogenic and salt mineral particles (Rich Reynolds, personal  
608 communication).

609 Particle aggregation facilitated by diagenetic salts and carbonate minerals is prevalent in the dust-  
610 emitting sediments sampled in the Mojave Desert, akin to the equivalent sediments found in the  
611 Moroccan Sahara. The average grain size of the crusts from both regions is similar, with MDPSD values  
612 of  $113 \pm 79 \mu\text{m}$  for Morocco and  $92 \pm 74 \mu\text{m}$  for the Mojave Desert, and FDPD values of  $37 \pm 77 \mu\text{m}$   
613 and  $37 \pm 48 \mu\text{m}$ , respectively. These patterns contrast with the lower aggregation state and finer  
614 MDPSD observed in Icelandic dust ( $55 \pm 62 \mu\text{m}$ ) (Table 4).

615 In terms of mineralogy, crusts from the Mojave Desert are enriched in feldspars, clay minerals, Na-  
616 salts, and gypsum, whereas crusts from the Moroccan Sahara are enriched in quartz and carbonates  
617 (Table 4). The mineralogy of Icelandic top sediments (loose surface sediments in Iceland according to  
618 González-Romero et al. (2024)) differs due to their volcanic origin; however, both the Mojave Desert  
619 crusts and Icelandic top sediments contain similar amounts of zeolites. Salt enrichment in the crusts  
620 is primarily attributed to interactions with the groundwater table as shown in previous studies (Nield  
621 et al. (2016a and b), Urban et al. (2018) and Goudie (2018) (Figure 11).

622 The total iron content (FeT) remains consistent throughout the samples collected in the Mojave  
623 Desert, with slightly higher levels observed in the Ivanpah crust, albeit diluted by the high salt content  
624 in the wet playa lake crusts or the elevated gypsum content in the Mesquite Lake. While the total Fe  
625 content is comparable between the Mojave Desert and Moroccan Sahara crusts (3.0 and 3.6 wt %,   
626 respectively), it is substantially lower than in Icelandic top sediments (9.3 wt %). Exchangeable Fe  
627 proportions in FeT are similar among the three environments. The proportion of Fe from hematite and  
628 goethite in Mojave Desert crusts fall between those of Moroccan Sahara crusts and Icelandic top  
629 sediments (17, 31, and 0.5 wt %, respectively). The proportion of maghemite/magnetite in Mojave  
630 Desert crusts is much lower compared to Icelandic top sediments (2.1 and 15 %, respectively). Finally,  
631 the proportion of structural Fe in the samples is similar across the three environments.

632 In conclusion, the dust-emitting sediments collected from the Mojave Desert exhibit distinct  
633 signatures in mineralogy and modes of occurrence of Fe compared to those from the Moroccan  
634 Sahara, despite similar particle sizes. These differences can influence emitted dust properties, and  
635 associated impacts. Similarities in fully disturbed and minimally disturbed particle size distributions  
636 support comparable dust emission mechanisms, with saltation bombardment playing a prominent  
637 role.

638 **Code availability.** The Tetracorder code used in this paper is provided by Clark (2023,  
639 <https://github.com/PSI-edu/spectroscopy-tetracorder>).

640 **Data availability.** Data used in this paper are given in the main paper itself and in the Supplement. If  
641 needed, data are also available upon request by emailing the authors.

642 **Author contribution.** Sample permits were obtained by BLE, RG and AK. The samples were collected  
643 by CPG-P, AGR, AK, RG and XQ and analysed by AGR, MHC and NM. EMIT mineralogy maps were  
644 produced by RG, PB and RC. PG provided the FoO map. AGR analysed the data and wrote of the original

645 draft manuscript supervised by CPG-P and XQ. CPG-P and XQ re-edited the manuscript and all authors  
646 contributed to data discussion, reviewing and manuscript finalization.

647 **Competing interests.** At least one of the (co-)authors is a member of the editorial board of  
648 Atmospheric chemistry and Physics.

## 649 **Acknowledgements**

650 We thank Richard Reynolds and another anonymous reviewer for the helpful comments and  
651 suggestions to improve the manuscript.

