Abstract. Re-examination of sediment samples collected from the Bay of Bengal via laser-ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) Rb-Sr geochronology demonstrates the viability of the Rb-Sr system for use as a detrital chronometer. The age population defined by the Rb-Sr dates essentially reproduces that previously published for detrital ⁴⁰Ar/³⁹Ar dates. The assumed initial ⁸⁷Sr/⁸⁶Sr on the calculated population has some influence on the age of the final population, but that influence can be ameliorated by filtering for higher ⁸⁷Rb/⁸⁶Sr ratios. The ⁸⁷Rb/⁸⁶Sr ratio cut-off used for such filters to minimize the effect of initial ⁸⁷Sr/⁸⁶Sr on the final population is strongly dependant on the age of the material being analysed (i.e. $\sim > ^{87}\text{Rb}/^{86}\text{Sr} = 500 @ 250 \text{ Ma}$ and $\sim > ^{87}\text{Rb}/^{86}\text{Sr} = 50 @ 2500 \text{ Ma}$). Finally, Ti-in-biotite temperatures calculated based on data collected during LA-ICP-MS overlap with those calculated for the same material based on electron probe microanalyzer data demonstrating the potential for petrochronology based on the Rb-Sr system.

1 Introduction

Detrital geochronology is a commonly used approach to assess a wide variety of geological questions. For example, detrital zircon age information can provide information about the maximum depositional age for a sedimentary unit, likely sediment sources, and timescales of exhumation and sediment transport (e.g. Gehrels 2014; Thomas 2011; Malusà and Fitzgerald 2020). Moreover, detrital zircon chemistry can provide additional insight into the nature of the source rocks, such as crystallization depth and degree of fractional crystallization (e.g. Stevenson and Patchett 1990; Iizuka et al. 2010; Howard et al. 2009; Mueller et al. 2008). Similarly, detrital geochronology (often referred to as thermochronology) of mineral phases dated via radio-decay systems that may record cooling rather than crystallization, such as ⁴⁰Ar/³⁹Ar on mica, or fission track and U-Th-He dating of U bearing minerals is well suited to quantify rates of exhumation and/or burial in active orogenic systems (e.g. Ruiz, Seward, and Winkler 2004; Najman et al. 1997, 2004). Critical to detrital geochronology, in all forms, is analysing enough material to characterise the statistical variation in the material being examined. Prior to the development of spot geochronology analytical techniques, analysing enough material (e.g. Verbeeck 2004) to characterise a specimen was time-consuming and expensive. The proliferation of laser ablation inductively coupled plasma mass spectrometry-based geochronology has enabled the rapid acquisition of large datasets.

While this is especially true for detrital U-Pb zircon geochronology, limitations still exist for other methods. For example, $^{40}\text{Ar}/^{39}\text{Ar}$ LA-ICP-MS geochronology still requires irradiation of samples prior to analyses, which increases the expense and time it takes to generate data.

35 The development of *in situ* beta decay geochronology techniques (e.g. Zack and Hogmalm 2016; Simpson et al. 2021) now allow additional detrital geochronometer options, with the critical caveat that these are typically isochron-based methods. As such, quantifying a non-radiogenic intercept is an integral part of calculating a date. In the absence of a measured co-genetic non-radiogenic phase to constrain that intercept, multiple radiogenic data points, which typically have varying initial isotopic reservoirs, can be regressed through to define a date. Such isochrons (regressions) rely on all analyses comprising a single closed isotopic system, which is incompatible with detrital geochronology. It is possible, however, to assume an initial, non-radiogenic intercept for isochron-based data and calculate two-point regressions through that intercept and each datapoint to calculate an effective spot date. For both Lu-Hf and Rb-Sr the possible/expected initial ratios typically span a rather narrow range of values (e.g. 0.281-0.283 and 0.699-0.78; Rösel and Zack 2022; Fisher and Vervoort 2018). Moreover, the more radiogenic the spot analyses are, the less control the initial ratio exerts on the final two-point isochron date. This dependence is demonstrated in Larson et al. 2022, who show that correcting Rb-Sr data for common ^{87}Sr based on the current $^{87}\text{Sr}/^{88}\text{Sr}$, which effectively mimics the result of a two-point isochron through 0.71, effectively reproduces the isochron regression dates for samples with Rb/Sr. The coincidence of the isochron and spot-dates derived independent of the measured initial $^{87}\text{Sr}/^{88}\text{Sr}$ indicates that detrital Rb-Sr geochronology may be a viable alternative or addition to detrital $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology, eliminating the potential time-consuming step of irradiation.

40

45

50 This study presents the results of *in situ* Rb-Sr analysis of rutile grains picked from sand samples collected from the Bay of Bengal that have either previously been dated via $^{40}\text{Ar}/^{39}\text{Ar}$ detrital geochronology or are directly adjacent to samples that were (see Najman et al. 2019). The potential viability of Rb-Sr as a detrital chronometer is compared against the published $^{40}\text{Ar}/^{39}\text{Ar}$ data. Moreover, the derivation of additional information (i.e., titanium-in-biotite temperature) from the mica grain via LA-ICP-MS is also investigated.

55 2 Methods

To test the viability of detrital Rb-Sr samples (1450-24-25F; 1450-100-104-108F; 1451-47-49F, 1451-86F), collected from late Miocene to middle or late Pleistocene sediments during the Bengal Fan Ocean Discovery Program (IODP) Expedition 354, were examined. For simplicity, the sample names have been shortened here to 25F, 108F, 49F, and 86F, respectively. These same samples, or closely adjacent ones, have been previously investigated for detrital white mica $^{40}\text{Ar}/^{39}\text{Ar}$, zircon fission track, apatite U-Pb, and/or rutile U-Pb geochronology (Najman et al. 2019). Given the propensity for biotite (*sensu lato*) to be more radiogenic than white mica (e.g. Fournier, Camacho, and Lee 2016), and the sensitivity of low radiogenic material to the initial value of an isochron, biotite were targeted in this study. The biotite grains were either

60

manually picked from sediment separates and mounted in epoxy, or the sediments were poured directly into an epoxy mount. After polishing, biotite targets were verified via microXRF elemental mapping of each mount prior to analysis.

