1 Abstract

2 The Tibetan Plateau (TP) plays a key role in regional environment and global climate change, however,
3 the lack of vertical observation hinders a deeper understanding of the atmospheric chemistry and
4 atmospheric oxidation capacity (AOC) on the TP. In this study, we conducted MAX-DOAS
5 measurements at Nam Co, central TP, to observe the vertical profiles of aerosol, water vapor, NO₂,
6 HONO and O₃ from May to July 2019. In addition to NO₂ mainly exhibiting a Gaussian shape with the
7 maximum value appearing at 300-400 m, other four species all showed an exponential shape and
8 decreased with the increase of height. The maximum values of monthly averaged aerosol (0.17 km⁻¹)
9 and O₃ (66.71 ppb) occurred on May, water vapor (3.68 × 10¹⁷ molec cm⁻³) and HONO (0.13 ppb)
10 appeared on July, while NO₂ (0.39 ppb) occurred on June at 200-400 m layer. Water vapor, HONO and
11 O₃ all exhibited a multi-peak pattern, and aerosol appeared a bi-peak pattern for their averaged diurnal
12 variation. Moreover, we found O₃ and HONO were the main contributors to OH on the TP. The
13 averaged vertical profiles of OH production rates from O₃ and HONO all exhibited an exponential
14 shape, and decreased with the increase of height with the maximum values of 2.61 ppb/h and 0.49
15 ppb/h at the bottom layer, respectively. In addition, source analysis for HONO and O₃ were conducted
16 based on vertical observations. The heterogeneous reaction of NO₂ on wet surfaces was a significant
17 source of HONO, which obviously associated with water vapor concentration and aerosol extinction.
18 The maximum values of HONO/NO₂ appeared around water vapor being 1.0 × 10¹⁷ molec cm⁻³ and
19 aerosol being larger 0.15 km⁻¹ under 1.0 km, and the maximum values usually accompanied with water
20 vapor being 1.0-2.0 × 10¹⁷ molec cm⁻³ and aerosol being larger 0.02 km⁻¹ at 1.0-2.0 km. O₃ was
21 potentially sourced from south Asian subcontinent and Himalayas through long-range transport. Our
22 results enrich the new understanding of vertical distribution of atmospheric components and explained
23 the strong AOC on the TP.

24

25 1 Introduction

26 The Tibetan Plateau (TP) spans 2.5 million square kilometers with an average altitude of over 4000 m.
27 Therefore, the TP is called the “Third Pole” of the earth (Ma et al., 2020; Kang et al., 2022). It is the
28 home to tens of thousands of glaciers and nourishes more than 10 of Asia’s rivers, thus it also acts the

29 role of “Water Tower of Asia” (Qu et al., 2019; Ma et al., 2022). Due to its special topography, the TP
30 is the heat source of atmosphere due the strong solar radiation, which as the driven force to profoundly
31 affect the regional atmospheric circulation, global weather conditions and climate change (Yanai et al.,
32 1992; Boos et al., 2010; Chen et al., 2015; Liu et al., 2022; Zhou et al., 2022). Monsoon rainfall in Asia,
33 flood over the Yangtze River valley, and El Niño in the Pacific Ocean are strongly associated with the
34 TP (Hsu et al., 2003; Li et al., 2016; Lei et al., 2019). In addition, the cyclone circulations caused by
35 the TP heat source also can inhibit the diffusion of atmospheric pollutants in the areas around the TP,
36 such as the Sichuan Basin, causing regional pollution (Zhang et al., 2019). Therefore, to improve
37 knowledge of the spatiotemporal evolutions and sources of atmospheric pollutants on the TP is of great
38 meaning and importance.

39 However, deciphering the atmospheric environment of the TP is highly challenging and dangerous, due
40 to its complex topography and harsh environment (Barnett et al., 2005; Bolch et al., 2012; Cong et al.,
41 2015; Kang et al., 2016). In order to unveil the feature of atmospheric composition over the TP and
42 their corresponding climate feedback, a large number of field observation stations have been
43 established, and a series of field campaigns have continued to be carried out recently, especially after
44 the performance of “the Second Tibetan Plateau Scientific Expedition and Research Program” (Che and
45 Zhao 2021; Wang et al., 2021; Ran et al., 2022). The China National Environmental Monitoring Center
46 (CNEMC) has established an in-situ monitoring network with more than 12 stations over the TP, such
47 as Lhasa, Shigatse, Shannan, Nyingchi, Nagqu, Ngari, Qamdo, Diqing, Aba, Guoluo, Xining, and
48 Haixi, to continuously monitor the surface concentrations of six atmospheric components (i.e. PM₁₀,
49 PM_{2.5}, NO₂, SO₂, O₃ and CO) since 2013 (Gao et al., 2020; Li et al., 2020; Sun et al., 2021). The
50 Institute of Tibetan Plateau Research, Chinese Academy of Sciences, has also established six long-term
51 field observation stations to measure meteorological parameters and small amounts of atmospheric
52 composition (i.e. black carbon, aerosol optical density (AOD)) (Ma et al., 2020). In addition, scientists
53 are relying on advancements in satellite remote sensing technology, such as TROPOMI, OMI, MODIS
54 and CALIPSO, to monitor the spatial and temporal evolutions of atmospheric composition on the TP
55 (Zhu et al., 2019; Li et al., 2020; Rawat and Naja 2022). Their advantage is to obtain the column
56 densities of pollutants in a large-scale space of the TP. Although CALIPSO could detect aerosol
57 vertical profiles, the spatiotemporal resolution (i.e. ~5.0 km horizontal resolution, 0.06 km vertical
58 resolution and ~16 d temporal resolution) is limited and the data uncertainty in the planetary boundary
59 layer (PBL) is large due to the low signal-to-noise ratio (Huang et al., 2007). However, several studies
60 also revealed that the formation, aging and transport processes of atmospheric composition on the TP
61 occurs not only near the ground surface but also at high altitudes (Xu et al., 2020; Xu et al., 2022). The
62 high PBL on the TP caused by its strong solar radiation and undulating terrain promotes the
63 atmospheric exchange between the bottom troposphere and stratosphere (Yang et al., 2003; Seidel et al.,
64 2010). Therefore, the lack of vertical profiles of hinders the understanding of the evolution of trace
65 gases and their environmental and climate effects over the TP. In recent years, balloon and lidar
66 vertical measurements on the TP are occasionally carried out (Fang et al., 2019; Zhang et al., 2020;
67 Dong et al., 2022), but their limited detection species (i.e. aerosol and O₃) and high cost are obstacles
68 that limit long-term continuous observation and the conduction of more in-depth scientific research.
69 Multi-axis differential optical absorption spectroscopy (MAX-DOAS) has the technical advantage of
70 low-cost continuous observation of multiple atmospheric components (i.e. aerosol, O₃ and their
71 precursors) (Xing et al., 2017, 2019, 2020, 2021; Wang et al., 2018). Combining these data with better
72 scientific models can reduce the modeling bias and promote to better understand the physical, chemical
73 and dynamical processes.