652 The field campaign and its associated research, including this work, was funded by the European  
653 Research Council under the Horizon 2020 research and innovation programme through the ERC  
654 Consolidator Grant FRAGMENT (grant agreement No. 773051) and the AXA Research Fund through  
655 the AXA Chair on Sand and Dust Storms at BSC. CGF was supported by a PhD fellowship from the  
656 Agència de Gestió d'Ajuts Universitaris i de Recerca (AGAUR) grant 2020\_FI B 00678. KK was funded  
657 by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – 264907654;  
658 416816480. MK has received funding through the Helmholtz Association's Initiative and Networking  
659 Fund (grant agreement no. VH-NG-1533). We acknowledge the EMIT project, which is supported by  
660 the NASA Earth Venture Instrument program, under the Earth Science Division of the Science Mission  
661 Directorate. We are grateful to Claire Blaske and Sahil Azad for assistance sampling in the Mojave  
662 National Preserve. Samples within the preserve were collected under permit MOJA-2022-SCI-0034.  
663 We thank Rose Pettiette at the BLM office in Needles, CA, for advice and allowing sampling on BLM  
664 land. We thank Jason Wallace and Anne Kelly from CSU Desert Studies Center at Zzyzx for their support  
665 during the campaign. BLE, RG, and AMK thank the Resnick Sustainability Institute at Caltech for partial  
666 support. Without all of them, the sampling campaign would not have been successfully feasible.

949 **Figure captions:**

950 **Figure 1:** Study area map including the playa lakes studied together with a geologic map, simplified  
951 from Jennings et al. (1962) and Miller et al. (2014). The star represents the Zzyzx complex and green  
952 dots the samples used in this study. Basemap: Imagery data from © Google Earth Pro v: 7.3.6.9345.

953 **Figure 2:** Map of Frequency of Occurrence (FoO) of dust optical depth > 0.1 over the study region  
954 derived from MODIS C6.1 Aqua (1:30PM equatorial passing time) Level 2 Deep Blue aerosol products  
955 at 0.1 degree resolution. A dust occurrence is counted when DOD > 0.1, Angstrom Exponent < 0.3 and  
956 DOD at 412 nm > DOD at 470 nm. Blue iso-contours represent 5 and 10 % of daily occurrences per  
957 year averaged over 20 years (2003-2022). Green dots represent the samples collected and used in this  
958 study. Basemap: Imagery data from © Google Earth Pro v: 7.3.6.9345.

959 **Figure 3:** EMIT scenes emit20231015T215209\_color-visRGB and emit20230728T214142\_color-visRGB  
960 at 60 m per pixel showing the diversity of Fe<sup>2+</sup>, Fe<sup>3+</sup> and Fe<sup>2+</sup> and Fe<sup>3+</sup> bearing minerals and the  
961 carbonates, salt and phyllosilicates minerals.

962 **Figure 4:** Examples of samples collected in the Mojave Desert including crusts (a), aeolian ripples (b),  
963 massive compact crust (c) and a salty spongy crust (d).

964 **Figure 5:** Fully dispersed particle size distribution (FDPSD) and minimally dispersed particle size  
965 distribution (MDPSD) for crusts and aeolian ripples from the Mojave Desert (median PSD from all the  
966 samples), Soda, Mesquite, Cronese, Ivanpah and Coyote Lakes. In shaded blue and brown the standard  
967 deviation of each PSD (n° of samples used in Table 1), except for Ivanpah and Coyote Lakes (only 1  
968 sample each).

969 **Figure 6:** % of mass fractions from the dry sieved size fractions (250-50, 80-250, 63-80, 40-63, 20-40  
970 and <20 µm). The range of the enrichment factors of each mineral group for each dry size fraction of  
971 the 16 crust samples (blue) and for the 4 aeolian ripples samples (red).

972 **Figure 7:** Box-plot showing averaged mineral contents for all samples, crusts and aeolian ripples (wt  
973 %).

974 **Figure 8:** Geological cross section and mineralogy of the crusts of the Soda Lake. Top panel represent  
975 major mineralogy composition. Mid panel represents the position of the samples, the Zzyzx complex,  
976 and the path of the cross section. Bottom schematic cross section simplifying the position in the basin.  
977 Basemap: Imagery data from © Google Earth Pro v: 7.3.6.9345.

978 **Figure 9:** Cross-correlation plots of the clay contents and amphibole with the FeT (a) and clay minerals  
979 and FeA (b), all in wt % in crusts.

980 **Figure 10:** Modes of occurrence of Fe comparison between the crusts (C) playa lakes analysed in this  
981 study, the average of the crusts and ripples (R) at Mojave Desert, Morocco and Iceland Top surface  
982 (TS). FeA is referred to the exchangeable Fe and nano Fe oxides, FeD is the Fe content in hematite and  
983 goethite, FeM is the Fe content in maghemite/magnetite and FeS is the Fe content in Fe bearing  
984 minerals.

985 **Figure 11:** Conceptual model of wet and dry playa lakes differences due to groundwater differences  
986 and how this can affect the mineralogy of the surface in the playa lakes. Also illustrated is the expected  
987 dust emission rate, major mineralogy and modes of occurrence of Fe differences expected in the  
988 emitted dust.