65 2.1 Rb-Sr geochronology

Rb-Sr geochronology was carried out via laser ablation inductively coupled plasma tandem mass spectrometry following the basic method outlined in Zack and Hogmalm (2016) and Hogmalm et al. (2017) as described in Larson et al. (2023; 2023). Analyses were carried out in the Fipke Laboratory for Trace Element Research (FiLTER) at the University of British Columbia, Okanagan (UBCO) using an ESL NWR 193 laser with a TwoVol3 ablation cell paired with an Agilent 70 8900 triple quadrupole (QQQ) ICP-MS. A circular laser spot, with a diameter of 65 microns, an estimated fluence of 3 J/cm² and repetition rate of 5 Hz was used for all unknowns and natural mica reference materials. Analyses of the glass reference material NIST610 (Jochum et al. 2011) were carried out using both 60 and 30 diameter laser spots to ensure analyses measured in both pulse and analogue detector modes for cross calibration (e.g. Zack and Hogmalm 2016). Instrument drift and down-hole fractionation was corrected based on analyses of NIST610 using an in-house data reduction scheme (Larson 75 2024) developed for Iolite v.4.8 (Paton et al. 2011). Matrix fractionation was corrected based on repeated analyses of NIST610 (986 ± 5 Ma; Camacho et al. 2020) and verified based on the analyses of CA-550 (Mt. Dromedary - 98.7 ± 1.9 Ma, Li et al. 2008). During run 1 (108F and 47-49F), GA-1550 returned an isochron date of 99.6 ± 3.5 Ma (mean squares weighted deviates (MSWD) = 0.93, n = 14/15, initial ⁸⁷Sr/⁸⁶Sr = 0.7049 ± 0.0017). During run 2 (25F and 86F), GA-1550 returned an isochron date of 98.1 ± 2.3 Ma (MSWD = 0.93, n = 17/17, initial ⁸⁷Sr/⁸⁶Sr = 0.7049 ± 0.0017) while an additional reference 80 material, Mica 1B (990 ± 6 Ma; Camacho et al. 2012), returned an isochron date of 997 ± 6 Ma (MSWD = 1.17, n = 17/20, initial ⁸⁷Sr/⁸⁶Sr = 0.7035 ± 0.0005). Full Rb-Sr data are provided in Tables S1 and S2.

2.2 Ti-in-biotite thermometry

Titanium, magnesium, and iron contents for each Rb-Sr geochronology analytical spot were measured with the radiogenic ratios via LA-ICP-MS using 1 ms, 0.5 ms, and 1 ms dwell times, respectively. Concentrations were normalized to repeated 85 measurements of the NIST610 glass reference material (Jochum et al. 2011) assuming stoichiometric Si (16.36 weight (wt.) % Si or 35 wt % SiO₂), typical of metamorphic biotite from greenschist through granulite grade (e.g. Dyck et al. 2021). Titanium concentrations (ppm) were converted to molar weight per cation TiO₂ equivalents and then normalized to calculated Si content based on an assumed 5.4 atoms per formula unit (a.p.f.u.) Si per 22 O as detailed in Eq. (1):

$$(1) \text{Ti a.p.f.u.} = (c\text{Ti}/_{\text{WT}}\text{TiO}_2/10000/_{\text{M}}\text{TiO}_2) * (5.4/_{\text{A}}\text{Si})$$

90 Where, cTi = concentration of Ti in ppm, _{WT}TiO₂ = weight proportion of Ti in TiO₂, _MTiO₂ = molar weight per cation, and _ASi is the molar weight per cation Si assuming 35 wt % SiO₂. Ti-in-biotite temperatures were calculated using the equation of Henry et al. (2005), which requires Ti a.p.f.u and Mg# (=Mg/(Mg+Fe)) for each analysis. The values for Mg# were calculated using ppm concentrations of Fe and Mg. The 1σ uncertainty of the Ti-in-biotite temperatures is <24 °C at 480 °C decreasing to 12 °C at 800 °C (Henry, Guidotti, and Thomson 2005).

95 To verify the LA-ICP-MS derived Ti-in-biotite temperatures, the chemistries of the same mica grains were analysed using the Cameca SXFive FE electron probe microanalyser (EPMA) also housed in the FiLTER facility. Quantitative spot analyses were carried out with an acceleration voltage of 15kV, regulated beam current of 20nA and a spot size of 5µm. Elemental x-ray data were collected using a dwell time of 30s on peak and 15s on background and were calibrated to the known composition of synthetic and natural mineral reference standards from Micro-Analysis Consultants Ltd. The EPMA data
100 were converted to atoms per formula unit biotite on the basis of 22 oxygen whereby:

(2) cation (a.p.f.u.) = cation proportion * # oxygen (a.p.f.u.) / sum of oxygen proportions,

(3) oxygen proportion = cation proportion * (½) cation charge,

(4) cation proportion = oxide wt. % / oxide molecular wt.

Given that the biotite analysed was collected as detritus from the Bengal Fan, and the tendency of biotite to weather (e.g.
105 Wilson 2004), alteration was expected. To avoid the most altered material, EPMA data were filtered for K concentrations > 1.1 a.p.f.u. Plotting K a.p.f.u against Mg# or calculated temperature shows that analyses with K a.p.f.u. > 1.1 rarely form outliers (Fig. 3). While it is recognized that an a.p.f.u of 1.1 K is significantly lower than that expected of unaltered biotite, K is expected to leave the mineral via hydrated cation exchange as part of the initial weathering stage/vermiculitization (Price and Velbel 2014; Gilkes and Suddhiprakarn 1979). In contrast, Fe, Mg and Ti are relatively immobile until more advanced
110 alteration of biotite to goethite or kaolin (Gilkes and Suddhiprakarn 1979). For EPMA data are provided in Table S3.

