Abstract. We analyzed the ionosonde observations at Okinawa (26.7°N, 128.1°E) for the years from 1972 to 2023. Okinawa is at the border between the low latitude and the mid-latitude ionosphere. The influences of sudden stratospheric warmings (SSWs) on the ionosphere are strong at low latitudes but less obvious at middle and high latitudes. We divided the dataset into winters with major SSWs in the northern hemisphere (SSW years) and into winters without major SSWs (no SSW years). During the SSW years, the daily cycle of the F2 region electron density maximum (NmF2) was stronger than in the no SSW years. The relative NmF2 amplitudes of solar and lunar tidal components (S_2 , O_1 , M_2 , MK_3) are stronger by 3 to 8% compared to no SSW years. The semidiurnal amplitude, averaged for 29 SSW events, has a significant peak at the central date of the SSW (epoch time 0 of the composite analysis). The SSW influence is not strong: the semidiurnal amplitude is about 38.2% in SSW years and about 32.9% in no SSW years (relative to NmF2 of the background ionosphere). However, there is a sharp decrease of the amplitude by about 10% after the SSW peak was reached. The amplitude of the diurnal component does not show a single peak at the central date of the SSW. We present the maximal semidiurnal amplitudes of the SSWs since 1972. The SSW of 31 December 1984 has the strongest amplitude (162%) in the ionosphere above Okinawa. The most surprising finding of the study are the strong lunar tides with relative amplitudes of about 10% and the discovery of a terdiurnal lunar tide (5%) in NmF2 during SSW years. The periods of the ionospheric lunar tides agree with the periods of ocean tides.

1 Introduction

It has been observed and simulated that sudden stratospheric warmings (SSWs) affect the whole atmosphere and ionosphere of the Earth (Pedatella et al., 2018). Sudden stratospheric warmings can be divided into minor and major SSWs (McInturff, 1978). Contrary to minor SSWs, major SSWs are causing a reversal of the stratospheric polar vortex. The central date of an SSW (SSW onset) is defined as the time point of the reversal of the stratospheric zonal wind at 10 hPa (about 30 km altitude) and at 60°N latitude. There can be also SSWs in the southern hemisphere but they are quite rare while the major SSWs in the northern hemisphere occur every 1-2 years.

In the present study, we only consider the influence of major SSWs in the northern winter hemisphere on the ionosphere. The reversal of the stratospheric polar vortex is caused by planetary wave breaking. In addition, severe disturbances, splitting or breakdown of the stratospheric polar vortex are observed during SSW events. A major SSW is associated with a rapid increase

25 in the polar stratospheric temperature and a reversal of the vortex from eastward to westward flow for at least 5 days (Matsuno, 1971; Schoeberl, 1978; McInturff, 1978; Matthewman et al., 2009).

It is well established that variations in polar stratospheric winds can affect mesospheric temperatures through changes in the filtering of gravity wave fluxes, which drive a residual circulation in the mesosphere. SSWs are often associated with mesospheric cooling since the breakdown of the stratospheric polar vortex leads to an enhanced gravity wave flux from below
30 into the mesosphere with associated upwelling and adiabatic cooling of the mesosphere. In the weeks after the SSW onset, an elevated stratopause appears in the polar mesosphere. The elevated stratopause slowly descends downward during several weeks to about 50 km in altitude (Zülicke and Becker, 2013).

The present knowledge of the influences of SSWs on the ionosphere have been reviewed by Goncharenko et al. (2021). Particularly, the upward propagating solar and lunar tides could have different propagation conditions due to SSW effects on
35 the middle atmosphere. The excitation, propagation and dissipation of solar and lunar tides have been described by means of a classical tidal theory which linearises the primitive equations providing Laplace's tidal equations (Lindzen and Chapman, 1969). The ionospheric effect of an SSW is most obvious in the low latitude ionosphere where a strongly amplified semidiurnal pattern in total electron content, equatorial vertical ion drift and equatorial electrojet have been observed (Goncharenko et al., 2021, 2013; Yamazaki et al., 2012). Yamazaki et al. (2012) also found that the geomagnetic lunar tide at the equator is enhanced
40 in 70% of the SSW events. However, the role of lunar and solar tidal variability for generation of the ionospheric effects of SSWs is still under investigation. The relative amplitudes of the semidiurnal lunar tide (M_2 , period 12.42 hour) is about 5% at low latitudes relative to the mean background electron density (Forbes and Zhang, 2019; Pedatella, 2014). Forbes and Zhang (2019) also mentioned that the quasi-diurnal lunar tide O_1 (period 25.82 hours) is important in the ionosphere. At mid-latitudes, the SSW effects on the ionosphere are more an increase of the mean electron density than ionospheric tidal variability (Mošna
45 et al., 2021).

