Abstract

Measurements during episodes of African dust, made with two Wideband Integrated Bioaerosol Spectrometers (WIBS), one on the northeastern coast of Puerto Rico and the other in the city of León, Spain, show unmistakable, bioaerosol-like fluorescing aerosol particles (FAP) that can be associated with these dust episodes. The Puerto Rico event occurred during a major incursion of African dust during June 2020. The León event occurred in the late winter and spring of 2022 when widespread, elevated layers of dust inundated the Iberian Peninsula. Satellite and back trajectory analyses confirm that dust from Northern Africa was the source of the particles during both events. The WIBS measures the size of individual particles in the range from 0.5 μm to 30 μm , derives a shape factor and classifies seven types of fluorescence from the FAP. In general, it is not possible to directly determine the specific biological identity from fluorescence signatures; however, measurements of these types of bioaerosols in laboratory studies allow us to compare ambient fluorescence patterns with whole microbial cells measured under controlled conditions. Here we introduce some new metrics that offer a more quantitative approach for comparing FAP characteristics derived from particles measured under different environmental conditions. The analysis highlights the similarities and differences at the two locations and reveals differences that can be attributed to the age and history of the dust plumes, e.g., the amount of time that the air masses were in the mixed layer and the frequency of precipitation along the air mass trajectory.

Keywords: African Dust, Bioaerosols, Fluorescing Aerosol Particles, WIBS, fluorescing particle finger prints.

1.0 Introduction

Fungal spores, spread by air currents, are some of the most abundant components of the bioaerosol population (Després et al., 2012). Their presence in the atmosphere has been linked to the formation of cloud condensation and ice nuclei (CCN and IN), thus playing a key role in the hydrological cycle (Huffman et al., 2013; Woo et al., 2018; Lawler et al., 2020). However, they also may have a negative environmental impact as many of them are described as important phytopathogens and constitute a hazard to animal and human health (Fröhlich-Nowoisky et al., 2016). Although there is a large fungal biodiversity, the most abundant taxa are Ascomycetes and Basidiomycetes (Fröhlich-Nowoisky et al., 2009; Dietzel et al., 2019). The airborne spore load varies depending on the location and the season since such loading is closely linked to the vegetation and the meteorological conditions (Kasprzyk et al., 2015; Grinn-Gofroń et al., 2019; Anees-Hill et al., 2022; Rodríguez-Fernández et al., 2023). Nevertheless, the annual airborne dynamics can be altered by extreme weather phenomena such as thunderstorms, frontal systems or dust intrusions (Wu et al., 2004; Pulimood et al., 2007).

Dust intrusions are especially important because these long-distance, spore transport events allow them to colonize new environments (Rodríguez-Arias et al., 2023). In fact, some of these African dust (AD) events have been related to important environmental hazards such as decline of Caribbean coral reefs (Shinn et al., 2000; Hallegraeff et al., 2014). Agglomeration processes may also occur during these dust events, facilitating the adhesion of particulates with small diameters (40-90 nm) onto the surfaces of the pollen grains and spores. Gravitational coagulation has been identified as the most likely mechanism of deposition on particle surfaces of about 20 μm (pollen grains) during long distance transport (Choël et al., 2022); however, other mechanisms of particle scavenging should not be underestimated. Fungal spores typically carry an electrostatic charge due to the complex chemical composition of their cell walls (Hannan, 1961; Leach, 1976; Feofilova, 2010; Wargenau et al., 2011). The differences in electrostatic charges can cause other particles to bind to the spore surface (Visez et al., 2020). The agglomeration process may increase the allergenic potential of airborne spores and pollen due to chemical reactions, increasing the health risk for allergy sufferers (Sénéchal et al., 2015).

The arid regions of Northern Africa are some of the largest sources of desert dust in the world. These regions emit about 800 Tg yr⁻¹, corresponding to approximately 70% of the annual, global dust loading (Prospero et al., 2014; Ryder et al., 2019). A large fraction (~182 million tons yr⁻¹) of these emissions moves westward, ~2500 km across the Atlantic Ocean, extending in a continuous AD plume over the Caribbean basin (Yu et al., 2015, 2021). Similarly, the transport of AD over Europe has a clear seasonality whereby such events are more frequent from late autumn to early winter (February to June) (Escudero et al., 2005; Garcia Valero et al., 2022). With climate change contributing to further desertification, not only on the Africa continent, but in Asia and other parts of the world, dust incursion events will likely increase in intensity and duration in the coming decades.

Fluorescence from dust particles has also been detected with lidar, such as the measurements reported Sugimoto et al. (2012) and by Wang et al. (2023) who report relatively strong, broad fluorescence from Asian dust and air-pollution aerosols transported from urban and industrial areas at wavelengths between 343nm and 526nm.

The majority of studies that have evaluated the transport of bioaerosols by AD have used samplers that captured the particles on substrates that were subsequently analyzed in the laboratory under a microscope or using Deoxyribonucleic acid (DNA) analysis. These analysis methodologies are the most robust for identifying specific taxa of biological spores; however, online techniques offer the advantage of larger sample sets that can be evaluated in much higher temporal resolution. Techniques that use Ultra-violet Laser Induced Fluorescence (UV-LIF), such as the Wideband Integrated

95 Bioaerosol Spectrometer (WIBS), provide detailed information on the size, shape and fluorescence
96 intensity of individual particles in real time (Kaye et al., 2004). The recent investigation by Morrison
97 et al. (2020) employed a WIBS that was situated at the Sao Vicente Cape Verde Atmospheric
98 Observatory, off the west coast of central Africa, measuring continuously from September 2015 to
99 August 2016. Their measurements found strong seasonal changes in absolute concentrations of
100 fluorescing aerosol particles (FAP) with significant enhancements during winter due to the strong
101 island inflow of air masses originating from the African continent. Their results indicate that the
102 relative contribution of bioaerosol material in dust transported across the tropical Atlantic throughout
103 the year is relatively uniform, consisting mainly of mixtures of dust and bacteria and/or bacterial
104 fragments. They support their conclusions by comparing the WIBS measurements with those from a
105 Laser Ablation Aerosol Particle Time of Flight mass spectrometer (LAAP-ToF). The latter
106 measurements show a high correlation between particles with mixed bio-silicate mass spectral
107 signatures and UV-LIF bio-fluorescent signatures, leading to the conclusion that the FAP
108 concentrations are dominated by these mixtures.
109

110 The measurements reported here, in our current study, complement those of Morrison et al. (2020)
111 with results from locations farther down-wind than their study site of Cape Verde. Our objectives are
112 to *1) expand the database of real time measurements related to long-range transported African
113 dust and the FAP associated with these events, 2) evaluate the relative changes in the multi-faceted
114 patterns of fluorescing particles, measured with the UV-LIF technique, as they relate to the air
115 mass sources and ages, 3) introduce new metrics, unique to the UV-LIF technique that provide
116 additional quantification of the FAP properties and 4) compare the real time fluorescence
117 signatures to those bioaerosols measured with off-line techniques.*
118

119 **2.0 Measurement locations, sensor description and analysis methodology**

120 **2.1 Study zones**

121
122 The Caribbean measurement site is the Cape San Juan (CSJ) atmospheric observatory (18°22.85'N,
123 65°37.07'W and 60 m, asl) located on the most northeastern point on the coast of Puerto Rico (PR).
124 The European measurements were made at the University of León, León, Spain, located in the
125 northwest region of the Iberian Peninsula (42° 36' N, 05° 35'W and 838 m, asl). Cape San Juan is a
126 remote, coastal research site managed by the Atmospheric Chemistry and Aerosols Research (ACAR)
127 group at the University of Puerto Rico – Rio Piedras Campus (UPR-RP). This measurement site has
128 been frequently used for sampling aerosols of non-anthropogenic origin (Novakov et al., 1997;
129 Mayol-Bracero et al., 2001; Allan et al., 2008) because the predominate airflow is from the northeast
130 and the particles are typically those generated from the ocean. i.e. sea salt, non-sea salt sulfates and
131 organic carbon (Allan et al., 2008) Furthermore, CSJ is also a recognized site for the World
132 Meteorological Organization's Global Atmospheric watch (WMO GAW) (Andrew et al., 2019) and
133 the National Aeronautics and Space Administration (NASA) network for AERONET, PANDORA,
134 and MPLNET.
135

136 The city of León is located in the northwest of the Iberian Peninsula. The climate has Mediterranean
137 maritime as well as continental features (Calvo et al., 2018). The sampling site is on the roof of the
138 Faculty of Veterinary, 15 m above ground level, at the León University Campus. The university is
139 located in the northeast suburban region of the city, which is largely devoid of local industrial
140 emissions, although there are daily anthropogenic emissions from vehicular traffic whose organic
141 compounds, like polyaromatic hydrocarbons (PAH), will fluoresce and need to be removed from the
142 evaluation as non-bioaerosols, a procedure discussed below.
143

144 **2.2 Data sets and sources**

145

146 The data used in the present study comes from several sources of in-situ and remote sensor
 147 measurements, as well as air mass back trajectories derived from archived meteorological data. Table
 148 I lists the data sets that have been evaluated, their sources and the parameters that were extracted. The
 149 primary source of particle information comes from the Wideband Integrated Bioaerosol Spectrometer
 150 (WIBS) since the main focus of our study is on the FAP that is being transported by AD. Ancillary
 151 information about the origins of the air masses, complementary measurements of the particle optical
 152 properties and the state of the local environments, e.g., meteorology, are included in order to better
 153 understand the impact of the AD intrusions.

155 Given the importance of the WIBS measurements, the following section focuses on the WIBS's
 156 measurement principles, limitations and uncertainties, the filtering necessary to minimize artifacts in
 157 the data, the corrections applied for dead-time losses and the parameters that are derived that provide
 158 tracking of the unique patterns that are found in the particle properties.