74 The strong convergent airflow formed under the combined action of monsoon, subtropical anticyclone
75 and the airflow of subtropical westerlies could promote the accumulation of O₃ on the TP in summer
76 (Ye and Gao 1997). Therefore, several studies have revealed the high O₃ concentration on the TP (Li et
77 al., 2022; Yang et al., 2022; Yu et al., 2022). The strong solar radiation, high O₃ concentration and
78 relatively high humidity on the TP provide great potential for high OH production. Lin et al. (2008) and
79 Ye (2019) also confirmed that the high OH over the TP is mainly related to the reaction between O(¹D)
80 and water vapor. The O(¹D) is produced from the photolysis of O₃ by UV radiation. Therefore, a

81 hypothesis of “strong atmospheric oxidation capacity (AOC) over the TP” was put forward. Previous
82 studies pointed out that nitrous acid (HONO) also play an important role in AOC at low-altitude areas,
83 and its contribution to OH can reach 40-60%, and even more than 80% in the early morning (Michoud
84 et al., 2012; Ryan et al., 2018; Xue et al., 2020). However, few HONO studies on the TP have been
85 reported. Our previous study operated at QOMS-CAS revealed that the HONO mainly distributed in
86 the lower PBL and peaked in summer with 1.11 ppb, which is comparable to the average level of
87 HONO in other low-altitude areas (Luo et al., 2010; Xing et al., 2021a, 2021b; Yang et al., 2021). It
88 indicates that it is also necessary to study the contribution of HONO to AOC on the TP. Furthermore,
89 understanding the vertical distribution of OH is of great significance for learning about the atmospheric
90 chemical processes and the evolution of atmospheric components on the TP (Zhou et al., 2015).
91 Identifying the sources of O₃ and HONO is the basis for studying the AOC on the TP. The limited
92 researches concluded that the atmospheric HONO on the TP is mainly sourced from the emissions of
93 vehicles, biomass burning and soil, except for the NO₂ heterogeneous reaction on aerosol surfaces
94 (Xing et al., 2021). The lower tropospheric O₃ on the TP is mainly dominated by local photochemical
95 reactions, regional horizontal transport, vertical mixing and the intrusion from stratosphere (Yin et al.,
96 2017; Xu et al. 2018).

97 In this study, we firstly analyzed the temporal and vertical characteristics of several atmospheric
98 components (i.e. aerosol, H₂O, NO₂, HONO and O₃) based on MAX-DOAS observations in Nam Co.
99 Afterwards, the contributions of O₃ and HONO to OH in the vertical space were discussed through the
100 TUV radiative transfer model and MAX-DOAS measurements. Finally, the potential sources of O₃ and
101 HONO at different altitudes were analyzed based on the MAX-DOAS retrievals.

102 **2 Method and methodology**

103 **2.1 Measurement site**

104 The Nam Co Monitoring and Research Station for Multisphere Interactions, CAS (NAMORS)
105 (30.774°N, 90.988°E; 4730 m a.s.l.) is located at the southeast banks of Nam Co lake and the foothills
106 of the northern Mt. Nyainqêntanglha (Fig. 1). The station land is covered by alpine meadows with soil
107 type of sandy silt loam. The southwest monsoon can carry abundant moisture from Indian Ocean to this
108 station in summer to increase humidity and precipitation there. Moreover, due to the summertime huge
109 evaporation from Nam Co lake, the atmospheric water vapour around CAS (NAMORS) is more
110 abundant than in other areas of the TP, resulting in lush grass vegetation and making the area around
111 this station an important summertime pasture. In addition, there are not large industries and cities
112 within 100 km of the CAS (NAMORS). The closest town to CAS (NAMORS) is Dangxiong county
113 which is about 60 km away from this station and lower about 500 m than this station. Only a small
114 number of vehicles pass through this area during summer tourism season. Therefore, no obvious
115 anthropogenic sources of air pollutants exist near this station. Averaged spatial distributions of aerosol
116 optical depth (AOD), O₃, NO₂ and HCHO monitored by satellite from May to July 2019 are shown in
117 Fig. S1. Elevated AOD, O₃, NO₂, and HCHO are mainly distributed in South Asian subcontinent (e.g.
118 India and Nepal), the southern foothills of the Himalayas, which is located in the upwind direction of
119 the southwest monsoon potentially affecting the atmospheric composition over CAS (NAMORS).

120
121

Figure 1. Geographical location of CAS (NAMORS) on the Tibet plateau.

122 **2.2 Instrument setup and data processing**

123 The MAX-DOAS instrument installed at CAS (NAMORS) was operated from 01 May to 09 July 2019.
 124 It consists of three major parts: telescope unit, spectrometer unit and control unit. The detailed
 125 description of this instrument can be found in Xing et al. (2021). In this study, the elevation angle
 126 sequence was set to 1, 2, 3, 4, 5, 6, 8, 10, 15, 30, and 90° with an exposure time of 60 s to each
 127 individual spectrum. The azimuth angle was set to 56° pointing to Nagqu direction. Moreover, only
 128 spectra collected under solar zenith angle (SZA) less than 75° was used for spectral analysis to avoid
 129 the strong stratospheric absorption.

130 The differential slant column densities (DSCDs) of the oxygen dimer (O₄), water vapor (H₂O), NO₂,
 131 HONO and O₃ were retrieved using QDOAS software (<http://uvvis.aeronomie.be/software/QDOAS/>)
 132 developed by Royal Belgian Institute for Space Aeronomy (BIRA-IASB). The zenith spectrum
 133 measured at every sequence were selected as scan Fraunhofer reference spectrum. The retrieval
 134 configurations of O₄, H₂O, NO₂, HONO and O₃ followed Xing et al. (2017), Lin et al. (2020), Xing et
 135 al. (2021), Wang et al. (2020) and Wang et al. (2018), respectively. The detailed DOAS fit settings of
 136 above five species were listed in Table 1. Corrected I₀ (Aliwell et al., 2002) was used in this study. Fig.
 137 2 shows a typical DOAS retrieval example for above five species. DOAS fit results with root mean
 138 square (RMS) values larger than 5 × 10⁻⁴, 5 × 10⁻⁴, 5 × 10⁻⁴, 1 × 10⁻³, and 6 × 10⁻⁴ for O₄, H₂O, NO₂,
 139 HONO, and O₃, respectively, were filtered out. In addition, we calculated color index (CI) to remove
 140 cloud effect (Wagner et al., 2016). The data filter criteria according to CI followed by Ryan et al. (2018)
 141 and Xing et al. (2020). Afterwards, the quantified DSCDs of O₄, H₂O, NO₂, HONO, and O₃ remained
 142 91.33%, 91.97%, 92.16%, 86.42% and 81.09%, respectively.

143 The vertical profiles of aerosol and trace gases (i.e. H₂O, NO₂, HONO and O₃) were retrieved using
 144 algorithm based on optimal estimation method (OEM). A linearized pseudo-spherical vector discrete
 145 ordinate radiative transfer model VLIDORT was used as forward model and a Gauss-Newton (GN)
 146 scheme was used as the inversion strategy (Wedderburn et al., 1974). The detailed description of this
 147 algorithm can be found in Liu et al. (2021), Xing et al. (2021) and Wang et al. (2018). In this study, the
 148 initial a priori profile shape of above five species was set to exponential decreasing shape, and the
 149 AOD and VCDs simulated by WRF-Chem were also used as initial input a priori information to
 150 constrain the retrieval process. For the O₃ profile retrieval, the stratospheric O₃ profile was deducted
 151 using TROPOMI O₃ profile (Zhao et al., 2021). We set 20 vertical layers from 0.0 to 4.0 km with a
 152 vertical resolution of 0.2 km. The correlation height was set to 1.0 km. Moreover, the surface albedo,
 153 single scattering albedo and asymmetry parameter were set to fixed constant of 0.08, 0.85 and 0.65,
 154 respectively (Irie et al., 2008). The retrieved vertical profiles were removed under the condition of
 155 degree of freedom (DOF) and relative error less than 1.0 and 100%, respectively.