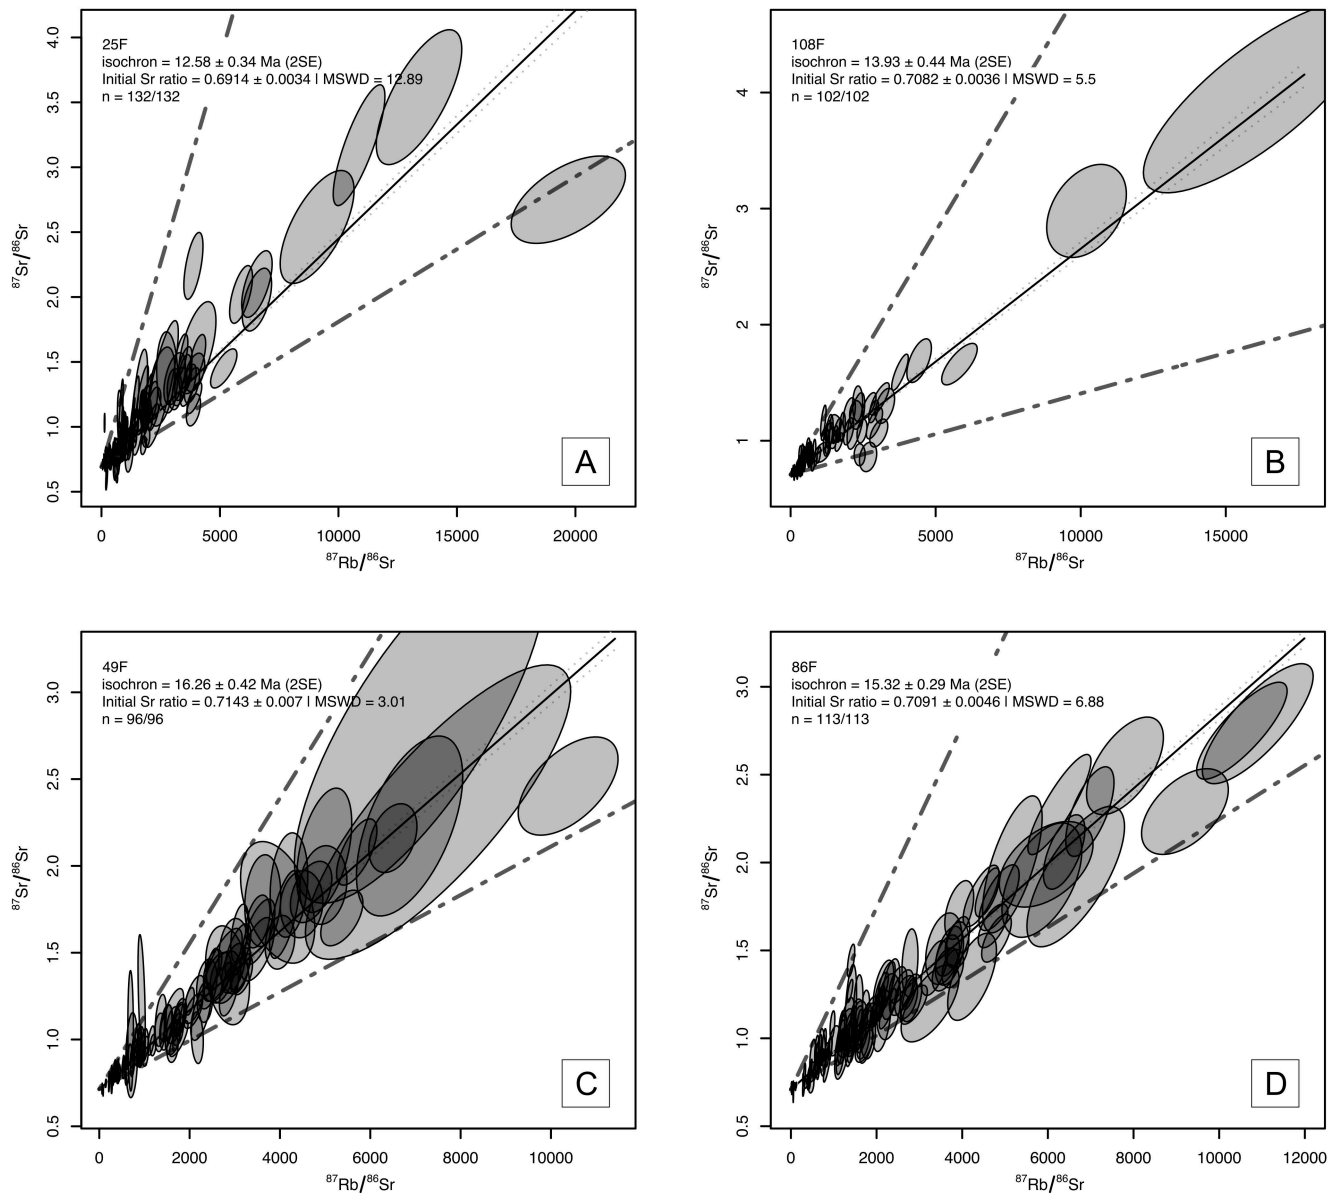

3 Results

3.1 Rb-Sr geochronology

All Rb-Sr results were filtered for Rb/Sr (>3), Fe + Mg (between 15 and 26 wt. %), and Ti (>0.1 a.p.f.u) to avoid spurious analyses. One hundred and thirty-two of 137 spot analyses of biotite from specimen 25F remained after filtering. The data
115 spread between isochrons at 45 and 8 Ma and define an over-dispersed 13 Ma isochron (Fig. 1A). Similarly, One-hundred and thirty-eight spots in biotite from 108F yield 102 viable analyses that spread between 5 and 30 Ma isochrons. The data define an over-dispersed isochron (MSWD = 5.5) at ca. 14 Ma (Fig. 1B). Ninety-six of 104 analyses in biotite separated from 49F spread between isochrons at 10 and 30 Ma, defining an over-dispersed (MSWD = 3.01) isochron at ca. 16 Ma (Fig. 1C). Finally, 113 of 117 biotite analyses of material from 86F spread between reference isochrons at 37 and 11
120 Ma and comprise an over-dispersed (MSWD = 6.88) isochron at ca. 15 Ma (Fig. 1D).