160
161
162

Table I
Data sets used in the Analysis

Data Set Description	Data Source	Extracted Parameters	Measurement Sites
Single particle aerosol properties	WIBS-V ¹	Aerosol particle equivalent optical diameter, 0.5 – 30 μm , autofluorescence, Asphericity factor, non-FAP and FAP number concentrations.	PR and LUC
Fog properties	FM-120 ¹	Fog droplet equivalent optical diameter, droplet number concentration, liquid water content.	LUC
Aerosol Particle mass	MET-1 ² ,	Mass concentration in particles with aerodynamic diameter < 10 μm (50% cut size)	LUC
Filter samples	Hirst spore trap (VPPS 2000, Burkard) ³	Morphological identification of fungal spore and pollen taxa.	PR and León
Aerosol optical properties	Aethalometer ⁴ , AERONET Sun photometer ⁵	370 nm and 880 nm absorption coefficient, Multi-wavelength optical depth	PR
Local environments state parameters and radiation	Meteorological weather stations ⁶	Temperature, humidity, pressure, wind speed and direction and visibility	PR, LUC
MERRA-2	Modern-Era Retrospective analysis for Research and Applications version 2 ⁷	Column mass density of aerosol components (black carbon, dust, sea salt, sulfate, and organic carbon), surface mass concentration of aerosol components, and total extinction (and scattering) aerosol optical thickness (AOT) at 550 nm	PR, LUC
Air mass back trajectories	Hysplit ⁸	Location and meteorology at hourly intervals	PR, LUC

164 **2.3 Wideband Integrated Bioaerosol Spectrometer (WIBS)**

165 166 **2.3.1 Principles of operation, uncertainties and limitations**

167
168 The WIBS measurement principles are based on Ultraviolet light-induced fluorescence (UV-LIF)
169 (Kaye et al., 2005; Stanley et al., 2011). The current instrument model, the WIBS-V, differs from
170 earlier models only in how the data are formatted and how deadtime losses are taken into account.
171 The supplementary material describes the WIBS in greater detail, along with the specific algorithms
172 used to filter and correct the measurements prior to analysis and interpretation. All WIBS models
173 bring individual particles into the instrument with an internal pump and direct them through a
174 collimated laser beam using aerodynamic focusing. The light scattered from each particle is used as
175 a signal to trigger two xenon flash lamps, which activate sequentially, illuminating the particle as it
176 leaves the laser beam with light filtered at 280 nm and 370 nm, respectively. Two detectors, one with
177 a bandpass filter at 310-400 nm and the other with a 420-650 nm filter, receive light emitted by
178 autofluorescence if there is material in the particle that is excited to fluoresce at one or both excitation
179 wavelengths. The equivalent optical diameter (EOD) is derived from the light scattered by the particle
180 as it transits the laser beam and an “asphericity/asymmetry factor” (AF) is derived from a quadrant
181 detector that is illuminated by the forward scattered light from this same particle.
182

183 A number of naming conventions have been introduced in the literature over the years for labeling
184 the fluorescence combinations that are possible with the WIBS measurements; however, they all
185 agree on using FL1 (Channel A) and FL2 (Channel B) to denote signals from the excitation at 280
186 nm, emissions at 310-400 nm and 420-650 nm, respectively, and FL3 (Channel C) to indicate signals
187 from excitation at 370 nm and emissions at 420-650 nm. As is often the case, the fluorescence from
188 a single particle may be a combination of any two or three of these excitation/emission pairs, leading
189 to as many as seven possible fluorescent types. Following the convention first proposed by Perring et
190 al. (2015), we will label these seven types as A, B, C, AB, AC, BC and ABC throughout the remainder
191 of this presentation.
192

193 The two major sources of uncertainty are fluorescence artifacts and missed fluorescence signals due
194 to electronic deadtime. Both of these uncertainties, and steps taken to minimize or to correct for them,
195 are discussed in greater detail in the supplemental material, as well as in previous publications (Calvo
196 et al., 2018; Sarangi et al., 2022). In short, there are two types of fluorescence artifacts: 1) light
197 detected by the fluorescence detectors that wasn't fluorescence from ambient particles and 2) light
198 detected by the fluorescence detectors that is produced by non-biological materials.
199

200 If the chamber where particles are illuminated by the flash lamps is not cleaned after regular use,
201 material may accumulate that will fluoresce, albeit at a fairly low level. Nevertheless, this
202 fluorescence represents a source of background noise that needs to be quantified and removed from
203 the signal produced by legitimate FAP. A second source of fluorescence artifacts is the light from the
204 Xenon lamps themselves, a small fraction of which can leak through the filters in front of the
205 fluorescence detectors since these filters are not 100% efficient at removing light at wavelengths
206 outside their wave band. Non-biological materials, such as polycyclic aromatic hydrocarbons (PAH)
207 or black carbon, which can also fluoresce when illuminated, are considered here as artifacts with
208 respect to differentiating them from fluorescing bioaerosols (Gabey et al., 2013; Perring et al., 2015;
209 Pöhlker et al., 2012; Toprak and Schnaiter, 2013). These artifacts cannot be completely removed from
210 the analysis but can be minimized by removing from the processing any particles whose fluorescence
211 falls below a preset threshold. As described in the supplementary material, we follow the
212 methodology of Perring et al., (2015) and Morrison et al (2020) by creating daily frequency
213 histograms of the FL1, FL2 and FL3 type FAPs and use a threshold that is the mode of the frequency
214 distribution plus nine standard deviations (9σ) as the minimum threshold that has to be exceeded
215 before a fluorescing event is accepted as valid.

216

217 The aforementioned uncertainty due to electronic deadtime is associated with the eight milliseconds
218 that is required to recharge after each Xenon lamp flash. During this period, if the lamps receive a
219 trigger signal, they will not discharge so if the particle that is passing through the chamber is an FAP,
220 it will not be identified as such since it won't be excited by the lamps. The WIBS registers the
221 particle's size but a statistical correction is needed to account for the fraction of particles each second
222 that might have been FAP but passed through the Xenon chamber during a "dead time". The
223 supplementary material discusses how this correction is derived.

224

225

226 2.3.2 FAP features extracted from laboratory bioaerosol studies

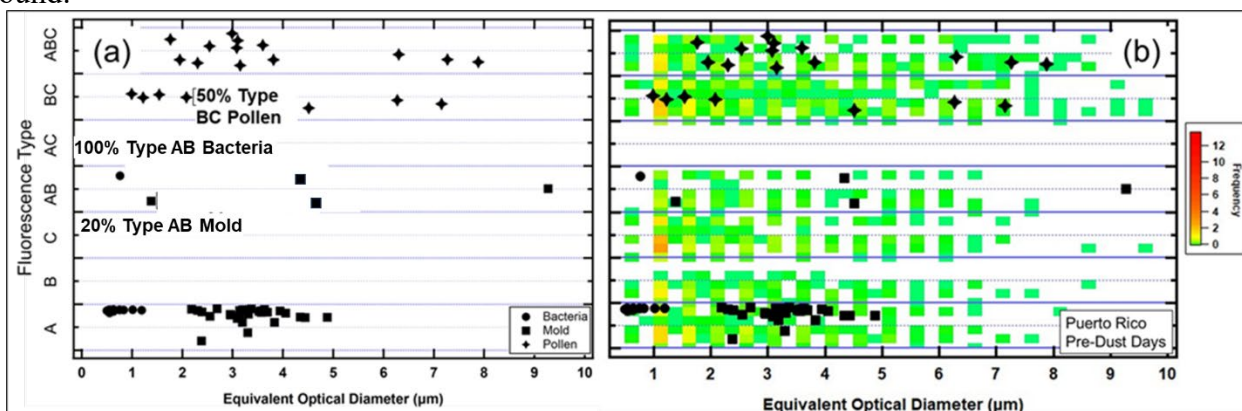

227

228 The FAP that were measured for the current study are assumed to be bioaerosols since we have taken
229 care to minimize artifacts; however, we are unable to *a priori* use the FAP properties to label the
230 particle as a specific taxa of bioaerosol, i.e. bacteria, fungal spores or pollen (BSP), to name the three
231 bioaerosol types most commonly found in the ambient environment (henceforth, we will group these
232 three types of bioaerosols and refer to them as BSP). We will take, instead, the same approach as in
233 Calvo et al. (2018) and refer to a specific FAP, for example, as "bacteria-like" or "fungi-like" when
234 a specific set of FAP metrics in the environmental measurements match the same metrics derived
235 from laboratory measurements. Here we are making the assumption that ambient conditions like
236 temperature and humidity do not change the fluorescence properties of a particular taxa from those
237 measured in the laboratory for the same taxa.

238

239 We have reprocessed the data set that was used in the Hernandez et al. (2016) laboratory studies: 15
240 types of bacteria, 29 types of common fungal spores and 13 varieties of pollen, those typically found
241 in the natural environment. Figure 1a shows a composite of the fluorescence type and EOD of the 57
242 different varieties of BSP. Figure 1b shows an example of these same varieties superimposed on a
243 composite of measured FAP for a non-dust day in PR. This illustrates how the environmental data
244 clusters by FAP type and EOD in patterns very similar to those formed from the laboratory
245 measurements. The color scale in Fig. 1b denotes how frequently during the two-day period the FAP
246 types and EODs fell within the different FAP Type vs EOD regions. In this example, although the
247 environmental FAPs fall in regions where the lab data show bacteria, fungal spores and pollen, quite
248 a few of the FAP were in the regions of FAP types C and AB where very few of the lab results were
249 found.

250

251 **Figure 1. a) A BSP map showing how 15 bacteria, 29 mold and 13 pollen, of different taxa were measured in the**
252 **laboratory by a WIBS, as a function of FAP type and EOD and b) the same BSP map with FAP measurements from**
253 **a non-dust day in Puerto Rico plotted using the same definitions for FAP type and EOD. The color scale denotes how**
254 **frequently during the two-day period the FAP types and EODs fell within the different regions. In this example,**
255 **although the environmental FAPs fall in regions where the lab data show bacteria, mold and pollen, quite a few of the**
256 **FAP were in the region of FAP types C and AB where very few of the lab results were found.**

257

258 Although this method of comparing lab BSP patterns with environmental FAP cannot be construed
259 as a quantitative way to relate the WIBS measurements directly to BSP taxa, the laboratory data
260 provides a reference data set to which we can compare the measured BSP maps and evaluate relative
261 changes in patterns related to the AD intrusions.
262

263 **2.3.3 Working Hypothesis and Analysis Metrics**

264

265 From our work, and from those of others, we have sufficient measurements to conclude that
266 fluorescence intensity, regardless of the BSP taxa, is too variable to be used as a FAP property that
267 can be unequivocally or unambiguously related to a bioaerosol type. Likewise, the asymmetry factor
268 can be used as a rough indicator of asphericity but cannot provide finer structural details. The
269 fluorescence emission intensity is a complex interaction between the uniformity of the excitation
270 radiation over the surface of the FAP, the orientation of the particle as it is exposed to the incident
271 light, the non-isotropic nature of the fluorescence emissions and fluorescence quenching by material
272 mixed with the FAP (Lakowicz, 2006). Adding to these uncertainties are the observations from
273 microscopic analysis that a significant fraction of bioaerosols in the natural environment are not
274 intact, i.e. they are fractured pieces that can still fluoresce but with less intensity and with shapes
275 unrepresentative of a whole particle.
276

277 The specific pairs of excitation/emission wavelengths employed in the WIBS were originally selected
278 by Kaye et al., (2005) due to their responsiveness to tryptophan (280 nm/310-400 nm) and
279 nicotinamide adenine dinucleotide (NAD; 370 nm/420-650 nm). Given that these two fluorophores
280 are omnipresent in plant tissues and microbiological cells they are good fluorescent markers for
281 bioaerosols. Nevertheless, the aforementioned uncertainties prevent more definitive speciation of the
282 FAP without complementary analysis using samples captured on filters or substrates that can undergo
283 microscopic analysis and classification by human observers or more intensive DNA analysis.
284