The present study investigates the ionospheric effects of major SSWs at the northern border of the low latitude ionosphere. We take advantage on the long-term series of ionospheric peak electron density NmF2 which has been observed by an ionosonde at Okinawa. Kalita et al. (2015) analyzed the seasonal and diurnal variability of NmF2 at Okinawa and the influence of the equatorial ionization anomaly (EIA) at this location. The attribution of the ionospheric changes to SSW events
50 is relatively difficult since the ionospheric effect can be delayed or advanced by several days with respect to the central date of the SSW. Thus, a composite analysis of many SSW events is required for characterization of the average behaviour of the SSW-induced ionospheric changes. In addition, the solar and lunar tides are modulated by mesospheric winds. The mesospheric wind field is still not well observed but necessary for ionospheric predictions (Harvey et al., 2022). It has been observed that the migrating diurnal solar tide at the equator is reduced in the amplitude by SSW events (Siddiqui et al., 2022; Hocke, 2023).
55 The ionosonde series allows the discussion of variability of solar and lunar tides during the SSW events. It is still an open question whether solar or lunar tidal variability is more important for the ionospheric effects of SSWs. The long-term ionosonde series recorded at several places in the world also give us a unique opportunity to study historical SSW events of the 1950s or even earlier when stratospheric observations were rare but ionospheric observations were already common.

2 Dataset and data analysis

60 The ionogram records tracings of high-frequency (HF) radio pulses reflected in the ionosphere. It is produced by the vertical
incidence ionospheric sounder (ionosonde) at Okinawa (26.7°N, 128.1°E), Japan. The sounding frequency is swept from 1 to
30 MHz. Ionograms are obtained at regular intervals of 15 min and contain several important factors such as the ordinary mode
critical frequency or maximum reflection frequency foF2 of the ionospheric F₂ layer. In the present study, we use the manually
scaled ionospheric parameter foF2 which is provided with a time resolution of 1 hour from 1972 to 2023 by the World Data
65 Center for Ionosphere and Space Weather at the National Institute of Information and Communications Technology in Tokyo.
The parameter foF2 is closely related to the maximum electron density NmF2 of the ionospheric F₂ layer by

$$NmF2 = 1.24 \times 10^{10} (foF2)^2 \quad (1)$$

where NmF2 is in [m⁻³] and foF2 in [MHz] (Davies, 1990; Chuo, 2012). In the present study, we mainly analyse the time
series of NmF2. The relative amplitudes are computed with respect to a temporal average of NmF2 which is either the mean of
70 the depicted time interval or a 60 day-lowpass filtered series of NmF2.

For the data analysis, we used a digital non-recursive, finite impulse response bandpass filter. Zero-phase filtering is ensured
by processing the time series in forward and reverse directions. A Hamming window was selected for the filter. The number of
filter coefficients corresponds to a time window of three times the central period, so that the bandpass filter has a fast response
time to temporal changes in the data series. The variable choice of the filter order permits the analysis of wave trains with a
75 resolution that matches their scale. The bandpass cut-off frequencies are at $f_c = f_p \pm 10\% f_p$, where f_c is the cut off frequency
and f_p is the central frequency. For the semidiurnal variation, the cut-off frequencies are 1.8 and 2.2 cycles per day (cpd).
Further details about the bandpass filtering are provided by Studer et al. (2012). In case of the 60 day-lowpass filter, we used
the cut-off frequencies 0 and 1/(60 days).

For the case study of the SSW of 6 January 2013, we compare the Okinawa ionosonde data to data of the ionosonde at Wuhan
80 (30.5°N, 114.4°). The Wuhan ionograms have a time resolution of 15 min, and the foF2 values are automatically determined.