Spot dates for each analysis can be calculated in different ways: 1) two-point dates can be calculated based on a regression between each analysis and a specified initial ⁸⁷Sr/⁸⁶Sr value or 2) spot dates can be calculated based on the regression and intercept defined by the entire dataset as implemented in IsoplotR (Vermeesch 2018), calculation of the second method evaluates each analysis relative to the bulk regression removing a degree of freedom from the calculation relative to a two-
125 point regression. Such a calculation results in smaller uncertainties and more limited variability in the resulting dates.

For each specimen, spot dates were calculated using both methods (see Tables S4-S7). For the two point regression method, dates were calculated assuming initial $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.71, 0.72, 0.73, 0.74, 0.75 and 0.76, covering the range of expected values for most plutonic and metamorphic sources (Rösel and Zack 2022). The dates calculated for each specimen are provided in Table SX and depicted in Fig. 2 as kernel density estimations (KDE; bandwidth = 3). In general, the KDEs have a single peak for > 0 Ma dates. If a spot analysis has a $^{87}\text{Sr}/^{86}\text{Sr}$ < than the initial $^{87}\text{Sr}/^{86}\text{Sr}$, a negative date will be calculated, a situation exacerbated in young material that has not had time to accumulate radiogenic ^{87}Sr product - see Table SX). The half-widths of the KDE peaks for each specimen are generally smallest for the dates calculated based on the isochron regressed through the bulk data and increase in width, decrease in height, and move to a younger position with two-point dates calculated with progressively higher initial $^{87}\text{Sr}/^{86}\text{Sr}$ (Fig. 2).