285 The advantage and power of the WIBS is the high-resolution information that it extracts from
286 individual particles, information that provides a statistically large sample that describes the sizes,
287 shapes and fluorescence patterns of an ensemble of particles in air masses whose properties can
288 change over relatively short time periods. Hence, even though there are large variations in these
289 properties, particle by particle, over periods as short as five to ten minutes, tens of thousands of
290 particles in the size range of 0.5 to 30 μm can be analyzed. Not only are the average properties
291 important, but their variances also contain valuable information about the composition and potential
292 sources of these particles.
293

294 The analysis methodology that is selected to evaluate the WIBS data needs to be tailored to the
295 specific questions that are being addressed. Much progress has been made in the past 10 years in the
296 use of cluster analysis to identify features of the FAP, which are indirectly related to the type of
297 bioaerosol (Robinson et al., 2013; Crawford et al., 2015; Morrison et al., 2020). In our study, however,
298 we are asking a different set of questions, where knowing the type of bioaerosol is not as important
299 as understanding how the FAPs are transported and their properties transformed while in AD plumes.
300 Hence, we take a more heuristic approach whereby we concentrate on evaluating the nine parameters
301 (size, shape and seven FAP types) that can be extracted from individual particles, and we use these
302 to address the following questions:
303

- 304 1. Are the FAP that are found within the AD plumes, which inundate the Caribbean and Iberian
305 Peninsula, internally or externally mixed with the dust particles?
- 306 2. What features of the FAP change from normal background conditions to periods when the
307 AD is present?
- 308 3. Can the observed changes in the FAP properties be physically linked to the air mass histories?
309

310 Starting with the assumption that the properties of aerosols in dust plumes will differ significantly
 311 from those of aerosols in the local environments of PR and León, *we hypothesize that 1) the*
 312 *bioaerosols that are in the dust plumes will be a mixture of bioaerosol types that differ from those*
 313 *found in the PR or León ambient environments and 2) the majority of FAP in the AD plumes will*
 314 *be attached or internally mixed with dust particles.*
 315

316 To provide answers to these questions, and to test our working hypotheses, we focus on how the size
 317 distributions of number concentration, fluorescence intensity and shape factor differ within the
 318 populations of non-FAPs and FAP. These differences, between the PR and León sites, before and
 319 during AD events, can be quantified using comparisons of the size distribution metrics. These metrics
 320 can be visualized by referring to Fig. 2 that shows example size distributions of the FAP Type ABC
 321 fluorescence intensity (Fig. 2a), number concentration (Fig. 2b) and shape factor (Fig. 2c), before
 322 (green curve), and during (brown) a dust intrusion. An EOD of 5 μm has been arbitrarily selected as
 323 the threshold between “small” and “large” particles.
 324

325
 326 **Figure 2.** Examples of size distributions of Type ABC fluorescing aerosol particles before (green curve) and during
 327 (brown curve) a dust intrusion, highlighting the features that are used as metrics in the analysis methodology. (a)
 328 Average fluorescence intensity as a function of EOD. The vertical and horizontal blue arrows highlight increases in
 329 intensity and size, respectively, with the incursion of AD. The size distributions have been divided into “small particle”
 330 (shaded) and “large particle”. (b) average number concentration as a function of size and (c) average asphericity as
 331 a function of size
 332

333 The metrics that are derived from these size distributions, and that we will use in our comparative
 334 analyses, are:

- 335 1. The change in fluorescence intensity, number concentration and shape factor of small
 336 particles
- 337 2. The change in fluorescence intensity, number concentration and shape factor of large
 338 particles
- 339 3. The change in the ratio between the concentration of small to concentration of large particles
- 340 4. The change in median diameter

341
 342 From the examples shown in Fig. 2, for the FAP Type ABC, there is a significant increase in the
 343 average fluorescence intensity and number concentration of small and large EOD particles with the
 344 intrusion of AD; however, the shape factor size distributions are similar. As will be highlighted below,
 345 these differences can be interpreted in the context of the relative mixture of FAP types and also how
 346 these FAP are physically mixed with non-FAP.
 347

348 2.4 Complementary measurements

349
 350 Meteorological data, including temperature ($^{\circ}\text{C}$), relative humidity (RH, %), rain (mm), pressure
 351 (mb), wind speed (WS, m s^{-1}) and wind direction ($^{\circ}$) were accessed from the weather station (Vaisala,
 352

353 WXT 530) mounted on the top (30' from the ground) railing of an aluminum tower at the Puerto Rico
354 measurement site (CSJ).

355 The optical properties of the particles in PR were measured in situ with an aethalometer (Magee
356 Scientific) and remotely with a sun photometer. The aethalometer derived the absorption coefficients
357 from measurements of attenuations at 370 nm and 880 nm. The spectral Aerosol Optical Depth
358 (AOD), Ångström exponent, and volume size distributions were accessed from the sun/sky CIMEL
359 CE_318 sun photometer that measures the direct solar irradiances with a field of view of
360 approximately 1.2° and the sky radiances at spectral wavelengths of 340, 380, 440, 500, 675, 870,
361 1020, 1640 nm, respectively. The CIMEL Sun photometer at CSJ is a component of NASA Aerosol
362 Robotic NETwork (AERONET) that provides long-term records of columnar aerosol optical
363 characteristics (Holben et al., 1998) since 2004.

364 In addition to the particle mass (PM) measurements made with the PM Beta monitor at the Junta de
365 Castilla and León air quality stations, an FM-120 fog monitor was operated in parallel with the WIBS
366 in León. The FM-120, developed by Droplet Measurement Technologies LLC, measures the EOD of
367 individual environmental particles from 2 - 50 µm. The FM-120 was originally developed to measure
368 fog droplet properties; however, the measurements are not specific to fog and in the presence of dust
369 particles it will measure their size distributions but with a larger uncertainty because these particles
370 will not be spherical nor will they have a refractive index of water (1.33). The estimated uncertainty
371 due to shape and refractive index uncertainty is approximately ±30%.

372
373 Fungal spores and pollen were collected with Hirst samplers (Hirst, 1952) in PR and León where they
374 were subsequently analyzed and classified by inspection under a microscope.

375 376 **3.0 Results**

377
378 Prior to delving into the details of the in situ WIBS measurements, we use remote sensing data to
379 provide the complementary evidence for the large dust incursions on those days where the WIBS
380 measured particle properties that were anomalous when compared to those normally encountered
381 during the respective summer and spring seasons in PR and León.

382 383 **3.1 Remote Sensing Observations**

384
385 Satellite images from the Suomi National Polar-Orbiting Partnership (Suomi NPP,
386 <https://ncc.nesdis.noaa.gov/VIIRS/>) show a high frequency of dust intrusions over the North Atlantic
387 during the spring and summer of 2020. One of these events was an intense, widespread dust plume
388 that was observed over the eastern North Atlantic, clearly originating from the African Sahara region.
389 The June 23, 2020, satellite image, shown in Fig. S1, reveals a large region of dust over the Caribbean
390 with another extensive layer of dust leaving northern Africa. This dust plume, which at some point
391 had a size equivalent to the area of continental USA (around 8,000,000 km²), impacted the Caribbean
392 region and parts of South America, Central America, Gulf of Mexico, and the Southern USA from
393 June 21 to July 1. On June 20, when the first dust layer began to affect the Caribbean, a second layer
394 was clearly seen leaving Africa (Fig. S1a), but smaller in extent than the first one (Yu et al., 2021).
395 This second dust layer impacted the same area as the first plume from 26th of June to July 1. On June
396 22-23, PR received the leading edge of the dust plume followed by a second dust incursion on June
397 28-29 (Fig. S1a). This event has been reported by a number of research groups (Francis et al., 2020;
398 Pu and Jin, 2021; Yu et al., 2021; Asutosh et al., 2022). According to Pu and Jin (2021), the
399 meteorology behind this dust plume is unprecedented: the surface wind speed (the strongest since the
400 previous 42 years) increased the dust emissions in Africa followed by an intensified African Easterly
401 Jet (AEZ) moving the dust plume westward. Francis et al (2020) posit that the extreme dust event
402 was caused by the development of a subtropical high-pressure system over northwest Africa that led

403
404
405
406
407

to the strong north-easterlies that were sustained over the Sahara generating four days of continuous dust emissions. This dust event is also clearly seen from the Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2), shown in Fig. 3a for June 23, 2020, which shows clearly the same patterns that were derived from the Suomi NPP satellite products (Fig. S1a).

421
422
423

The Iberian Peninsula is also frequently inundated by Saharan dust outbreaks due to its proximity to large dust-emitting areas of the Sahara and Sahel deserts and to the atmospheric dynamics and meteorological conditions (Alastuey et al., 2016; Escudero et al., 2007; Querol et al., 2014; Rodríguez et al., 2001). Previous studies reported that most of the outbreaks occur between spring and summer when the dust transportation is regulated by the anticyclonic activities over the east or southeast of the Iberian Peninsula (Lyamani et al., 2015; Rodríguez et al., 2001; Salvador et al., 2013). In winter, Saharan dust intrusions are scarce and are usually dominated by the cyclonic activities over the west or south of Portugal (Díaz et al., 2017; Rodríguez et al., 2001). However, in late winter, 2022, an unprecedented dust storm impacted the Iberian Peninsula. The dust layer traveled over a large portion of Europe, initially on 16-17 March 2022, followed by a secondary dust plume that covered an extended region 27-30 March 2022. The satellite imagery obtained with the Suomi NPP clearly shows

424 the dust layer over the Iberian Peninsula on March 16 and 17 2022 (Figs S1b and c) and also seen in
425 the images derived from the MERRA-2 data (Fig. 3b)