The composite analysis is limited to major SSWs during northern hemispheric winter. The central date of a major SSW is
defined as when the eastward wind changes to westward wind at 10 hPa, northward of 60° N McInturff (1978). The central
date gives the onset time of the major SSW and are used as the timing mark for the composite analysis of major SSWs (Hocke
et al., 2015). Of course, there are other processes in the mesosphere which may introduce an SSW or may follow the SSW
85 onset. For example, an elevated stratopause can be observed in the polar region in the weeks after the SSW onset (Manney
et al., 2008).

Palmeiro et al. (2023) determined the central dates of major SSWs by using the zonal wind data of the fifth-generation
ECMWF atmospheric reanalysis (ERA5, Hersbach et al. (2020)). Using Table 1 of Palmeiro et al. (2023), we obtain about 31
central dates of major SSWs in the time from 1972 to 2023 (selected ionosonde series at Okinawa) fulfilling the U60 criterium
90 (reversal of zonal wind U at 60°N). Since Table 1 of Palmeiro et al. (2023) ends in January 2021, we added the major SSW of
20 March 2022 (Vargin et al., 2022).

In the present study, we also use a list of “no SSW events” with central dates from December to March in northern hemispheric winters from 1972 to 2023 when no major SSW occurred. We selected the no SSW events close to the SSW years in order to have no large difference between solar activity and geomagnetic activity of SSW years compared to no SSW years. Thus, we did not put no SSW events into the large gap of SSW events in the 1990s. The mean geomagnetic activity A_p was 12.1 nT in the selected no SSW years and 11.7 nT in the selected SSW years. In case of solar activity, the solar radio flux at 10.7 cm (F10.7) was 122 in SSW years and smaller with 111 in no SSW years. It can be that SSW years have different conditions (e.g., solar activity, ENSO activity) than no SSW years. We performed composite analysis for F10.7 and A_p and found no significant changes at the epoch time 0 (SSW onset time). The composite lines were flat. Thus, we are sure that the SSW-induced characteristics of the NmF2 composites in the present study are not influenced by solar or geomagnetic activity.

For the spectral analysis of the solar and lunar tides in NmF2, we calculated the fast Fourier transform (FFT) spectrum of the relative NmF2 variations comprising the data from 5 weeks before the central date to 5 weeks after the central date of the SSW. This data segment was folded with a Hamming window. For enhancement of the frequency resolution we performed zero padding (4 years of zeros at the begin and at the end of the data segment). The spectral analysis and the calculation of the relative amplitude were tested and calibrated by means of an artificial sine wave of a known amplitude and frequency. The length of the data interval (10 weeks) is sufficient for a separation of the solar and lunar tidal components as we have verified by means of artificial sine waves by applying the same data analysis procedure.

2.1 Results

We start with the case study of the major SSW of 6 January 2013. Figure 1 shows the observed NmF2 at Okinawa and Wuhan from 5 days before the SSW onset to 15 days after the SSW onset. Obviously, the daily cycle is quite different at both stations, though the stations just differ in latitude by 3.8 degrees. In addition, it is difficult to see a significant change in NmF2 which could be related to the SSW event.

However, Goncharenko et al. (2013) reported about a strong amplification of the semidiurnal cycle in vertical ion drift and total electron content (TEC) at the magnetic equator. This amplification of the semidiurnal pattern was maximal from 15 to 19 January 2013 which corresponds to epoch time 9 to 13 days. The maximal values of the upward ion drift were between 30 and 43 m/s (Goncharenko et al., 2013). Thus, we applied a 12 hours-bandpass to the ionosonde data at Okinawa and Wuhan. Figure 2 shows the relative amplitude of the semidiurnal cycle of NmF2. The relative amplitude is calculated with respect to the background mean of NmF2 averaged from epoch time -30 days to 50 days. The amplitude curves agree well for Okinawa and Wuhan. Both curves show a maximum at epoch time 10 days which corresponds to 16 January 2013. This maximum of the semidiurnal cycle in NmF2 agrees well with the date of the maximal amplification of the semidiurnal pattern in vertical ion drift and TEC at the magnetic equator reported by Goncharenko et al. (2013).

The case study of 6 January 2013 motivated us to perform a statistical study of the SSW effects in the semidiurnal cycle of the critical frequency foF2 from 1972 to 2023 in Okinawa. We start with foF2 since the composite shows a clearer effect than for NmF2. It could be that the composite results are optimal for foF2 since it is an original measurement parameter of the ionosonde. The foF2 series is bandpass filtered at a central frequency of 2 cpd which correspond to the semidiurnal cycle.