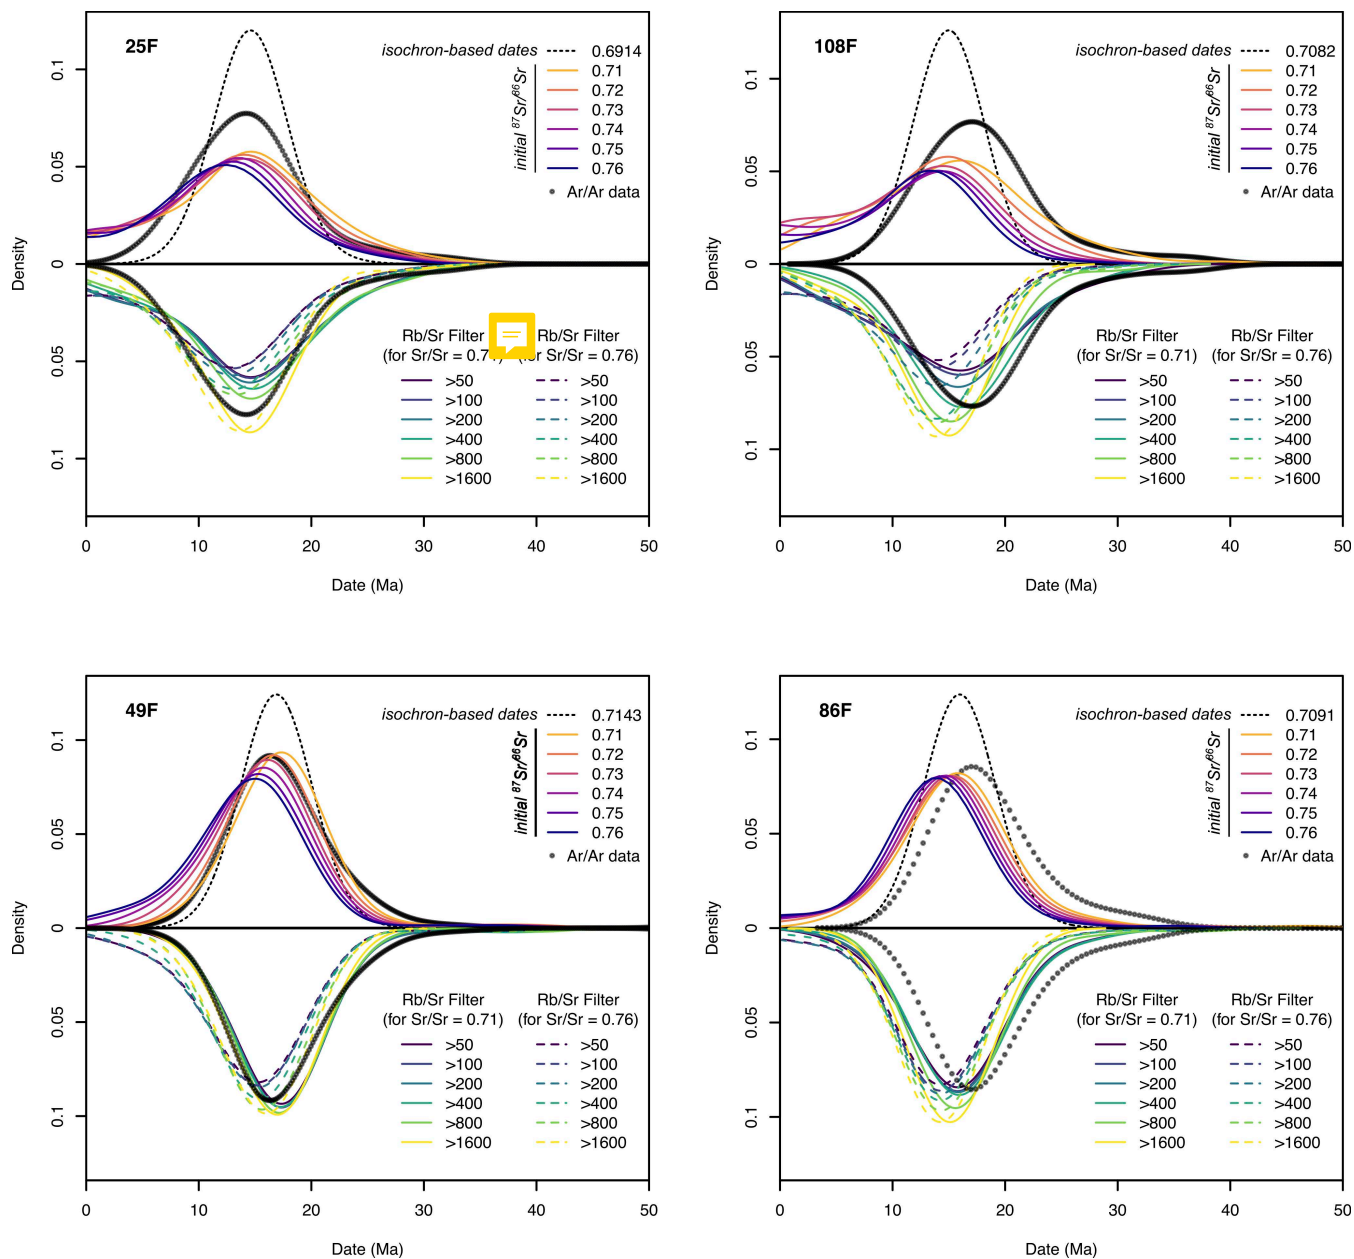

135

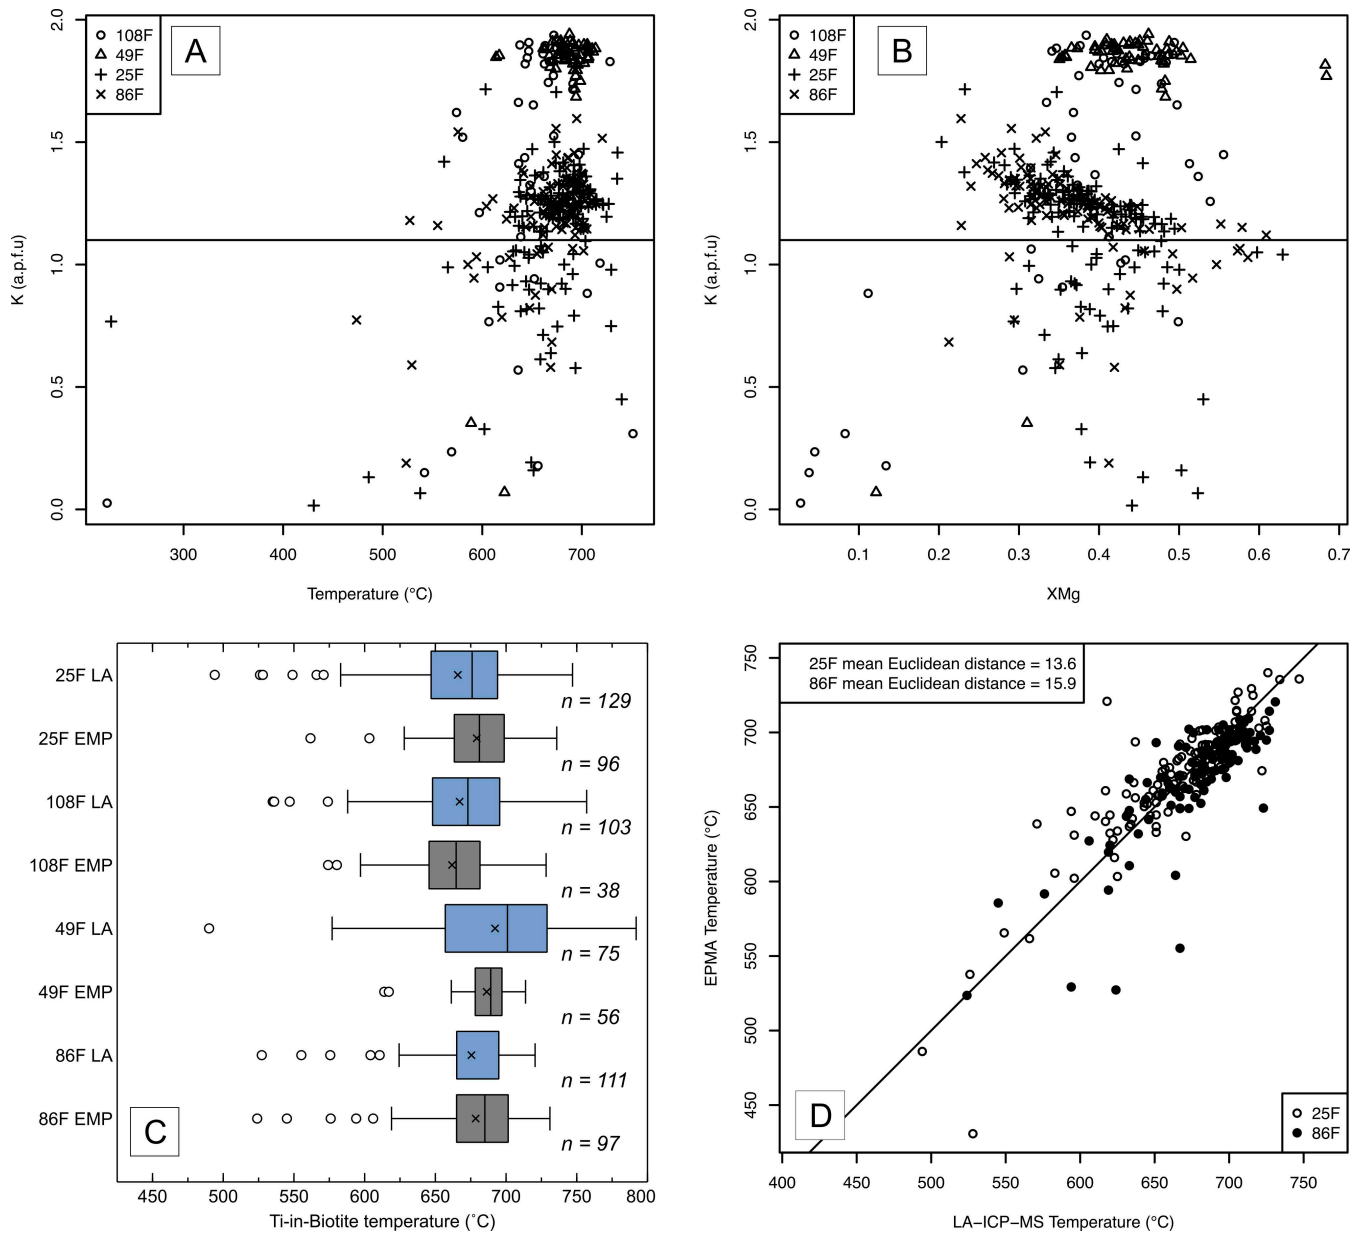

Figure 1: $^{87}\text{Rb}/^{86}\text{Sr}$ versus $^{87}\text{Sr}/^{86}\text{Sr}$ isochron plots of data collected from each sample investigated (A-D). Dashed grey lines denote the approximate envelope of each dataset with corresponding dates as marked. $^{40}\text{Ar}/^{39}\text{Ar}$ dates quoted are from Najman et al. (2019) and correspond to data from samples 1450-38-40F, 1450-98F, 1451-31-33-37F, and 1451-86F for 25F, 108F, 49F and 86F, respectively. 

140 3.2 Ti-in-biotite thermometry

Ti-in-biotite temperatures calculated via LA-ICP-MS data generally range between ~ 650 and 725 °C for most samples (Fig. 3). While the precision of Ti data generated by LA-ICP-MS is lower than EPMA data, the second and third quartile temperatures overlap (within uncertainty) with those calculated using EPMA data for each specimen (Fig. 3).

145 Figure 2: Kernel density estimation (KDE) plots of Rb-Sr data from samples analysed and $^{40}\text{Ar}/^{39}\text{Ar}$ of the same, or spatially
 adjacent, samples. The kernel bandwidth was 3 Ma for all plots. Each diagram shows two different datasets. The data plotted
 above the median line includes $^{40}\text{Ar}/^{39}\text{Ar}$ white mica dates and unfiltered Rb-Sr dates as marked. The 'isochron-based' dates
 are those calculated based on the bulk regression through the dataset, whereas the initial $^{87}\text{Sr}/^{86}\text{Sr}$ dates are calculated as two-point
 150 isochrons. Both types of dates were calculated using IsoplotR (Vermeesch, 2018). The data plotted below the median line represent
 the results of applying different $^{87}\text{Rb}/^{86}\text{Sr}$ filters, as noted.

Figure 3: A) Plot of K atoms per formula unit (a.p.f.u; based on 22O) as calculated from electron probe microanalyser (EPMA) data versus derived Ti-in-biotite temperature. A horizontal line is drawn at K a.p.f.u = 1.1. B) Plot of K a.p.f.u. versus Mg# (Mg# = Mg/(Fe + Mg)) based on EPMA data. A horizontal line is drawn at K a.p.f.u = 1.1. C) Whisker and box plot of calculated Ti-in-biotite temperatures calculated for each sample via EPMA (grey fill) and laser ablation inductively coupled plasma mass spectrometer (LA-ICP-MS) data (blue fill). D) Plot of EPMA versus LA-ICP-MS temperatures for adjacent spot analyses on the same grains in samples 25F and 86F. Average Euclidean distance between the data points for each sample are shown.