426

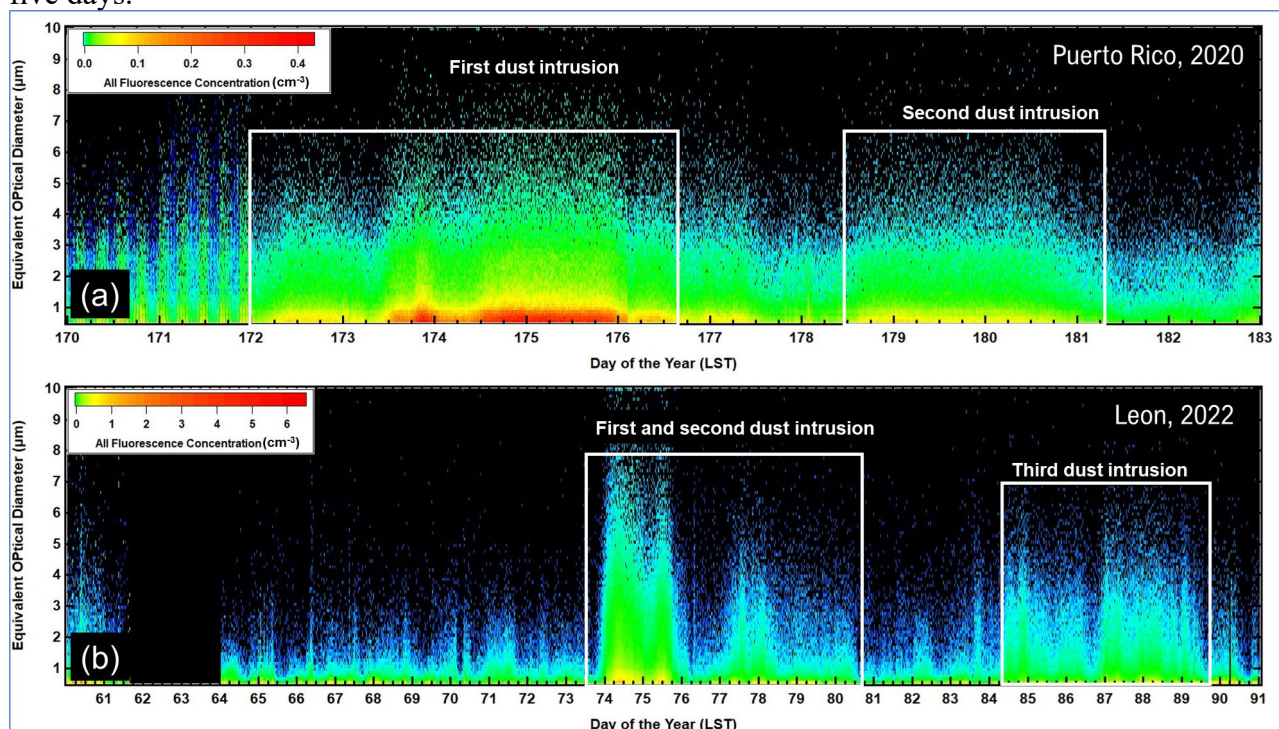

427

428 3.2 WIBS Observations

429

430 The arrival of the AD over PR and León is reflected in large increases in the number concentration
431 as seen in the time series of the FAP size distributions shown in Figs. 4a and b, respectively. In PR,
432 the first dust intrusion is seen on June 21 (day of the year, DOY, 172) and then approximately six and
433 a half days later the second AD layer arrives on June 27 (DOY 179). Likewise, in León the first AD
434 incursion is detected by the WIBS on March 16 (DOY 74) and lasts for more than five days. This
435 event was followed 10 days later by the second inundation on March 26 (DOY 84) lasting another
436 five days.

437

438 **Figure 4. a)** Time series of the size distributions of FAP number concentrations measured at PR, Puerto Rico. The
439 white boxes delineate the periods when the satellite and back trajectory analyses indicate that AD has arrived over the
440 island, **b)** similar to (a) but for FAP concentrations measured in León, Spain.

441

442 The influence of these dust incursions on the general aerosol population can be observed by the
443 changes in particle asphericity, shown in the size distributions of the shape factor (percent asphericity)
444 drawn in Fig. 5. These size distributions are of the non-FAP aerosols and show that the shape factor
445 increases from quasi-spherical, i.e. shape factor < 10%, to > 30% during the periods of AD in PR and
446 León.

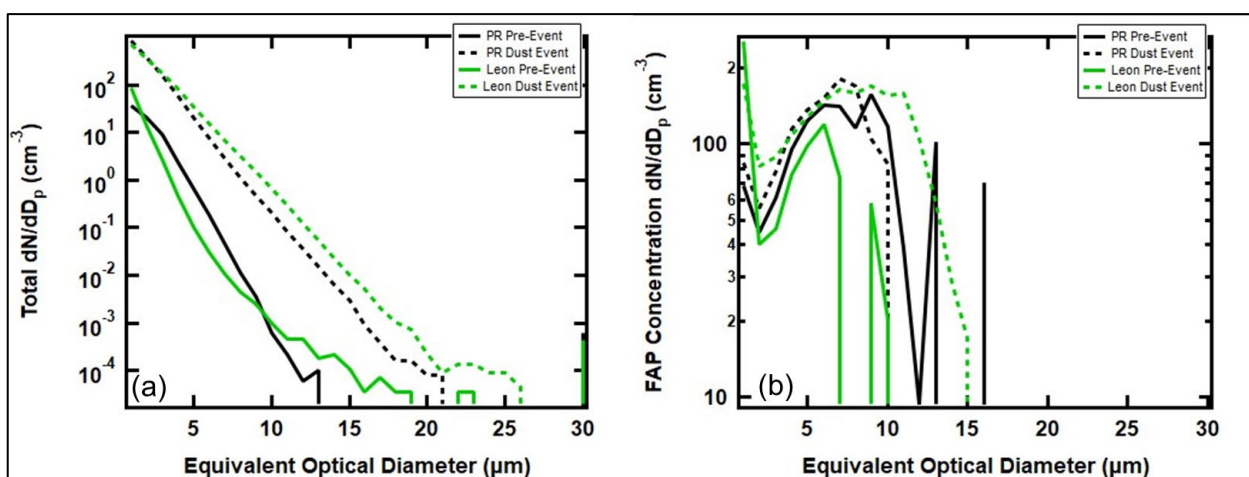

447

448 The size distributions shown in Fig. 6 highlight the similarities and differences between the PR and
449 León aerosol populations and illustrate how the arrival of the AD significantly changes how the non-
450 FAP and FAP number concentrations vary with size. The PR and León distributions are drawn in
451 black and green, respectively, solid lines for pre-dust events, dashed for dust intrusions. The pre-dust
452 size distributions of all aerosol particles, non-FAP and FAP (Fig. 6a), are almost identical at both
453 sites, with a small fraction of the León particle population larger than those in PR. The arrival of dust
454 leads to almost two orders of magnitude increase in both the PR and León concentrations, over all
455 sizes, and brings significant numbers of particles larger than 10 µm. For the non-FAP aerosols the
456 relationship between concentration and size during the AD event is nearly the same for PR and León.

457

459 **Figure 5. a)** Time series of the size distributions of non-FAP asphericity measured at PR, Puerto Rico. The white boxes
 460 delineate the periods when the satellite and back trajectory analyses indicate that AD has arrived over the island, b)
 461 similar to (a) but for non-FAP asphericity measured in León, Spain.
 462
 463

464 **Figure 6. Average size distributions in PR and León, before and during AD events for the (a) number concentrations**
 465 **of the non-FAP aerosol population in the size range of the WIBS, b) number concentrations of the FAP.**
 466
 467

468 A comparison of the FAP size distributions (Fig. 6b) tells a very different story. Below 2 µm, the
 469 León FAP concentrations exceed those in PR by about a factor of four; however, the PR FAP pre-
 470 dust size distribution is much broader than the FAP in León, extending beyond 10 µm while the FAP
 471 in León ends around 7 µm. The arrival of the dust does little to change the general shape of the PR
 472 size distribution other than slightly narrowing it. In contrast, the León size distribution broadens
 473 significantly out to 15 µm. This difference between PR and León offers the first clue that there is a
 474 difference between PR and León with respect to how FAP are mixed with non-FAP in the AD plumes
 475 that inundate these two sites.
 476

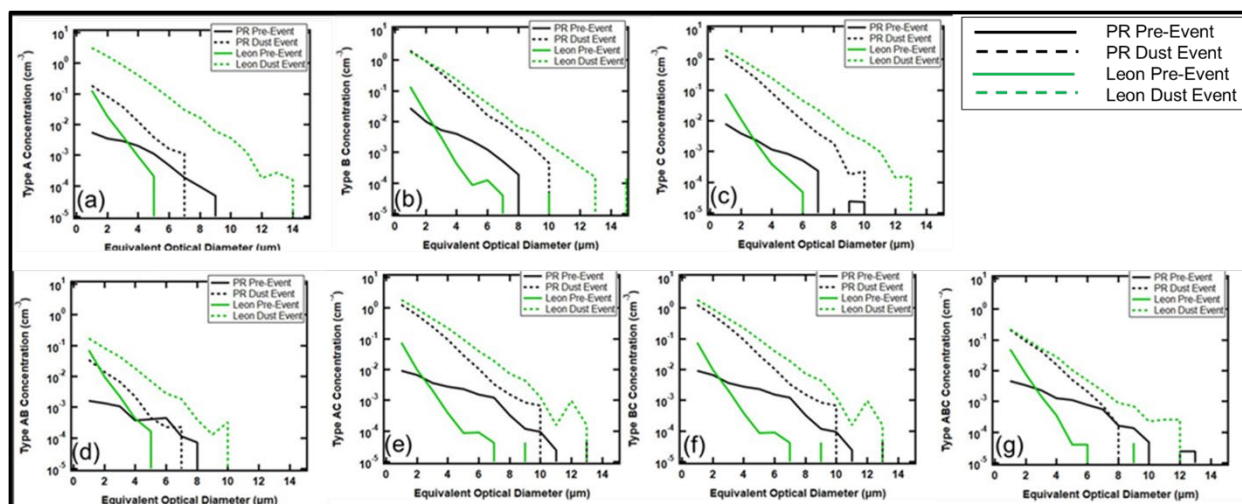

477 The average number concentration of non-FAP and FAP, the ratio of FAP to non-FAP concentrations,
 478 and the median, equivalent optical diameters (MEOD) of non-FAP and FAP are bulk parameters that
 479 are extracted from the size distributions and are shown in Fig. 7 for periods with no influence from
 480 AD and those in the presence of dust. Whereas Figs. 6a and b only showed one period with no-dust

481 and one period with AD for PR and León, Fig. 7 includes the second periods of dust, for the two
 482 locations, accompanied by periods before and after the dust intrusion. This more comprehensive data
 483 set demonstrates that for both PR and León there are clear differences in the bulk parameters under
 484 no-dust and dust conditions. The total and FAP number concentrations increase by an order of
 485 magnitude in PR and León when the AD arrives, as compared to the no-dust periods (Figs. 7a and b).
 486 The ratios of FAP to all particles (Fig. 7c) increase by a factor of two in PR and León under AD
 487 conditions; however, the León FAP ratios are three times larger than PR in the presence of AD.
 488 Likewise, although the arrival of dust in PR and León leads to increases in the average MEOD of all
 489 particles and FAP (Fig. 7c and d), the increase in León is much more than in PR, 200-300% vs 30%,
 490 respectively.
 491
 492