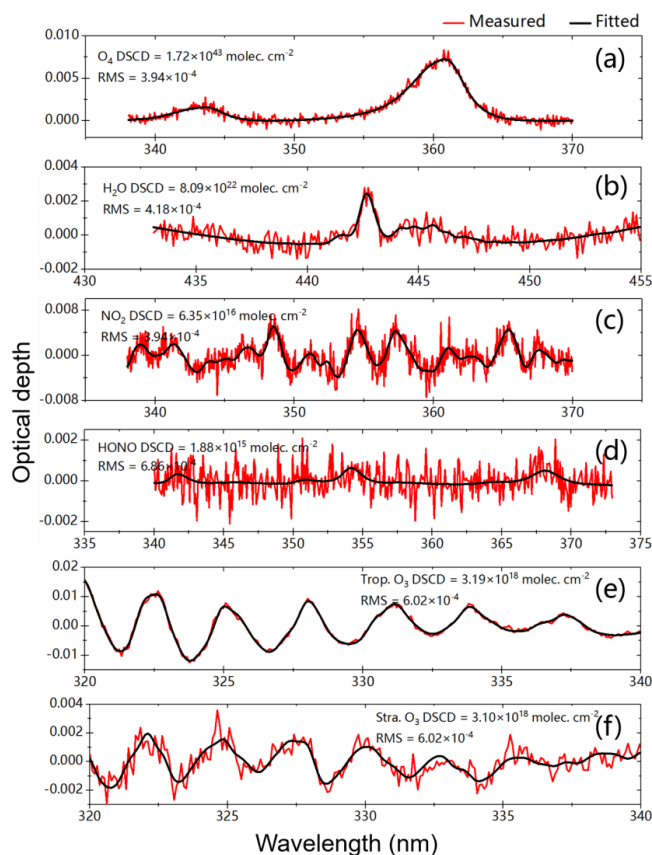

156 **Table 1.** Detailed DOAS retrieval settings for O₄, H₂O, NO₂, HONO and O₃.

Parameter	Data source	Fitting intervals (nm)				
		O ₄	H ₂ O	NO ₂	HONO	O ₃

Wavelength range		338-370	433-455	338-370	340-373	320-340

157

158

159 Figure 2. DOAS fit examples of O₄, H₂O, NO₂, HCHO, tropospheric O₃ and stratospheric O₃. The red
160 line and black line represent the measured and fitted results, respectively.

161 **2.3 TUV model**

162 The calculation of photolysis rates of HONO and O₃ used tropospheric ultraviolet and visible (TUV)
163 radiation model
164 (<https://www2.acom.ucar.edu/modeling/tropospheric-ultraviolet-and-visible-tuv-radiation-model>)
165 based on a full FORTRAN code, and this model usually runs accurately in clean, sunny and cloudless
166 days. The initial input parameters were as follows: the aerosol optical depth (AOD) at 361 nm was
167 derived from aerosol extinction profiles measured by MAX-DOAS; the daily total ozone column
168 density was measured by TROPOMI with a value range of 260-280 DU; the single scattering albedo
169 (SSA) was calculated based on the regression analysis of multi-wavelength (361 and 477 nm) O₄
170 absorptions measured by MAX-DOAS (Xing et al., 2019); fixed Ångström exponents of 0.508, 0.581
171 and 0.713 were used in May, June and July, respectively, referring to Xia et al. (2011).

172 **2.4 Backward trajectory, PSCF and CWT analysis**

173 The 48-h backward trajectories at five heights of 200, 600, 1000, 1400 and 1800 m were calculated
174 using the Hybrid Single-particle Lagrangian Integrated Trajectory (HYSPLIT) model based on the
175 Global Data Assimilation System (GDAS) to identify the major transport pathways of O₃ (Draxler and
176 Hess, 1998). Moreover, the calculated backward trajectories were clustered into three groups using
177 Ward's variance method and Angle Distance algorithm.

178 In order to determine the potential source locations of O₃ over CAS (NAMORS), the Potential Source
179 Contribution Function (PSCF) model and Concentration Weighted Trajectory (CWT) model were used
180 (Hong et al., 2019; Ou et al., 2021). The PSCF was calculated through the number of air trajectory
181 endpoints being divided by the number of air trajectory endpoints. Moreover, a weighting function was
182 introduced to reduce the increased uncertainties of PSCF with the increase of the distance between the
183 grid and sampling point. In this study, the set of this weighting function referred to Yin et al. (2017).
184 CWT can be used to calculate the weight concentration through averaging the concentrations
185 associated with trajectories crossing the grid cell. Above weighting function was also introduced to
186 calculate the WCWT (Hsu, et al., 2003). The detailed description of these two models can be found in
187 Wang et al., 2006.

188 **2.5 Ancillary data**

189 The surface NO₂, HONO and O₃ concentrations used to validate the corresponding MAX-DOAS
190 measurements were monitored by broadband cavity enhanced spectrometer (BBCES) (Fang et al.,
191 2017), long path absorption photometer (LOPAP) (Kleffmann et al., 2008) and Thermo Electron 49i
192 (Shi et al., 2009), respectively. The planetary boundary layer height (PBLH) was simulated using
193 Weather Research and Forecasting model (WRF) with spatiotemporal resolutions of 20×20 km² and
194 1.0 hour (detailed configurations in Appendix). Moreover, the large-scaled spatial distributions of AOD,
195 O₃, NO₂ and HCHO over CAS (NAMORS) were monitored by Himawari-8 (Bessho et al., 2016),
196 Ozone Monitoring Instrument (OMI) (Veefkind et al., 2004) and Tropospheric Monitoring Instrument
197 (TROPOMI) (Griffin et al., 2018; Su et al., 2020), respectively.

198 **3 Results**

199 **3.1 Overview of the measurements**

200 Figure 3 showed the averaged diurnal variation of AOD from 1st May to 9th July 2019, with an average
201 value of 0.076 km⁻¹ during 08:00-19:00. The AOD was 0.071 km⁻¹ at 08:00, and then gradually
202 decreased to a minimum value of 0.052 km⁻¹ at 12:00. Subsequently, the AOD increases significantly,
203 reaching maximum values during 15:00-17:00 (average of 0.107km⁻¹), which was about 1.408 times
204 the diurnal average value. Such an enhancement of AOD may be related to the long-range transport of
205 aerosol from southern Asia (Yang et al., 2020; Bi et al., 2023). Moreover, 15:00-17:00 was the active
206 time of tourists and local residents (i.e. cooking), and these kinds of anthropogenic sources contributed
207 to the atmospheric AOD of NAMORS through short-distance transport (Yin et al., 2017; Zhang et al.,
208 2017). After 17:00, the AODs decreased rapidly to 0.071 km⁻¹ at 18:00 and 0.081 km⁻¹ at 19:00,
209 respectively.