4 Discussion

4.1 Effect of initial $^{87}\text{Sr}/^{86}\text{Sr}$

160 As with any isochron method, the value of the initial intercept can have a significant impact on the results when calculating two-point isochron Rb-Sr dates. That effect, however, is less significant with older material and more radiogenic analyses. As shown in Fig. 4, the effect of initial intercept can be demonstrated by generating three artificial datasets with 1 analysis every 500 $^{87}\text{Rb}/^{86}\text{Sr}$ spread between 10 and 4510, one defining a 25 Ma isochron, one defining a 250 Ma isochron and one defining a 2500 Ma isochron, each with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.71. Two-point spot dates were calculated for each datapoint within each model for different initial $^{87}\text{Sr}/^{86}\text{Sr}$ ranging from 0.71 to 0.72 and the % change in two-point isochron date for each modelled point from the known date (i.e. 25, 250 or 2500 Ma) was quantified (Fig. 4). Plotting the % change in two-point isochron date versus $^{87}\text{Rb}/^{86}\text{Sr}$ demonstrates that for low $^{87}\text{Rb}/^{86}\text{Sr}$ and young material is most affected by changing the initial $^{87}\text{Sr}/^{86}\text{Sr}$. Moreover, the plot further demonstrates that for high $^{87}\text{Rb}/^{86}\text{Sr}$ (>2500), even in young material, the typical difference in initial $^{87}\text{Sr}/^{86}\text{Sr}$ encountered in most crustal rocks (i.e. 0.71 to 0.76; Rösler and Zack 2022), will have < 5% effect on the date calculated (Fig. 4). For older material, the $^{87}\text{Rb}/^{86}\text{Sr}$ cut-offs to minimize the effect of initial $^{87}\text{Sr}/^{86}\text{Sr}$ on dates (i.e. < 5%) drops significantly (i.e. $\sim >^{87}\text{Rb}/^{86}\text{Sr} = 500$ @ 250 Ma and $\sim >^{87}\text{Rb}/^{86}\text{Sr} = 50$ @ 2500 Ma; Fig. 4).