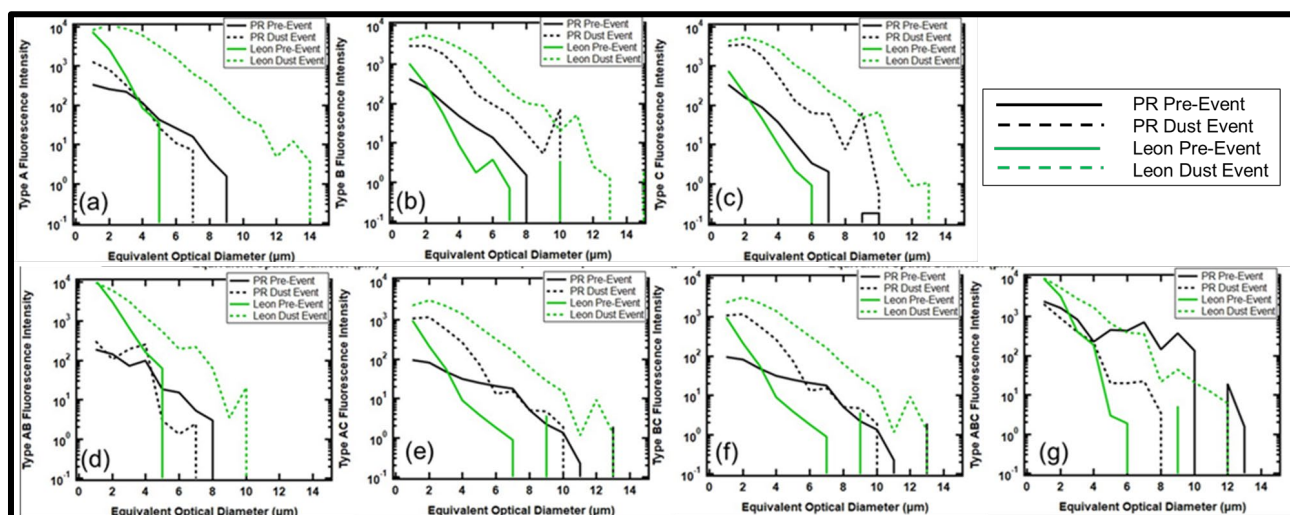

493 **Figure 7. Average values of derived parameters from WIBS measures before, during and after AD events. (a) Total**
 494 **number concentrations, (b) Number concentrations for all FAP, (c) Ratio of all FAP to all particles, (d) Median volume**
 495 **diameter (DMVD) of all particles between 0.5 and 30 μm and (e) DMVD of all FAP between 0.5 and 30 μm)**
 496

497 Figure 8 takes a closer look at the FAP, stratifying them by the fluorescing types. The pre-dust event
 498 aerosols in PR and León contain all seven types of FAP. Those measured in PR extend out to 10 μm,
 499 regardless of type. In León, at EODs < 2 μm, the number concentrations are always higher than those
 500 in PR but never exceed 7 μm in size. The arrival of the AD significantly changes the shapes of the
 501 size distributions, especially those in León, by bringing FAP that extend out to > 10 μm. The primary
 502 impact on the PR aerosols is to increase their number concentrations across all sizes and FAP types,
 503 while making little changes in the maximum EOD, except for the FAP Type B whose maximum EOD
 504 increases from 8 to 10 μm. The change in the size distributions of Type AC (Fig. 8e) with the arrival
 505 of the dust is particularly noticeable in PR and León. During non-AD periods the concentrations of
 506 Type AC FAPs is quite low at both measurement sites and then the arrival of AD increases the
 507 concentrations by several orders of magnitude, suggesting that the dust FAPs vary from the normal,
 508 background FAP in concentrations, size and types.

510 **Figure 8.** Average number concentration size distributions of FAP in PR (black) and León (green), before (solid) and
 511 during (dashed) AD events for (a) Type A, (b) Type B, (c) Type C, (d) Type AB, (e) Type AC, (f) Type BC, (g) Type
 512 ABC.

513
 514

515 **Figure 9.** Average fluorescence intensity of size distributions in PR (black) and León (green), before (solid) and
 516 during (dashed) AD events for (a) Type A, (b) Type B, (c) Type C, (d) Type AB, (e) Type AC, (f) Type BC, (g) Type ABC.

517
 518

519 Similar to Fig. 8, Fig. 9 illustrates the average fluorescence intensity as a function of size for the seven
 520 FAP types. Keeping in mind that the average fluorescence intensity is unrelated to the average number
 521 concentration, we observe that the average fluorescence intensity of the León pre-dust aerosols are
 522 greater than those in PR in the size range less than 2 μm , i.e., the difference in fluorescence intensity
 523 below 2 μm is not a result of higher concentrations in León, but possibly a different type of FAP.
 524 Similar to the comparison of the number concentrations, the PR FAP extends out beyond 8 μm for
 525 all types. The size distributions of Types B and C aerosols measured in PR and León, pre-dust, are
 526 quite similar in shape whereas the León size distributions are quite different from those in PR for the
 527 other types, suggesting a dissimilar population of bioaerosol taxa at the two locations. The arrival of
 528 the dust leads to shifts in the size distributions that are similar for the PR and León Types B and C;
 529 however, the León fluorescence intensity increases by more than two orders of magnitude while the
 530 PR intensities are about a factor of 10 higher in magnitude. Whereas the León intensities of all FAP
 531 types broaden from a maximum of 6 μm out to more than 10 μm , the PR distributions show little
 532 broadening except for Types B and C. The primary difference between the pre-dust and dust events
 533 in PR is an increase in intensity of FAP < 5 μm as compared to the increase in intensity over all sizes
 534 with the León distributions. The difference between the PR and León changes in size distributions
 535 with the arrival of the AD is particularly striking for the Type ABC aerosol. The León distributions

536 broaden from a maximum of 6 μm to 12 μm , the PR distributions narrow from 10 μm to 8 μm and
 537 the average fluorescence intensity decreases over this size range by more than a factor of 10. These
 538 contrasts between the PR intensity size distributions with those of León provide an additional piece
 539 to the puzzle associated with how FAP are mixed with AD when the plumes reach the respective
 540 locations.

541
 542 A comparison of the shape factor size distributions, shown in Fig. S4, informs us that FAP types A
 543 and AB are quasi-spherical ($AF < 15\%$) while the other FAP types are more aspherical ($>15\%$) at
 544 EODs between 6 μm and 10 μm . There is not a significant difference between PR and León FAP,
 545 either pre-dust or during the AD events.

547 Figure 10 highlights the transitions in the size distribution shapes, for all FAP types, by comparing
 548 the MEOD metric derived for all dust and no-dust periods, similar to what was shown in Figs. 7d and
 549 e. In this case, however, the MEODs were extracted from the size distributions of FAP number
 550 concentration (Fig. 10a) and fluorescence intensity (Fig. 10b). There is a stark difference seen
 551 between the background MEODs of number concentration and fluorescence intensity when
 552 comparing the background (no-dust) values from PR and León. The MEODs range between 5 μm
 553 and 8 μm in PR while the León MEODs are much smaller, between 2 μm and 5 μm . The second
 554 major difference between the PR and León MEODs is that the PR MEODs decrease with the intrusion
 555 of dust, with all FAP types except B and C, while the MEODs increase over all the FAP types. These
 556 differences were reflected in the size distributions where we see significant increases in the number
 557 concentration and fluorescence intensity of the FAP $< 5 \mu\text{m}$ in PR whereas it is the concentrations
 558 and intensities of FAP $> 5 \mu\text{m}$ that increase in León.

560 **Figure 10. (a) Average median equivalent optical diameters (MEOD) of the size distributions of the number**
 561 **concentrations for the seven FAP types. The color coding delineates the locations (PR and León) and dust event**
 562 **conditions (before, during and after). (b) Same as (a) except the MEODs are from the size distributions of the average**
 563 **fluorescence intensity.**

565 3.3 Complementary Meteorological and Aerosol Observations

566
 567 An evaluation of the meteorological state parameters and winds saw no indication of the dust arrival
 568 in PR or León, i.e., we observe no significant difference in temperature, relative humidity, wind speed
 569 or wind direction. Hence, the meteorological properties of the dust layer do not appear to have a
 570 noticeable impact on the local meteorology in PR or León (Fig. S5 and S6).

572 **Figure 11. Time series in Puerto Rico of (a) the aerosol optical depth (AOD) at 500 nm wavelength (black markers),**
 573 **Ångström exponent derived from the 500 nm and 870 nm AODs (green markers) and (b) Absorption coefficients at**
 574 **wavelengths of 370 nm (blue) and 880 nm (orange). The shaded areas demarcate the time periods when AD was in**
 575 **the region.**

576

577 Figure 11 illustrates the impact of the AD on the aerosol optical properties in PR where the shaded
 578 regions delineate the time periods with AD. In PR the trends in the absorption coefficients (Fig. 11b,
 579 blue and orange curves) suggest that the leading edge of the AD layer might have already arrived at
 580 the measurement site a day earlier than the measurements from the WIBS indicate (Figs. 4a and 5a).
 581 The 370 nm absorption coefficient shows an increase on DOY171, reaching a peak in the middle of
 582 the day before decreasing in the evening. The 880 nm absorption coefficient does not show the same
 583 trend because dust absorbs at 370 nm and very little at 880 nm. There were no increases in wind speed
 584 or shifts in wind direction (Fig. S1) that could indicate that these might be anthropogenic in origin,
 585 or possibly local dust. This pattern is also reflected by a small increase in the aerosol optical depth
 586 (Fig. 11a, AOD, black markers), which follows the same trend. The AOD, measured with a sun
 587 photometer, can't distinguish the actual altitude where these new particles might be located; hence,
 588 these could be dust particles that had been transported into the boundary layer where they would be
 589 measured by the MET-1 OPC. The main body of the AD layer, identified from the WIBS
 590 measurements (Figs. 4a and 5a) arrived on DOY172, where it is also seen clearly in the 370 nm
 591 absorption measurements (Fig. 11b) and the AOD (Fig. 11a). Note that the AOD and 370 nm
 592 absorption coefficients, although roughly correlated in time, will not follow the same trends if dust in
 593 the boundary layer and free troposphere is arriving with a different periodicity than the dust that is
 594 sedimenting or being transported downward by larger scale eddies. The other aerosol parameter
 595 plotted in Fig. 11a is the Ångström exponent derived from the 500 nm and 870 nm AODs. This
 596 parameter is roughly inverse-related to the average, median size of the aerosol particles. We observe
 597 in Fig. 11a (green markers), that during periods with no-dust, the exponent is larger than during
 598 periods of dust, an expected result given the significant increase in average EOD that was observed
 599 from the WIBS measurements.