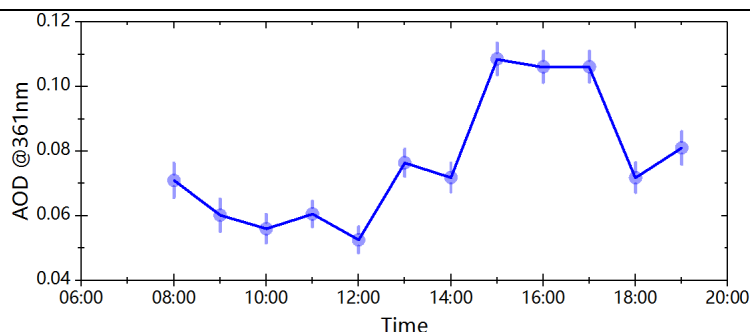

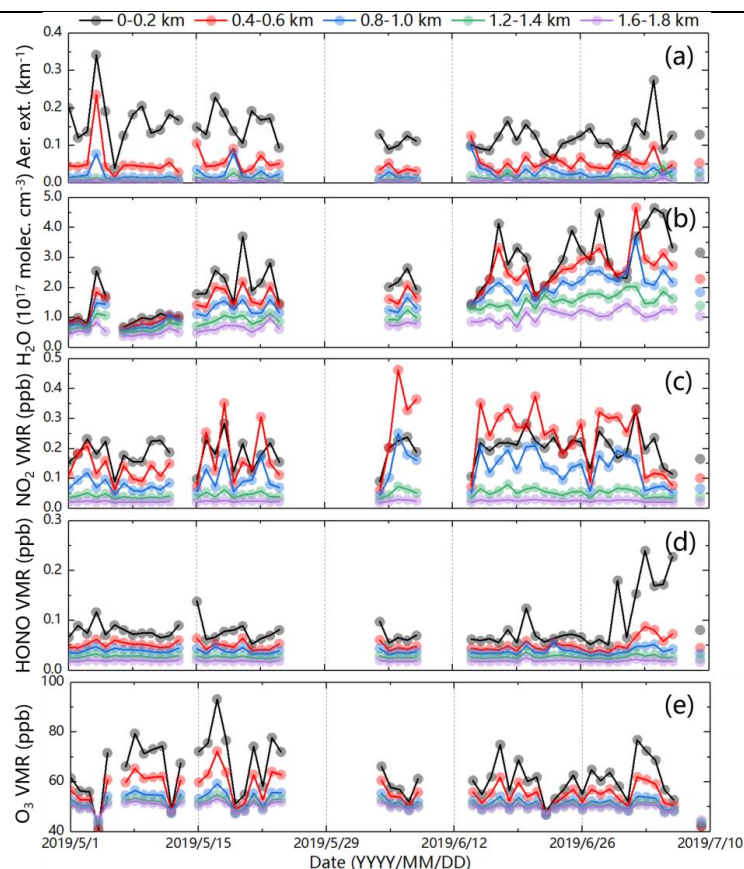

Figure 3. Averaged diurnal variation of AOD at CAS (NAMORS).

210

211

212 As shown in Figure S2, the diurnal variation of PBL in Nam Co from May to July 2019 shown lower in
 213 the early morning and late afternoon, and higher between 11:00 and 17:00 with the maximum PBL
 214 larger than 2.0 km. Zhang et al. (2017) and Yang et al., (2017) also reported that the PBL in Nam Co
 215 was usually larger than 1.0 km during daytime in spring and summer. Five typical height layers under
 216 the PBL (0.0-0.2 km, 0.4-0.6 km, 0.8-1.0 km, 1.2-1.4 km and 1.6-1.8 km) were thus selected to
 217 investigate the height-dependent variations of aerosol, H₂O, NO₂, HONO and O₃ during the
 218 observations.

219 Figure 4 showed the time series of the daily averaged aerosol, H₂O, NO₂, HONO and O₃ at above five
 220 layers from 1st May to 9th July 2019. Aerosol mainly distributed at 0.0-0.2 km with an average
 221 extinction coefficient of 0.138 km⁻¹, and the ratios of aerosol extinction at 0.4-0.6 km, 0.8-1.0 km,
 222 1.2-1.4 km and 1.6-1.8 km to those at 0.0-0.2 km were 39.34%, 18.77%, 7.29% and 2.62%,
 223 respectively. That indicated that the aerosol was usually local-emitted at the surface, and the
 224 occasionally appearance of strong aerosol extinction at 0.4-0.6 km, such as 13th and 30th June, was
 225 associated with long-range transport from south Asia (Wan et al., 2015; Li et al., 2016). The average
 226 concentration of H₂O at 0.0-0.2 km was 2.35 × 10¹⁷ molec cm⁻³, and the ratios of H₂O at 0.4-0.6 km,
 227 0.8-1.0 km, 1.2-1.4 km and 1.6-1.8 km to those at 0.0-0.2 km were 83.40%, 68.08%, 50.64% and
 228 35.74%, respectively, which should attribute to the transport of H₂O from Indian Ocean during the
 229 monsoon and the elevated evaporation from Nam Co lake to lead to its not obvious vertical gradient
 230 (Lei et al., 2014; Zhu et al., 2019). The average concentration of NO₂ at 0.0-0.2 km was 0.193 ppb, and
 231 its high concentration mainly distributed at 0.4-0.6 km after 15th May. The ratios of NO₂ at 0.4-0.6 km,
 232 0.8-1.0 km, 1.2-1.4 km and 1.6-1.8 km to those at the bottom layer were 104.03%, 59.05%, 24.62%
 233 and 12.84%, respectively. The elevation of the distribution height of high concentration NO₂ should be
 234 attributed to the transport process from the NO_x produced by ice and snow on the top of Mt. Tanggula
 235 under strong ultraviolet radiation (Boxe et al., 2005). As depicted in Figure S3, the WPSCF passing
 236 through Mt. Tanggula showed high values at 300-400 m layer, especially at 400 m (> 0.3). HONO
 237 mainly distributed at 0.0-0.2 km with an average value of 0.087 ppb, and the ratios of HONO at 0.4-0.6
 238 km, 0.8-1.0 km, 1.2-1.4 km and 1.6-1.8 km to those at 0.0-0.2 km were 58.49%, 44.64%, 31.30% and
 239 21.67%, respectively. That indicated that the primary and secondary sources of HONO were mainly at
 240 the surface (Section 4.2). The vertical gradient of O₃ concentration was also not obvious, which was
 241 associated with its vertical mixing and photochemical production (Yin et al., 2017). As shown in
 242 Figure S4, the corresponding TROPOMI O₃ profiles around Nam Co and several lidar and ozonesonde
 243 measured O₃ profiles on the TP in several previous studies also exhibited an exponential shape (Fang et
 244 al., 2019; Zhang et al., 2020; Yu et al., 2022). The O₃ average concentration at 0.0-0.2 km was 63.030
 245 ppb, and the ratios of O₃ at 0.4-0.6 km, 0.8-1.0 km, 1.2-1.4 km and 1.6-1.8 km to those at surface were
 246 89.25%, 82.44%, 80.16% and 79.13%, respectively.

247

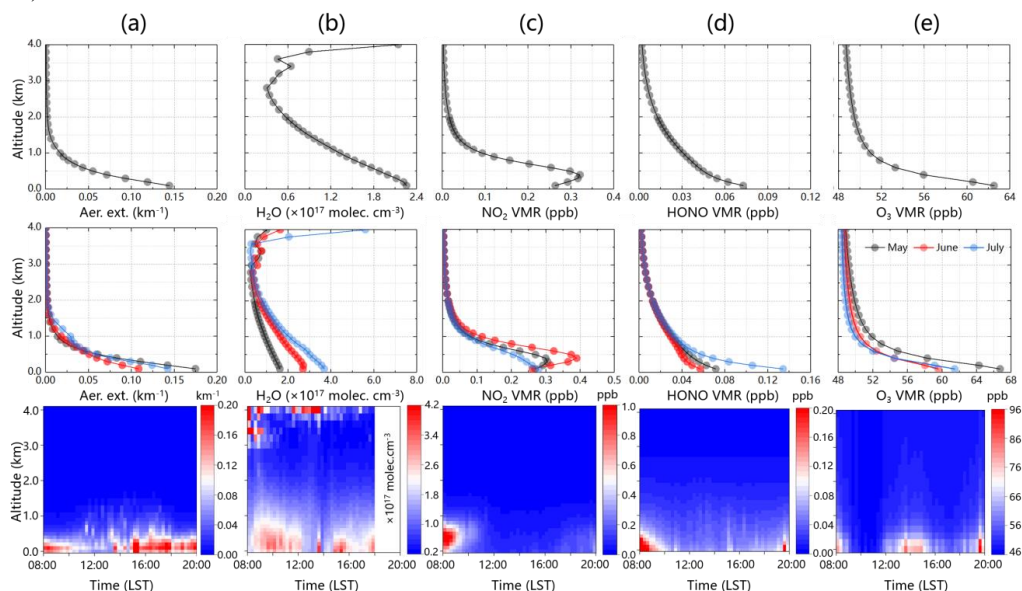

248 Figure 4. Time series of (a) aerosol extinction, (b) Water vapour, (c) NO₂, (d) HONO, and (e) O₃
249 monitored by MAX-DOAS at 0-0.2, 0.4-0.6, 0.8-1.0, 1.2-1.4 and 1.6-1.8 km five height layers from 01
250 May to 09 July 2019.