165

170

Figure 4: Plot of modelled data demonstrating the related effects of initial $^{87}\text{Sr}/^{86}\text{Sr}$ on calculated two-point isochron dates as a function of $^{87}\text{Rb}/^{86}\text{Sr}$. See text for discussion.

175 The effect of initial $^{87}\text{Sr}/^{86}\text{Sr}$ relative to $^{87}\text{Rb}/^{86}\text{Sr}$ can be further investigated using the real-world data presented herein. Filtering the two-point isochron dates based on $^{87}\text{Rb}/^{86}\text{Sr}$ for initial $^{87}\text{Sr}/^{86}\text{Sr}$ values of 0.71 and 0.76 demonstrates that the position of the main population of the data remains relatively invariant for each different $^{87}\text{Rb}/^{86}\text{Sr}$ but the half-width decreases and the density of the main population increases with higher $^{87}\text{Rb}/^{86}\text{Sr}$ cut-offs (Fig. 2). These results indicate that filtering detrital data by $^{87}\text{Rb}/^{86}\text{Sr}$ may help ameliorate the complication of unknown initial $^{87}\text{Sr}/^{86}\text{Sr}$ values.

180 4.2 Comparison with detrital $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology

Najman et al. (2019) present the results of various detrital geochronology methods employed on the samples examined in the current study and/or other proximal samples. These methods include $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology on white mica. White mica was targeted in that study both because of the common problem of excess Ar associated with biotite (Stübner et al. 2017; Larson, Button, et al. 2023) in the Himalayan system from which these samples were sampled (i.e. Himalayan detritus shed into the Bay of Bengal) and the resilience of white mica, relative to biotite, to weathering (Wilson 2004). Given the differences in clastic product retention between white mica $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology and biotite Rb-Sr geochronology it may not be expected that the data from the two systems would overlap. White mica has an estimated nominal closure temperature of $\sim 425\text{-}400\text{ }^\circ\text{C}$ for Ar diffusion (100 micron radius grain, $10^\circ\text{C}/\text{Ma}$ cooling rate, 5-10 kbar; Harrison et al. 2009), whereas closure to diffusion of Sr out of biotite is more varied with estimates ranging from $\sim 300\text{ }^\circ\text{C}$ (Jäger, Niggli, and Wenk 1967; Armstrong, Jäger, and Eberhardt 1966) to $\sim 400\text{ }^\circ\text{C}$ (Verschure et al. 1980; Del Moro et al. 1982) or even in $400\text{ }^\circ\text{C}$ depending on the specifics of the mineralogy and chemistries of the samples (Jenkin et al. 1995, 2001). That variability in chronometer ‘closure temperatures’ (e.g. Dodson 1973) may be reflected in variable offsets between the Rb-Sr and $^{40}\text{Ar}/^{39}\text{Ar}$ dates (Fig. 2).

The two-point isochron and bulk regression-derived Rb-Sr dates calculated for 108F and 86F define a density peak with a slightly younger offset in the $^{40}\text{Ar}/^{39}\text{Ar}$ dates, whereas for 49F and 25F both types of dates essentially reproduce the density peak in the $^{40}\text{Ar}/^{39}\text{Ar}$ dates (Fig. 2). Overall, the Rb-Sr data, regardless of the method in which the dates were calculated, define the same dominant, early-middle Miocene age (15-16 Ma) population (Fig. 5) noted by Najman et al. (2019), which was interpreted to demonstrate rapid exhumation of the Eastern and Central Himalayan with a < 4 m.y. lag time between exhumation through mica closure and clastic product diffusion and sedimentation. Given the similarities between the datasets, the detrital Rb-Sr geochronology would have led to the same conclusions as the $^{40}\text{Ar}/^{39}\text{Ar}$ data made by Najman et al. (2019).