601 **Figure 12. Time series in León of (a) PM_{2.5} (magenta) and PM₁₀ (blue) and (b) particle mass concentration (black**
 602 **curve) and median volume diameter (blue) measured with the FM120 in León. The shaded areas demarcate the time**
 603 **periods when AD was in the region.**

604

605 The AD incursion over León is reflected in the PM_{2.5} and PM₁₀ measurements (magenta and blue
 606 curves, respectively) shown in Fig. 12a. Unlike the trends in the PM measured in PR, there is a clear
 607 periodicity in León where daily peaks are observed on most days, regardless of if the AD is present;
 608 however, during the AD, the maximum PM is four to ten times larger than when the AD isn't present.
 609 Given that there doesn't appear to be any correlation with meteorological parameters, the trends are
 610 likely the result of changes in the depth of the boundary layer. As this layer grows during the day,
 611 due to radiative heating, the AD that is aloft in the free troposphere mixes downward and increases
 612 the PM near the surface. Figure 12b shows the mass concentrations derived from the FM120 size
 613 distributions (black curve) and the median volume diameter (blue curve). This complementary set of
 614 measurements, independent of the WIBS or air quality PM measurements, is highly correlated with
 615 the results from both instruments and show that the MEOD increases from $< 3 \mu\text{m}$ to $> 5 \mu\text{m}$ when
 616 the AD arrives. The very large mass concentrations are a result of the particles $> 10 \mu\text{m}$, as can be
 617 observed in the time series of the FM120 size distributions (Fig. S7). Between DOY 74 and 75 the
 618 size distribution is clearly bimodal with one peak at $5 \mu\text{m}$ and the other between 20 and $30 \mu\text{m}$. These
 619 large particles are what drive the very high PM values seen in Fig. 12b, which are much larger than
 620 registered by the PM₁₀ sensors in the air quality station.

621

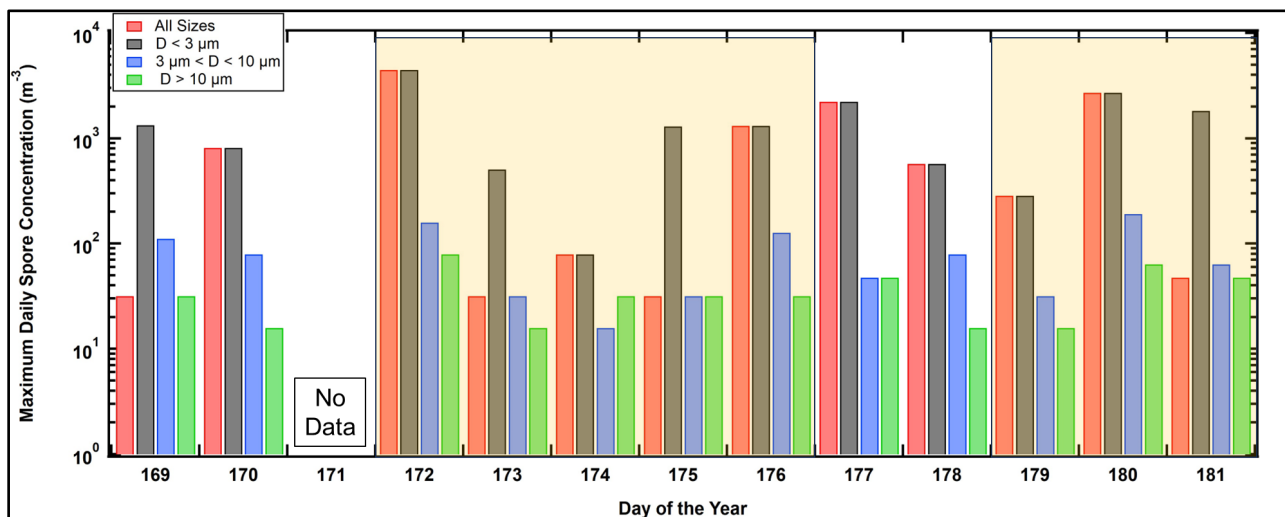

622

3.3 Hirst Sampler Observations

623

624 The timeseries of micro and macroconidia fungal spore concentrations, collected in PR and sorted by
 625 size range, are drawn in Fig. 13. The microconidia $< 3 \mu\text{m}$ (black bars) are always the highest in
 626 concentration, followed by the microconidia $> 3 \mu\text{m}$ and microconidia $< 10 \mu\text{m}$ (blue) and the
 627 macroconidia $> 10 \mu\text{m}$ (green). The shaded regions are highlighting the periods of AD. There are
 628 differences in the concentrations of these fungal spores when comparing periods with and without
 629 AD, but they are subtle. Given that the dust plume mixes with the ambient aerosols *a priori* we have
 630 no reason to expect the spore concentrations to increase or decrease. More significant is the
 631 appearance of spore types that were not identified during the no-dust periods. Table II provides more
 632 explicit detail regarding the redistribution of spore types. More important than the total number
 633 concentrations are the appearance of new spore types and disappearance of others during the AD
 634 episodes. These are highlighted in the table, light gray when periods of AD lack spores during no-
 635 dust periods, and dark gray when spore types appear that were not in the no-dust periods. In addition,
 636 cells in the table are shaded black when a spore type increases by $\geq 100\%$ from no-dust to dust.

637

638 **Figure 13** Time series of spore concentrations, stratified by size, in Puerto Rico. The shaded regions are periods of AD
 639 inundation.

640

641 There are two spore types, *Dreschlera Helmitosporum* and *Fusarium* that were measured on the no-
 642 dust days but were no longer identified during AD. Likewise, with the arrival of the dust, five new
 643 spores appeared that were not previously seen in the background environment: *Erysiphe/Oidium*,
 644 *Periconia*, *Spegazzinia*, *Tetrapyrgeos* and *Chaetomium*. Of these, the *Erysiphe/Oidium* had the highest
 645 concentration, four times higher than the others.

646

647 In León during March 2022 a total of 9 pollen types were identified. *Cupressaceae* and *Populus*, both
 648 in their main pollen season (MPS), were the most abundant types (abundance relative: 43% and 40%,
 649 respectively). The other pollen types presented relative abundance values lower than 5%. Some pollen
 650 types such as *Alnus*, *Corylus*, *Fraxinus* and *Ulmus* were finishing their MPS, whereas *Platanus*,
 651 *Poaceae* and *Pinus* were starting it. *Salix* was in the MPS during this period, although it is not an
 652 abundant pollen in the ambient atmosphere. During the two AD intrusions, an increase in pollen
 653 concentration compared to the previous day (DOY 75: >1000%; DOY 85: 300%) was registered
 654 (Figure 14). During the first one, most of the counted pollen belonged to *Cupressaceae*. Nevertheless,
 655 during the second AD inundation the predominant pollen was *Populus*. Days with AD inundation did
 656 not show differences in airborne pollen diversity compared to days without AD intrusion.

657

658

659 **Figure 14.** Time series of daily average pollen concentrations in León during the selected period. The orange shaded
 660 regions indicate the AD inundation.

665

666

667

668

669

670

Regarding the analysis of bi-hourly pollen concentration (Figure 15) it can be observed that days with AD presented the highest pollen concentrations from 2000 to 2400 UTC, which suggests pollen transport from emission sources far away from the monitoring station. In addition, airborne fungal spore taxa did not show significant concentrations during these days. The spore taxa identified during the selected period were Cladosporium, Alternaria, Pleospora, Tilletia and Leptosphaeria.

3.4 Back Trajectory Analysis

The origins and histories of the air masses were evaluated using the National Oceanic and Atmospheric Administration (NOAA) Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPLIT) back trajectory model, incorporating the Global Data Assimilation System (GDAS) with one degree resolution (Stein et al., 2015; Rolph et al. 2017). The model was run for thirteen and five days for PR and León, respectively, time periods commensurate with the number of days between when dust was seen in the satellite data to originate over northern Africa and arrive at the two destinations, respectively. The ending altitudes (Fig. S8) were chosen to be 100, 500 and 1000 m based on previous studies that have shown that the AD layers can range in thickness between 100 and 1000 m (Ramírez-Romero et al., 2021). Figure 16 shows representative back trajectories for PR on June 22, 2020, color coded by altitude and with markers (red) that indicate when and where the air was within the mixed layer and when the air mass encountered precipitation (light blue markers). These mixed layer parameters were selected to show where the originating air might have first picked up the dust and then later where the air might have interacted with other sources of aerosols, e.g. marine aerosols when passing over the Atlantic Ocean. The precipitation is added because it can contribute to cloud processing of aerosols and potential removal of particles before the air arrives at its destination.

696 *Figure 16. Thirteen day back trajectories of air masses arriving at 100 m (black curve), 500 m (blue curve) and 1000*
697 *m (green curve) over Puerto Rico. The red markers show every hour the air was in the mixed layer and the light blue*
698 *markers denote each hour where rain was encountered. These are from June 22, 2020 at (a) 0000 UTC, (b) 0600 UTC,*
699 *(c) 1200 UTC and (d) 1800 UTC.*

701 *Figure 17. The same as Fig. 16 but for five day back trajectories of air masses arriving over León on March 16, 2022*
 702 *at (a) 0000 UTC, (b) 0600 UTC, (c) 1200 UTC and (d) 1800 UTC.*

704 Over the 24-hour period that AD was arriving on June 22nd, at UTC 0000, 0600, 1200 and 1800 (Figs.
 705 16a-d) the air can be seen originating from over the African Sahara and Sahel. At UTC 0000 all three
 706 trajectories had been over this region and the red markers also show that they had been there in the
 707 mixed layer at different times, confirming that particles indigenous to that region would have
 708 originated there. At 0600, 1200 and 1800 UTC the 100, 500 and 1000 m trajectories do not always
 709 indicate being in the mixed layer, but at least one of them does; hence, the AD continues to be
 710 transported to PR over these time periods. It is also important to note that the 100 m trajectory, as
 711 well as sometimes the 500 m trajectory, arrive over PR after traveling several hundred kilometers (>
 712 24 hrs) in the mixed layer. With respect to cloud processing the HYSPLIT model indicates that
 713 throughout the day the air had encountered precipitation first over Africa and then on its travel over
 714 the Atlantic Ocean before arriving in PR.