251 3.2 Vertical distributions of aerosol, H₂O, NO₂ and HONO

252 The first row in Figure 5 provided the averaged vertical profiles of aerosol, H₂O, NO₂, HONO and O₃
253 from May to July 2019. We found that the vertical profiles of aerosol, H₂O, HONO and O₃ all
254 exhibited an exponential shape with maximum values near the surface, while NO₂ exhibited a Gaussian
255 shape with the maximum value of 0.321 ppb occurring at 0.3-0.4 km layer. In addition to the effect of
256 NO_x transport, Xu et al. (2018) also revealed that the long-range high-altitude transport process from
257 the northern south Asian subcontinent can significantly enhance the Nam Co's peroxyacetyl nitrate
258 (PAN) level which is a reservoir of NO_x. As shown in the second row of Figure 5, the monthly
259 averaged aerosol vertical profiles from May to July 2019 all exhibited an exponential shape, and varied
260 in the order of May (0.17 km⁻¹) > July (0.14 km⁻¹) > June (0.11 km⁻¹). Xu et al. (2018) and Neupane et
261 al. (2019) also reported a similar monthly variations of black carbon (BC) from May to July over the
262 TP, and revealed that it was mainly associated with the anthropogenic emissions (i.e. biomass burning)
263 and its transport from south Asia. The monthly averaged vertical profile of H₂O in May and July
264 exhibited an exponential shape, while its maximum concentration layer slightly elevated to 0.1-0.2 km
265 which was related to the strongest monsoon transport (Xu et al., 2020). It varied in the order of July
266 (3.68 × 10¹⁷ molec cm⁻³) > June (2.71 × 10¹⁷ molec cm⁻³) > May (2.26 × 10¹⁷ molec cm⁻³), and its
267 maximum concentration occurring in July was strongly associated with the enhanced evaporation from
268 the Nam Co lake (Xu et al., 2011). The monthly averaged vertical profiles of NO₂ all exhibited a
269 Gaussian shape from May to July, and its maximum values mainly distributed at 0.2-0.4 km layer
270 varying in the order of June (0.39 ppb) > May (0.31 ppb) > July (0.28 ppb). It indicated that the

271 regional transport from the NO_x produced from ice and snow under strong shortwave radiation (Figure
 272 S3), NO_2 emitted from vehicles due to the increased tourism, anthropogenic emissions from local
 273 residents (i.e. biomass burning and religious activities) played an important role in the vertical
 274 distribution characteristic of NO_2 (Boxe et al., 2005; Chen et al., 2019). The monthly averaged vertical
 275 profiles of HONO from May to July all exhibited an exponential shape, with maximum values near the
 276 surface varying in the order of July (0.13 ppb) > May (0.07 ppb) > June (0.06 ppb). The local direct
 277 emissions from biomass burning, vehicles and soil should be main sources of the surface HONO (Xing
 278 et al., 2021). Moreover, the heterogeneous reaction of NO_2 on wet surfaces should be another important
 279 source of HONO at different height layers (Section 4.2). For example, the aerosol extinction coefficient,
 280 and the concentrations of H_2O and NO_2 were all relatively large at the bottom layer in July,
 281 correspondingly, we observed the highest concentration of HONO near the surface in this month. The
 282 monthly averaged O_3 vertical profiles all showed an exponential shape from May to July, and its
 283 surface concentration varied in the order of May (66.71 ppb) > July (61.45 ppb) > June (59.55 ppb).
 284 This kind of monthly variation trend of O_3 was also reported by several previous studies (Yin et al.,
 285 2017; Xu et al., 2018). The O_3 in Nam Co was mainly sourced from stratospheric intrusion,
 286 photochemical reactions, long-range transport and local vertical mixing (Yin et al., 2017; Chen et al.,
 287 2019).

288

289 Figure 5. Vertical profiles of (a) aerosol extinction, (b) Water vapour, (c) NO_2 , (d) HONO, and (e) O_3 .
 290 The top row shows the averaged vertical profiles from 01 May to 09 July 2019. The middle row shows
 291 the monthly averaged vertical profiles. The bottom row shows the averaged diurnal vertical profiles
 292 from 01 May to 09 July 2019.

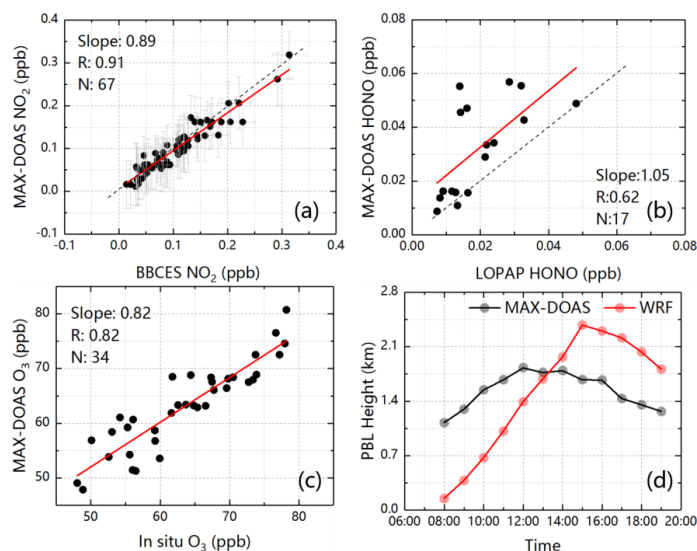

293 The third row in Figure 5 illustrated the averaged diurnal variations in vertical profiles of aerosol, H_2O ,
 294 NO_2 , HONO and O_3 from May to July 2019. Aerosol mainly distributed under 1.0 km, especially 0.6
 295 km, and its mixing height was gradually increased with the rise of the PBL height after 12:00.
 296 Moreover, the diurnal variation of aerosol showed a bi-peak pattern, which was in line with the
 297 investigation reported by Pokharel et al. (2019). The first peak occurred between 08:00-10:00, and
 298 another appeared after 15:00. This pattern was dominated by the local emission and regional transport
 299 of aerosol (Zhang et al., 2017; Pokharel et al., 2019). Moreover, the interaction between local sandy silt
 300 loam surface and local meteorology was another significant driving force with the wind speed less than
 301 2.3 m/s and 4.0 m/s under 10 m and 500 m, respectively (Figure S5). H_2O mainly distributed under 1.0
 302 km and above 3.0 km, and its diurnal variation exhibited a multi-peak pattern. The first peak appeared
 303 between 08:00-12:00, which was mainly affected by the monsoon driven long-range transport of H_2O

304 (Cong et al., 2009; Xu et al., 2020). The second and third peaks occurred at 15:00-16:00 and after
 305 17:00, respectively. In addition to long-range transport, the enhanced evaporation from the Nam Co
 306 lake also significantly contributed to the appearance of these two peaks of H₂O (Xu et al., 2011). NO₂
 307 mainly distributed at 0.2-0.4 km, and peaked before 10:00 and after 18:00 which were dominated by
 308 the effects of local emissions and regional transport (Figure S3) (Boxe et al., 2005; Chen et al., 2019).
 309 Moreover, its diurnal mixing height was obviously correlated to the diurnal evolution of PBL height.
 310 HONO mainly distributed under 1.0 km, especially 0.4 km. Its diurnal variation showed a multi-peak
 311 pattern with three obvious peaks before 10:00, 15:00-16:00, and after 19:00. In addition to local
 312 emissions (i.e. vehicle emission, biomass burning and soil emission), the heterogeneous reaction of
 313 NO₂ on wet surfaces should be also an important HONO source (Xing et al., 2021). We found that
 314 there were larger aerosol extinction (> 0.12 km⁻¹) and higher concentrations of NO₂ (> 0.20 ppb) and
 315 H₂O (> 2.27 molec cm⁻³) around three HONO peaks. O₃ mainly distributed under 0.4 km, and its
 316 diurnal variation exhibited a multi-peak pattern with three peaks appearing before 09:00, 13:00-15:00
 317 and after 19:00. The appearance of O₃ peaks was mainly associated with the influence of the complex
 318 topography of the TP, long-range transport, local vertical mixing and stratospheric intrusion (Yin et al.,
 319 2017; Chen et al., 2019; Qian et al., 2022). The active photochemical reaction should be another
 320 important source of O₃, especially for its second peak at 13:00-15:00.