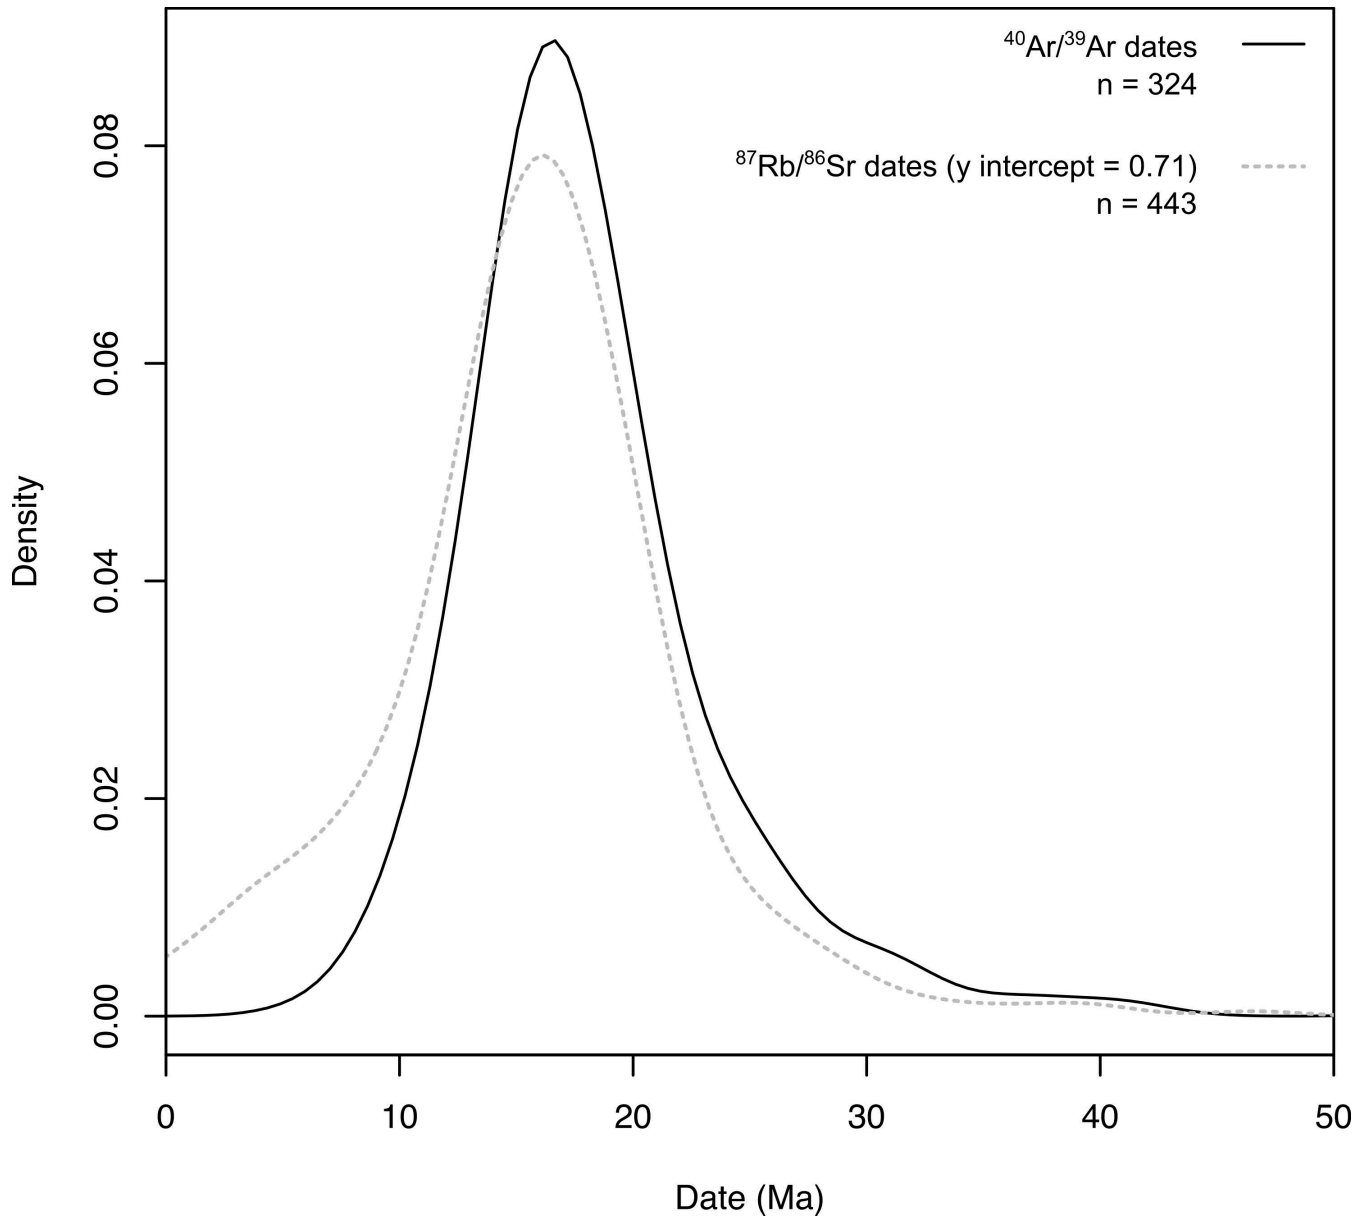

Figure 5: Kernel density estimations (bandwidth = 2) of all $^{40}\text{Ar}/^{39}\text{Ar}$ data reported by Najman et al. (2019) and $^{87}\text{Rb}/^{86}\text{Sr}$ spot-dates collected in the present study assuming an initial $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.71.

205 4.3 Ti-in-biotite thermometry

Comparison of EPMA and LA-ICP-MS thermometry results demonstrate that LA-ICP-MS data can yield results comparable with traditional methods (Fig. 3). The temperatures calculated for the spot data are consistent with derivation from amphibolite-facies metamorphic rocks or associated leucogranites (e.g. Waters 2019), which dominate the inferred exhuming Himalayan midcrustal source (Najman et al. 2019). The temperatures also broadly overlap with Zr-in-rutile temperature

210 measured in detrital rutile from the same samples (Ajman et al. 2019). Direct comparison of LA-ICP-MS and EPMA-
derived temperatures for the same grains from 25F and 86F define mean Euclidean distances of 13.6 and 15.9 °C,
respectively (Fig. 3). Because this approximately 15 °C uncertainty likely reflects the analytical precision of LA-ICP-MS
rather than solely due to the uncertainties stemming from natural variations in biotite chemistry nor the thermometer
215 in-biotite temperature estimates, whether EPMA or LA-ICP-MS derived, does not facilitate quantifying a change across the
sampled strata from all samples overlap (Fig.3).

The viability of quantifying Ti-in-biotite temperatures via LA-ICP-MS allows each Rb-Sr spot analysed to be associated
with a unique temperature. This kind of petrochronologic association opens the possibility of many different types of studies,
not unlike the linking of chemistry to spot dates did for U(-Th)-Pb geochronology in the early 2000s (e.g. Foster et al. 2004;
220 Gibson et al. 2004; Rubatto 2002).

5 Conclusions

LA-ICP-MS Rb-Sr geochronology appears to be a viable method to efficiently generate detrital biotite geochronological
datasets. The effect of unknown initial $^{87}\text{Sr}/^{86}\text{Sr}$ values can be mitigated for young (Cenozoic) material by filtering for
significantly radiogenic analyses ($^{87}\text{Rb}/^{86}\text{Sr} > 20$). Filtering can be less aggressive for older material (i.e. $>500 @ 250 \text{ Ma}$)
225 in which significant radiogenic ^{40}Ar product has accumulated. Finally, the benefits of biotite Rb-Sr geochronology can be
further extended by calculating a Ti-in-biotite temperature for each spot. Such information may allow for identification of
multiple sources in detrital samples with complex provenance.