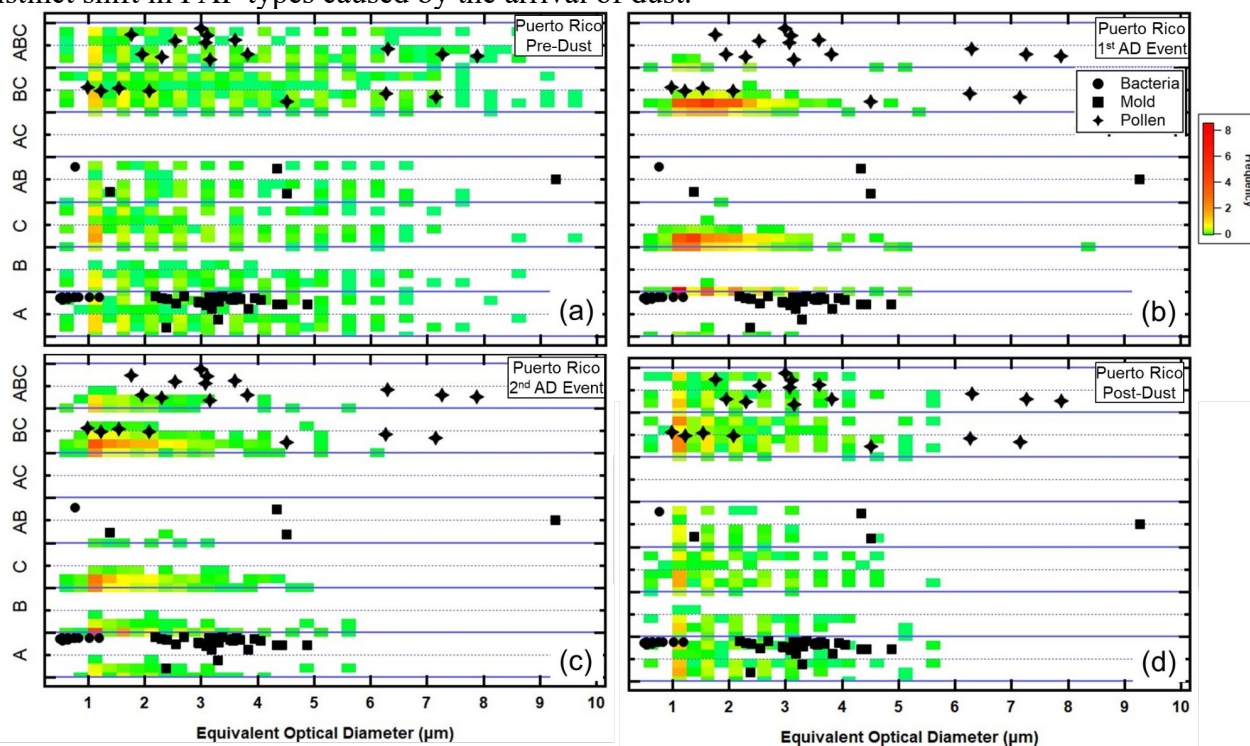

716 Figure 17 provides the same information for León over four five-hour time periods on March 16,
 717 2022. Similar to what was observed with the air masses that brought AD to PR, the air masses that
 718 arrived over León at 100, 500 and 1000 m had all been in the mixed layer in northern Africa for
 719 varying lengths of time. Whereas most of the AD that arrived over PR originated in western Africa,
 720 those air masses over León were bringing particles from regions in northern and northeastern Africa.
 721 Much of the air, particularly that which arrived at 500 m over León, had also encountered frequent
 722 periods of precipitation as indicated by the model.

724 4.0 Discussion

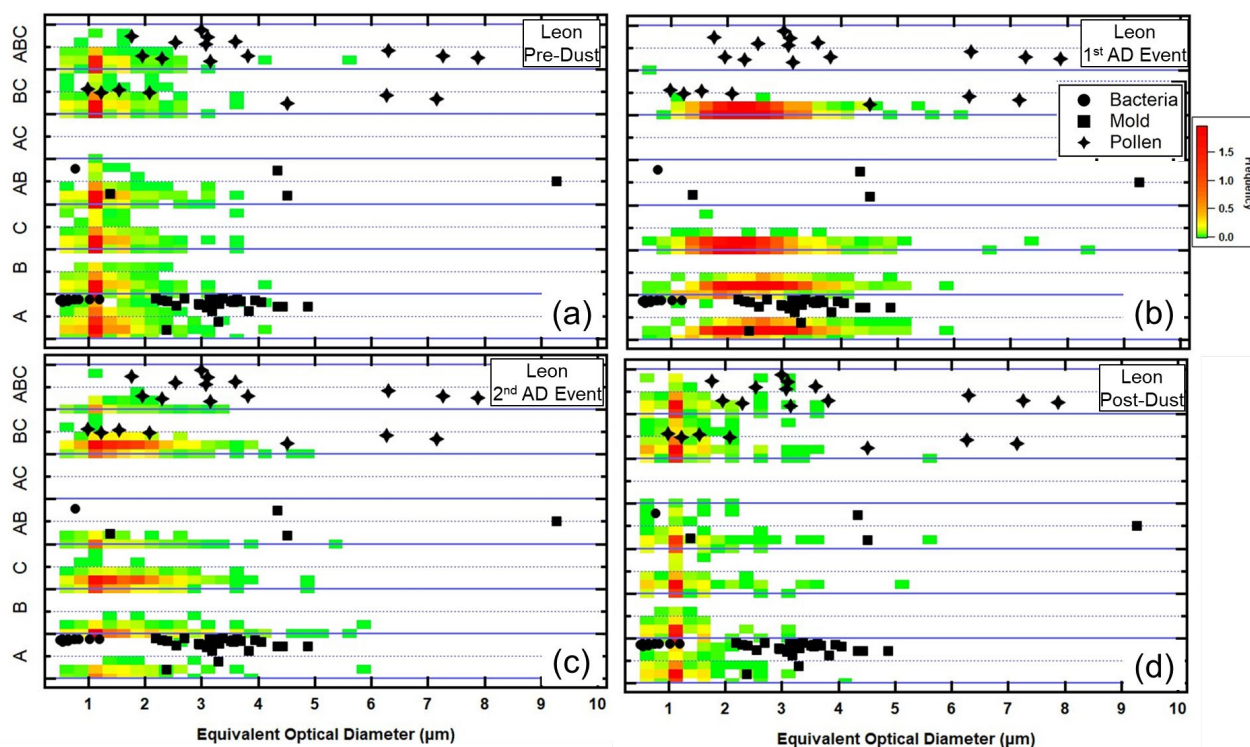

726 In Section 2.3.3 we posed questions related to how the WIBS measurements could be used to
 727 distinguish differences in bioaerosol taxa in the background FAP of PR and León and between
 728 background and dust events. Although the size distributions of the number concentrations and
 729 intensities of the FAP Types in PR and León cannot be used to speciate bioaerosols, the distinct
 730 differences in the relative fraction of total FAP in smaller and larger particles indicate that the

731 mixtures of BSP types, i.e., bacteria, mold or pollen, are clearly dissimilar. This is observed when
 732 comparing the two regional background aerosols and when comparing the changes when AD arrives.
 733

734 The contrasts in FAP properties are highlighted by placing their physical and fluorescing properties
 735 in the context of these same properties generated using laboratory studies, as was demonstrated in
 736 Fig. 2. Figures 18 and 19 summarize the FAP properties for the PR and León regions, before, during
 737 and after dust events as they compare to the FAP properties of bacteria, mold and pollen measured in
 738 the laboratory. A cursory examination of these two figures confirms that the FAP properties are
 739 significantly different between PR and León, without and with dust. While this result should not be
 740 considered surprising, displaying the FAP properties as illustrated in these figures offers a way to
 741 indirectly compare the ambient FAP properties with those of actual BSPs. The distribution of FAP in
 742 the PR background aerosol (Figs. 18a and d) corresponds mostly to the laboratory mold and pollen
 743 with only a small fraction falling into the bacteria type and size. The PR FAP that falls in the pollen
 744 region is mostly in EODs < 5 μm . There is a population of FAP types B, C and AB that are found in
 745 the ambient environment but have no corresponding laboratory BSP types that they can be associated
 746 with. With the arrival of the dust, the FAP maps shift significantly with the largest majority of the
 747 fluorescing particles appearing in the Type B, C and BC categories and at EODs < 5 μm . This is a
 748 distinct shift in FAP types caused by the arrival of dust.
 749

750 **Figure 18.** Similar to Fig. 2. Except the laboratory BSP maps are combined with the frequency of occurrence (color
 751 coded) of FAP types. The color scale denotes how frequently during the two day periods the FAP types and EODs fell
 752 within the different regions. (a) Puerto Rico two days before the AD event, (b) and (c) Puerto Rico during the 1st and
 753 2nd AD events and (d) Puerto Rico after the AD event.
 754

756 **Figure 19.** The same as Fig. 18, except for measurements in León.

757

758 The FAP patterns in the León aerosols are shown in Fig. 19 and suggest that the largest number of
 759 background aerosols should be considered bacteria-like and small, pollen-like as compared to the
 760 laboratory BSPs. The highest frequencies are found at EODs $< 2 \mu\text{m}$, evenly distributed over all FAP
 761 types except Type AC. This suggests that many of the FAP measured in León are different from the
 762 laboratory BSP taxa. The arrival of the dust dramatically shifts the pattern of the FAP – the highest
 763 frequencies are now in Types A, B, C and AC and the EODs are now centered between $4 \mu\text{m}$ and $6 \mu\text{m}$
 764 during the first AD event. These sizes decrease during the 2nd AD event before returning to mostly
 765 $< 2 \mu\text{m}$ in the post-dust time period. These results suggest that the background FAPs are mostly
 766 bacteria and pollen, with some fraction of FAP types that do not correspond to the taxa of the BSPs
 767 tested in the one laboratory study. The dust brings in bioaerosols whose FAP properties include those
 768 that are similar to bacteria, mold and pollen, but now with larger EODs.

769

770 The results shown in Figs. 18 and 19 offer compelling evidence that the WIBS measurements
 771 distinguish between types and compositions of bioaerosols and that the no-dust and dust cases can be
 772 clearly separated, as can the background populations of PR and León. What can we say about
 773 information on how FAP are physically mixed with non-FAP aerosol, in particular with dust? To
 774 address this question, we remind the reader of the differences between internally and externally mixed
 775 aerosol ensembles. In short, we do not expect to have only one or the other type of situation given
 776 that turbulent mixing will lead to the eventual combination of the two. Nevertheless, there are several
 777 reasons to expect that one or the other might dominate, depending upon the age of the air masses and
 778 the types of physical processes that can occur between the origin of the dust plume and when it arrives
 779 several hours or days later in PR and León.

780

781 Referring back to Fig. 10a we observe a clear difference between PR and León when comparing the
 782 changes in the MEODs, over all FAP types, when dust arrives. The MEODs *decrease* by 20-30% in
 783 PR and *increase* by 30-50% in León. These opposite changes were also seen in the size distributions
 784 shown in Figs. 8 and 9, i.e., in general, FAP concentrations in sizes $< 5 \mu\text{m}$ increased in PR and
 785 decreased in León. These differences can be explained, to some degree, by differences in the mixing
 786 state of FAP and dust during AD events. The large decrease in the FAP MEOD in PR suggests that
 787 the dust is bringing many more small FAPs than are found in the background; however, the increase

788 in the larger FAPs indicates that some of these FAP are also internally mixed with the larger dust
789 particles. Hence, the PR dust may be more externally than internally mixed. On the other hand, the
790 AD event in León increased the MEODs over all the sizes; however, the larger particles ($>5 \mu\text{m}$)
791 increased proportionately more than those $<5 \mu\text{m}$. This leads to the conclusion that the FAP in the
792 León AD event are more internally mixed, i.e., that a large fraction of the AD FAP are attached to or
793 mixed with the AD.