321 3.3 Validation with independent data

322 In order to validate the MAX-DOAS dataset, we extracted the concentrations of NO₂, HONO and O₃ at
 323 the bottom layer (0.0-0.1 km) from their corresponding vertical profiles to compare with in situ
 324 measurements. As shown in Figure 6(a-c), we found good agreements between MAX-DOAS and in
 325 situ observations with Pearson correlation coefficients (R) of 0.91, 0.62 and 0.82 (regression slope of
 326 0.89, 1.05 and 0.82) for NO₂, HONO and O₃, respectively. That indicated the good reliability of trace
 327 gases from MAX-DOAS retrievals. Moreover, we also compared the MAX-DOAS PBL and WRF PBL,
 328 and a similar variation trend was found. However, WRF PBL showed a significantly difference in
 329 height values with MAX-DOAS PBL before 12:00. That should be due to the simulation uncertainties
 330 for WRF model at Tibetan plateau with complex topography and meteorology (Yang et al., 2016; Xu et
 331 al., 2019).

332

333 Figure 6. Validations of (a) MAX-DOAS NO₂ vs in situ NO₂, (b) MAX-DOAS HONO vs LOPAP
 334 HONO, (c) MAX-DOAS O₃ vs in situ O₃, and (d) MAX-DOAS PBL vs WRF PBL.

335 4 Discussion

336 4.1 OH production

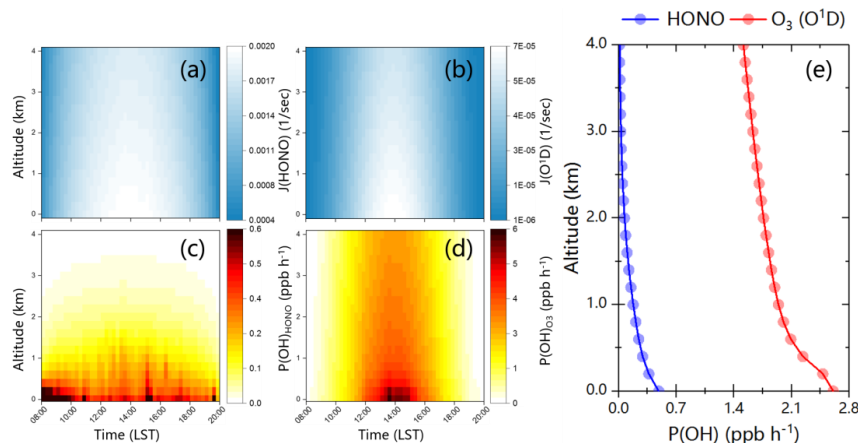

337 HONO and O₃ are two important precursors of OH radical to enhance the AOC (Kleffmann et al., 2005;
 338 Ryan et al., 2018; Xing et al., 2021). In order to evaluate the AOC on the TP, we tried to analyze the
 339 OH production from HONO and O₃ at different height layers through vertical observations and TUV
 340 calculations. The OH production rates from HONO and O₃ were calculated using the following two
 341 equations:

$$342 \quad P(OH)_{HONO} = J(HONO) \times [HONO]$$

$$343 \quad P(OH)_{O_3} = 2 \times f \times J(O(^1D)) \times [O_3]$$

344 Where $J(HONO)$ and $J(O(^1D))$ were the photolysis rates of HONO and O(¹D) calculated using TUV
 345 model. O(¹D) was the product from O₃ photolysis by UV radiation. f was the fraction of the process
 346 $O(^1D) + H_2O \rightarrow 2OH$.

347 Figure 7(a-b) showed the averaged diurnal vertical distributions of the photolysis rates $J(HONO)$ and
 348 $J(O(^1D))$ from May to July 2019. We found that the maximum $J(HONO)$ and $J(O(^1D))$ were all
 349 appeared at the bottom layer between 12:30 and 15:30 with values of 2.0×10^{-3} and $6.75 \times 10^{-5} \text{ s}^{-1}$,
 350 respectively. The maximum values were usually larger than that at low-altitude areas due to the
 351 stronger solar UV radiation on the TP (Su et al., 2008; Xing et al., 2021; Yang et al., 2021; Liu et al.,
 352 2022), but being consistent with the values on the TP reported by Lin et al. (2008). Moreover, it should
 353 be noted that the values of $J(HONO)$ and $J(O(^1D))$ all decreased with the increase of altitude, which
 354 was significantly different with previous studies in low altitudes (Ryan et al., 2018; Xing et al., 2021;
 355 Xu et al., 2021).

356

357 Figure 7. Averaged diurnal vertical profiles of the (a) photolysis rate $J(HONO)$, (b) photolysis rate
 358 $J(O(^1D))$, (c) OH radical production rates from HONO photolysis, (d) OH radical production rates from
 359 O₃ photolysis. (e) shows the averaged vertical profiles of OH radical production rates from HONO and
 360 O₃ photolysis from 01 May to 09 July 2019.

361 Figure 7(c-d) showed the averaged diurnal vertical profiles of OH production rates from HONO and O₃
 362 photolysis from May to July 2019. $P(OH)_{HONO}$ exhibited a multi-peak pattern which mainly appeared
 363 before 10:00, 15:00-16:00, and after 19:00 at 0-0.4 km with a maximum value of 0.81 ppb/h. While
 364 $P(OH)_{O_3}$ showed a unimodal pattern occurring at 13:00-15:00 under 0.4 km with a maximum value of
 365 6.20 ppb/h. The averaged vertical profiles of $P(OH)_{HONO}$ and $P(OH)_{O_3}$ during the observation were
 366 depicted in Figure 7(e). We found that the maximum values of $P(OH)_{HONO}$ (0.49 ppb/h) and $P(OH)_{O_3}$
 367 (2.61 ppb/h) all appeared at the bottom layer, and decreased with height. That indicated O₃ was the
 368 main contributor of OH production (> 80%) on the TP, which was about 5-6 times to HONO.
 369 Moreover, the OH production rates from HONO and O₃ in other cities of China were depicted in Table
 370 2. The contribution percentage of O₃ to $P(OH)$ in Nam Co was significantly higher than that in other
 371 cities, which was due to the relatively high concentrations of O₃ and H₂O, and the strong radiation in

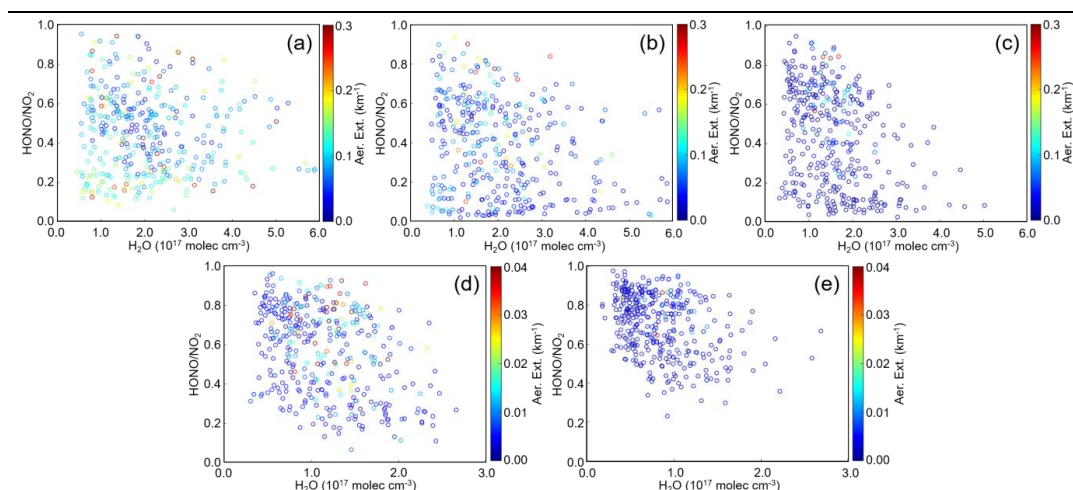

372 Nam Co. In addition, $P(OH)_{HONO}$ in Nam Co was close to that in relatively dry areas (i.e. Beijing and
 373 Xianghe), but slightly lower than that in areas with relatively high humidity which can enhance the
 374 heterogeneous production of HONO (Ryan et al., 2018; Liu et al., 2019; Xing et al., 2021).

375 Table 2. The maximum OH production rates contributed from HONO and O_3 at different locations.

376 4.2 Possible daytime HONO sources

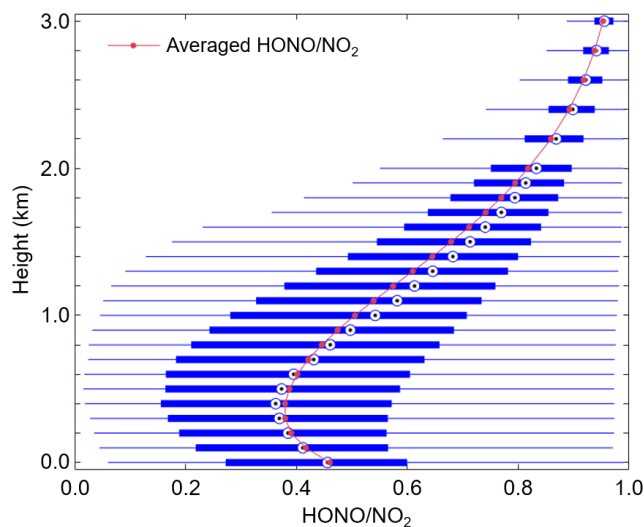

377 Atmospheric HONO mainly sourced from direct emission, homogeneous reaction and heterogeneous
 378 reaction (Fu et al., 2019; Ren et al., 2020; Chai et al., 2021; Crilley et al., 2021; Li et al., 2021). There
 379 were less anthropogenic emissions for HONO around NAMORS, however, the open burning of crop
 380 residues and soil emissions should be important HONO sources considering the pasture environment
 381 and large amounts of animal manure (Cui et al., 2021a; 2021b). Moreover, the background of low-level
 382 NO on the TP led to the homogeneous reaction not to be the main source of HONO at NAMORS
 383 (Lin et al., 2019; Xing et al., 2021; Li et al., 2022). Heterogeneous reaction of NO_2 on wet surfaces
 384 became an important potential source of HONO around NAMORS, which affected by the humidity,
 385 temperature, solar radiation, aerosol concentration and corresponding specific surface area. In order to
 386 remove the effect of diurnal PBL evolution, we used $HONO/NO_2$ to indicate the extent of the
 387 heterogeneous reaction process. As shown in Figure 8, scatter plots between $HONO/NO_2$ and water
 388 vapor were illustrated. We found that the maximum value of $HONO/NO_2$ appeared around water vapor
 389 being around 1.0×10^{17} molec cm^{-3} under 1.0 km, and being around $1.0-2.0 \times 10^{17}$ molec cm^{-3} at
 390 1.0-2.0 km height layer. This phenomenon of $HONO/NO_2$ first increasing and then decreasing with the
 391 increasing of water vapor (or relative humidity) was usually found in low-altitude areas in previous
 392 studies (Wang et al., 2013; Liu et al., 2019; Xing et al., 2021; Xu et al., 2021). When the water vapor
 393 was greater than above mentioned critical values at different heights, $HONO/NO_2$ gradually decreased,
 394 which was related to the efficient uptake of HONO and the decrease of NO_2 reactivity with the increase
 395 of water vapor (Liu et al., 2019; Xu et al., 2021). That indicated water vapor has significant
 396 enhancement for the conversion rate of NO_2 to HONO. Moreover, we found that the high value areas
 397 of $HONO/NO_2$ at above five height layers were all accompanied by high aerosol extinction (> 0.15
 398 km^{-1} under 1.0 km, and $> 0.02 km^{-1}$ at 1.0-2.0 km). It indicated that aerosol surface has contribution to
 399 the heterogeneous reaction process of NO_2 . The scatter plots between HONO and NO_2 at above five
 400 layers (Figure S6) also confirmed the possibility of the NO_2 heterogeneous reaction to generate HONO
 401 on the TP, and the contribution of atmospheric water vapor and aerosol extinction to this process.

402

403 Figure 8. Scatter plots between HONO/NO₂ and water vapor coloured by aerosol extinction at (a)
 404 0.0-0.2 km, (b) 0.4-0.6 km, (c) 0.8-1.0 km, (d) 1.2-1.4 km, and (e) 1.6-1.8 km from 1st May to 9th July
 405 2019.

406 In Figure 9, the vertical profile of HONO/NO₂ from May to July 2019 was depicted. We found that
 407 HONO/NO₂ firstly decreased and then increased with the increasing of height, which was opposite to
 408 previous studies in low-altitude areas (Meng et al., 2020; Zhang et al., 2020; Xing et al., 2021; Xu et al.,
 409 2021). The minimum average HONO/NO₂ occurred at 0.3-0.4 km height layer with a value of 0.37.
 410 The relatively high values of HONO/NO₂ at the bottom layer should be related to the non-deducted
 411 HONO direct emissions.

412

413 Figure 9. Vertical profile of HONO/NO₂ from 1st May to 9th July 2019.

414 4.3 Possible daytime O₃ sources

415 In addition to local photochemistry process, long-range transport was the main source of O₃ on the TP
 416 (Yin et al., 2017; Xu et al., 2018). To further understand the transport pathway and potential source of
 417 O₃, cluster analysis, WPSCF and WCWT models were used to assess the regional representativity of
 418 O₃ at five typical heights (200 m, 600 m, 1000 m, 1400 m and 1800 m). As shown in Figure S7 and
 419 Table 3, the backward trajectories arriving at NAMORS during the observation were classified into