794
795 If we assume that the AD that arrives in PR and León originated through similar processes over
796 northern Africa, whereby dust and FAP are lofted from the surface, then the differences that are
797 observed in the FAP properties when they arrive in León and PR are likely a result of the
798 transformations that occurred during their transport. The three primary processes that lead to these
799 transformations are coagulation, sedimentation and precipitation. The AD had traveled over much
800 longer distances and time before reaching PR than when arriving over León. The back trajectory
801 analyses showed that these air masses had also traveled many hours in the boundary layer prior to
802 reaching PR. Some of the FAP are likely attached to dust particles when they are lifted from the
803 surface at their origin, while others will collide with the dust during transport as a result of small scale
804 turbulent eddies, and sedimentation of the larger dust particles falling through the smaller FAP.
805 Electrical charging of the particles, leading to further coagulation cannot be discounted. Particles with
806 an aerodynamic diameter of $1 \mu\text{m}$ and a density of 2 g cm^{-3} fall at a speed of 6 m/day while a $10 \mu\text{m}$
807 particle falls at 500 m/day ; hence, the particles $\geq 10 \mu\text{m}$ will fall 2.5 km and 6.5 km during their 5-
808 and 13-day travel from Africa to León and PR, respectively. This type of removal of the larger
809 particles, while smaller particles remain aloft, can explain the difference between PR and León
810 mixtures of FAP and dust. Not only did the particles in the AD air masses that arrived in PR have
811 three times longer to fall than those in León, but the back trajectory analysis also revealed that the air
812 arriving in PR had been in the mixed layer many more hours than the air masses reaching León.
813 Traveling in this layer would place the particles much closer to the surface and have a shorter distance
814 to sediment and be removed.

815 816 **5.0 Data availability**

817
818 The WIBS data and complementary aerosol measurements described in this manuscript can be
819 accessed at the Zenodo repository, under [DOI .10.5281/zenodo.10680977](https://doi.org/10.5281/zenodo.10680977) (Baumgardner, 2024)

820 821 **6.0 Summary and Conclusions**

822
823 Two major African dust events, one over the island of Puerto Rico and the other over the city of León,
824 Spain have been analyzed, the former in June, 2020 and the latter in March, 2022. From measurements
825 with two Wideband Integrated Bioaerosol Spectrometers (WIBS) and complementary aerosol data
826 we make the following observations and conclusions:

- 827
828 1. The intrusion of dust over the Caribbean and Iberian Peninsula leads to a significant impact
829 on the size distributions and composition of the local populations of aerosols.
- 830 2. Differences in the FAP sizes and fluorescing properties, prior to the AD events, are clearly
831 seen in comparisons between the background aerosol populations in PR and León.
- 832 3. The arrival of AD over the two regions significantly alters the properties of the local aerosol
833 populations as observed in the WIBS and PM measurements. The magnitude of these altered
834 properties are different at the two locations, differences attributed to the age of the AD air
835 masses, five and 13 days old, when arriving in León and PR, respectively.
- 836 4. As deduced from changes in the shapes of the FAP size distributions, with the intrusion of the
837 AD the FAP is both internally and externally mixed with other non-FAP particles in the dust
838 plume; however, the AD that arrives in PR appears to have a much higher proportion of
839 externally mixed FAP than León.

- 840 5. The comparison of the maps of relative frequency of FAP Types and their average EOD,
841 juxtaposed with laboratory bacteria, mold and pollen, indicates that the mixtures of FAP and
842 dust in PR are significantly different than those in León. The AD dust over PR clustered most
843 in FAP types C and BC while in León the primary AD types were A, B, C and AC. When
844 compared with the laboratory FAP, Type A is related to bacteria and BC to pollen. Types B
845 and C were not common in the laboratory measurements used in this study (Hernandez et al.,
846 2016) nor did other similar laboratory studies, e.g., Savage et al. (2017), have these types of
847 FAP.
848

849 The analysis approach that has been introduced in this study highlights the importance of using
850 metrics that focus on relative changes in the number concentration and fluorescence intensity size
851 distributions of the seven types of FAP. The median equivalent optical diameter (MEOD) is a
852 sensitive metric that can quantitatively document these changes along with maps of the frequency of
853 FAP type versus EOD that highlight how the FAP types in AD are significantly different from
854 background FAP in PR or León.
855

856 These two data sets will be a useful contribution to the larger data bases of African and Asian dust
857 aerosols that have been transported large distances and that may be carrying bioaerosols, some which
858 may be similar to those found in the local regions inundated by this dust while other might be more
859 damaging to the environments where they eventually are deposited or inhaled.

1110 **Figure Captions**

1111

1112 *Figure 1. a) A BSP map showing how 15 bacteria, 29 mold and 13 pollen of different taxa were measured in the*
1113 *laboratory by a WIBS, as a function of FAP type and EOD and b) the same BSP map with FAP measurements from*
1114 *a non-dust day in Puerto Rico plotted using the same definitions for FAP type and EOD. The color scale denotes how*
1115 *frequently during the two-day period the FAP types and EODs fell within the different regions. In this example,*
1116 *although the environmental FAP falls in regions where the lab data show bacteria, mold and pollen, quite a few of the*
1117 *FAP were in the region of FAP types C and AB where very few of the lab results were found.*

1118

1119 *Figure 2. Examples of size distributions of Type ABC fluorescing aerosol particles before (green curve) and during*
1120 *(brown curve) a dust intrusion, highlighting the features that are used as metrics in the analysis methodology. (a)*
1121 *Average fluorescence intensity as a function of EOD. The vertical and horizontal blue arrows highlight increases in*
1122 *intensity and size, respectively, with the incursion of AD. The size distributions have been divided into “small particle”*
1123 *(shaded) and “large particle”. (b) average number concentration as a function of size and (c) Average asphericity as*
1124 *a function of size*

1125

1126 *Figure 3 The Aerosol Optical Thickness (AOT) at 500 nm, derived from the MERRA, show the air masses carrying*
1127 *dust from the African continent over (a) Puerto Rico, on 23 June, 2020 and then (b) another plume traveling over*
1128 *the Iberian Peninsula and Southern Europe on 16 March 2022. The blue and red markers indicate the locations of*
1129 *the PR and Leon measurement sites, respectively.*

1130

1131 *Figure 4. a) Time series of the size distributions of FAP number concentrations measured at PR, Puerto Rico. The*
1132 *white boxes delineate the periods when the satellite and back trajectory analyses indicate that AD has arrived over the*
1133 *island, b) similar to (a) but for FAP concentrations measured in León, Spain.*

1134

1135 *Figure 5. a) Time series of the size distributions of non-FAP asphericity measured at PR, Puerto Rico. The white boxes*
1136 *delineate the periods when the satellite and back trajectory analyses indicate that AD has arrived over the island, b)*
1137 *similar to (a) but for non-FAP asphericity measured in León, Spain.*

1138

1139 *Figure 6. Average size distributions in PR and León, before and during AD events for the (a) number concentrations*
1140 *of the total aerosol population in the size range of the WIBS, b) number concentrations of only FAP and c) asphericity*
1141 *for all particles.*

1142

1143 *Figure 7. Average values of derived parameters from WIBS measures before, during and after AD events. (a) Total*
1144 *number concentrations, (b) Number concentrations for all FAP, (c) Ratio of all FAP to all particles, (d) Median volume*
1145 *diameter (DMVD) of all particles between 0.5 and 30 μm and (e) DMVD of all FAP between 0.5 and 30 μm*

1146

1147 *Figure 8. Average number concentration size distributions of FAP in PR and León, before and during AD events for*
1148 *(a) Type A, (b) Type B, (c) Type C, (d) Type AB, (e) Type AC, (f) Type BC, (g) Type ABC*

1149

1150 *Figure 9. Same as Fig. 8 but for intensity size distributions.*

1151

1152 *Figure 10. (a) Average median equivalent optical diameters (MEOD) of the size distributions of the number*
1153 *concentrations for the seven FAP types. The color coding delineates the locations (PR and León) and dust event*
1154 *conditions (before, during and after). (b) Same as (a) except the MEODs are from the size distributions of the average*
1155 *fluorescence intensity.*

1156

1157 *Figure 11. Time series in Puerto Rico of (a) the aerosol optical depth (AOD) at 500 nm wavelength (black markers),*
1158 *Ångström exponent derived from the 500 nm and 870 nm AODs (green markers) and (b) Absorption coefficients at*
1159 *wavelengths of 370 nm (blue) and 880 nm (orange). The shaded areas demarcate the time periods when AD was in*
1160 *the region.*

1161

1162 *Figure 12. Time series in León of (a) PM_{2.5} (magenta) and PM₁₀ (blue) and (b) particle mass concentration (black*
1163 *curve) and median volume diameter (blue) measured with the FM120 in León. The shaded areas demarcate the time*
1164 *periods when AD was in the region.*

1165

1166 *Figure 13 Time series of spore concentrations, stratified by size, in Puerto Rico. The shaded regions are periods of AD*
1167 *inundation.*

1168

1169 *Figure 14 Time series of daily average pollen concentrations in León during the selected period. The yellow shaded*
1170 *regions indicate the AD inundation.*

1171

1172 **Figure 15** Bi-hourly values of total pollen concentration recorded by Hirst trap for the selected period in León. Days
1173 without AD inundation (●), Days with AD inundation (●).

1174
1175 **Figure 16.** Thirteen day back trajectories of air masses arriving 100 m (black curve), 500 m (blue curve) and 1000 m
1176 (green curve) over Puerto Rico. The red markers show every hour the air was in the mixed layer and the light blue
1177 markers denote each hour where rain was encountered. These are from June 22, 2020 at (a) 0000 UTC, (b) 0600 UTC,
1178 (c) 1200 UTC and (d) 1800 UTC.

1179
1180 **Figure 17.** The same as Fig. 16 but for air masses arriving over León on March 16, 2022 at (a) 0000 UTC, (b) 0600
1181 UTC, (c) 1200 UTC and (d) 1800 UTC.

1182
1183 **Figure 18.** Similar to Fig. 2. Except the laboratory BSP maps are combined with the frequency of occurrence (color
1184 coded) of FAP types. The color scale denotes how frequently during the two day periods the FAP types and EODs fell
1185 within the different regions. (a) Puerto Rico two days before the AD event, (b) and (c) Puerto Rico during the 1st and
1186 2nd AD events and (d) Puerto Rico after the AD event.

1187
1188 **Figure 19.** The same as Fig. 18, except for measurements in León.