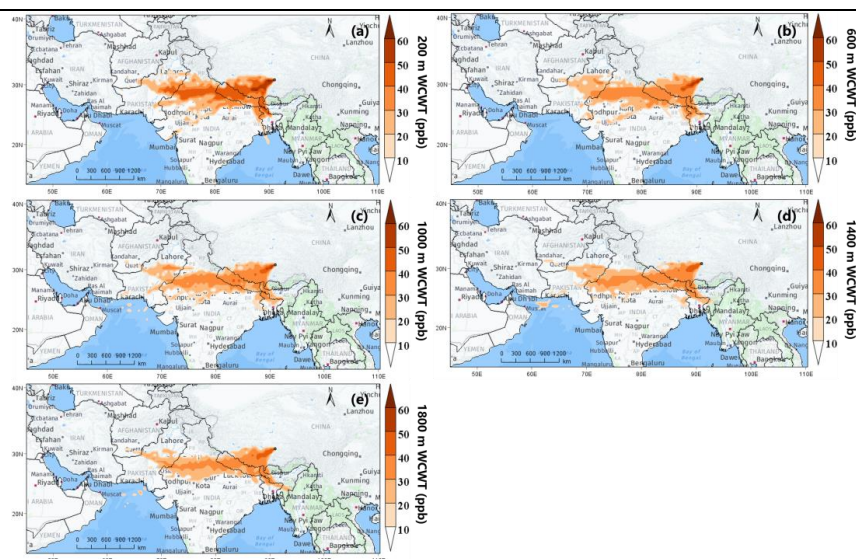

420 three clusters. We found that cluster 3 was associated with the highest O₃ concentration at 200 m
 421 (65.48 ± 17.41 ppb) and 1800 m (49.69 ± 2.21 ppb), and cluster 1 were related to the highest O₃
 422 concentration at 600 m (54.67 ± 6.94 ppb), 1000 m (51.61 ± 3.84 ppb) and 1400 m (50.51 ± 2.89 ppb).
 423 These two clusters were all originating from northwestern of south Asian subcontinent passing through
 424 Himalayas, which was also reported by Yin et al. (2017) during springtime from 2011 to 2015. In
 425 Figure S8 and 10, WPSCF and WCWT analysis told us that the high O₃ concentration at above heights
 426 potentially sourced from northern India, central Pakistan, Nepal, western Bhutan and northern
 427 Bangladesh through long-range transport. It should be noted that the potential contribution to O₃ at
 428 NAMORS at 200 m from above potential source areas were all over 40 ppb. These contributions from
 429 the mentioned potential source areas at other four heights were also over 20-30 ppb. The massive fire
 430 emissions during springtime were an important source of O₃ in south Asia (Jena et al., 2015), and the
 431 obvious burning during the observation was observed in Figure S9. Moreover, the abundant precursors
 432 and high photochemical activity were another significant sources of O₃ in south Asia (Kumar et al.,
 433 2012; Sharma et al., 2017).

434 In addition, several previous studies have revealed that the stratospheric O₃ intrusion events were
 435 frequent in the Himalayas during spring and summer (Cristofanelli et al., 2010; Chen et al., 2011;
 436 Škerlak et al., 2014; Putero et al., 2016). The O₃ invading from stratosphere also contributed to the O₃
 437 at NAMORS through long-range transport. Figure 10 showed that the contribution of O₃ transported
 438 from Himalayas can even up to 50 ppb, especially under 600 m.

439 Table 3. Trajectory ratios and averaged O₃ concentration for all trajectory clusters arriving in Nam Co
 440 at 200 m, 600 m, 1000 m, 1400 m and 1800 m from May to July 2019.

	Cluster	Traj_ratio	O ₃ concentration (ppb)
			Mean ± SD
200 m	1	55.86%	61.50 ± 18.15
	2	11.85%	54.57 ± 14.67
	3	32.28%	65.48 ± 17.41
	All	100.00%	61.14 ± 17.74
600 m	1	62.55%	54.67 ± 6.94
	2	14.32%	50.43 ± 6.64
	3	23.13%	53.27 ± 7.63
	All	100.00%	53.39 ± 7.26
1000 m	1	49.16%	51.61 ± 3.84
	2	8.81%	49.60 ± 3.99
	3	42.03%	51.51 ± 4.50
	All	100.00%	50.98 ± 4.30
1400 m	1	80.14%	50.51 ± 2.89
	2	4.95%	49.12 ± 2.73
	3	14.92%	49.44 ± 3.85
	All	100.00%	50.07 ± 3.15
1800 m	1	83.75%	49.68 ± 2.55
	2	0.00%	49.07 ± 2.23
	3	16.25%	49.69 ± 2.21
	All	100.00%	49.59 ± 2.49

443 Figure 10. Spatial distributions of WCWT values for O₃ at (a) 200 m, (b) 600 m, (c) 1000 m, (d) 1400
444 m, and (e) 1800 m height layers from 01st May to 09th July 2019 over CAS (NAMORS).

445 5 Summary and conclusions

446 MAX-DOAS measurements were performed to clarify the vertical distributions of several atmospheric
447 components (aerosol, H₂O, NO₂, HONO and O₃), and to explore the AOC in vertical space in Nam Co
448 from May to July 2019. The MAX-DOAS NO₂, HONO and O₃ agreed well with in situ measurements,
449 with correlation coefficients of 0.91, 0.62 and 0.82, respectively. We found that the averaged vertical
450 profiles of aerosol, H₂O, HONO and O₃ all exhibited an exponential shape, while NO₂ showed a
451 Gaussian shape with a maximum value of 0.32 ppb appearing at 300-400 m. The maximum
452 concentrations of monthly averaged aerosol (0.17 km⁻¹) and O₃ (66.71 ppb) appeared on May, H₂O
453 (3.68 × 10¹⁷ molec cm⁻³) and HONO (0.13 ppb) appeared on July, and NO₂ (0.39 ppb) occurred on
454 June. For the diurnal variation, above five species all mainly distributed under 1.0 km, and mostly
455 exhibited a multi-peak pattern considering the effect of regional transport and local chemical reaction.

456 O₃ and HONO were the main source of OH on the TP. The diurnal averaged OH production rate from
457 HONO during the observation exhibited a multi-peak pattern appearing before 10:00, 15:00-16:00 and
458 after 19:00 under 0.4 km with the maximum value of 0.81 ppb/h. The OH production rate from O₃
459 shown a unimodal pattern occurring at 13:00-15:00 under 0.4 km with the maximum value of 6.20
460 ppb/h which was obviously higher than that at low-altitude areas. In addition to direct emission, the
461 heterogeneous reaction of NO₂ on wet surfaces was also an important source of HONO in Nam Co. We
462 found that HONO/NO₂ first increasing and then decreasing with the increasing of water vapor. The
463 maximum value of HONO/NO₂ appeared around water vapor being around 1.0 × 10¹⁷ molec cm⁻³
464 under 1.0 km, and being around 1.0-2.0 × 10¹⁷ molec cm⁻³ at 1.0-2.0 km height layer. Moreover, high
465 values of HONO/NO₂ usually accompanied by high aerosol extinction. O₃ under 2.0 km were
466 potentially sourced from Himalayas, northern India, central Pakistan, Nepal, western Bhutan and
467 northern Bangladesh through long-range transport. Our results draw a picture of further understanding
468 the spatial and temporal variations in oxidation chemistry under PBL and provided a new perspective
469 for source analysis of major atmospheric components through vertical observation on the TP.

470 Acknowledgements

471 We firstly would like to thank @Tibet group for effectively organizing the Nam Co observation. We
472 also would like to thank Peking University (Chunxiang Ye's group) and Anhui Institute of Optics and
473 Fine Mechanics (Weixiong Zhao's group) to provide the DOAS validation data of HONO, O₃ and NO₂.

474 We thank the National Oceanic and Atmospheric Administration (NOAA) Air Resources Laboratory
475 (ARL) for providing the open HYSPLIT transport and dispersion model. This study was supported by
476 the National Natural Science Foundation of China (42225504 and U21A2027), the Anhui Provincial
477 Natural Science Foundation (2108085QD180), and the Presidential Foundation of the Hefei Institutes
478 of Physical Science, Chinese Academy Sciences (YZJJ2021QN06).