Figure 1. Time series of NmF2 at Okinawa (red) and Wuhan (blue) before and after the major SSW of 6 January 2013 (epoch time 0 corresponds to 6 January 2013).

The amplitude series of the semidiurnal cycle is used for a composite analysis where we added 29 SSW events to a composite. Figure 3 shows the result which is averaged with a 14 day-moving average. Obviously, there is a significant peak at epoch time 0 when we calculate the composite of the SSW years (red curve). The thin lines indicate the standard error of the composite. On the other hand, the peak at epoch time 0 disappears when we compute the composite of the no SSW years (blue curve).

130 There is also a seasonal variation of the amplitude since the central dates of the SSWs are always in northern hemispheric winter (December to March) when the diurnal and semidiurnal variations of foF2 are maximal (Zolotukhina et al., 2011). The foF2 values are in average higher in SSW years compared to no SSW years. This is due to a higher F2 peak electron density in SSW years because of a higher solar activity in SSW years (F10.7=122 s.f.u. in SSW years and F10.7=111 s.f.u. in no SSW years).

135 In the following, we will analyse the relative variations of the NmF2 series. First, the NmF2 series is filtered with a 60 day lowpass in order to obtain a background series. Then, the relative variations of NmF2 are calculated with respect to the background series of NmF2. The relative variations of NmF2 are bandpass filtered at a central frequency of 2 cpd which correspond to the semidiurnal cycle. The relative amplitude series of the semidiurnal cycle is used for a composite analysis where we added 29 SSW events to a composite. Figure 4 shows the result which is averaged with a 14 days-moving average.

140 Obviously, there is a significant peak at epoch time 0 when we calculate the composite of the SSW years (red curve). On the other hand, the peak at epoch time 0 disappears when we compute the composite of the no SSW years (blue curve). Generally,

Figure 2. Time series of the relative amplitude of the semidiurnal cycle of NmF2 at Okinawa (red) and Wuhan (blue) before and after the major SSW of 6 January 2013. There is a maximum at epoch time 10 days when the largest SSW effect was observed at the magnetic equator (Goncharenko et al., 2013).

the SSW effect is not so obvious as for foF2. It is an increase of the relative amplitude from 32.9% (no SSW years) to 38.2% (SSW years). The occurrence of the peak at epoch time 0 is a strong indication that the ionospheric effect is indeed related to the SSW onset. Please also note the sharp decrease of the amplitude by about 10% after the SSW peak at epoch time 0 was reached. We did not find such a peak when we performed the composite analysis for the diurnal variation.

It is also interesting to study the time series of maximum relative amplitudes of the semidiurnal cycle of NmF2. The maximum of the relative amplitude from two weeks before the central date to two weeks after the central date of the SSW is taken. Figure 5 shows the time evolution of the maximum relative amplitude of the semidiurnal cycle since 1972 for SSW years and no SSW years. It is evident that also no SSW years can have large amplitudes in the semidiurnal cycle. In average, the relative amplitudes are 69% in no SSW years and 78% in SSW years. The largest amplitude occurred for the SSW of 31 December 1984 (about 162%). Generally, the attribution of an amplitude increase to an individual SSW event is not easy because of the high variability of the ionosphere.

Finally, we take a composite of the FFT spectrum in SSW years and no SSW years in order to get an overview about the spectral components of possible solar and lunar tides. The data segment goes from five weeks before the SSW event to 5 weeks after the SSW event. Figure 6 shows the result in a zoom which does not cover the peak of the solar diurnal variation S_1 . The S_1 peak is at 96.4% in no SSW years and at 95.4% in SSW years. The semidiurnal components of the sun (S_2) and

Figure 3. Composite of the amplitude of the semidiurnal cycle of foF2 at Okinawa in SSW years (red) and no SSW years (blue). The curves are averaged with a 14 days-moving average. The thin lines denote the standard errors. In total, the composite consist of 29 SSW events from 1973 to 2022.

the moon (M_2 , period 12.42 hours) are enhanced during SSW years. In addition, we can see the lunar diurnal component (O_1 , period 25.82 hours) with 11.1% in SSW years and 8.8% in no SSW years. However there is a peak at the period 25 hours in no SSW years which is close to the lunar day (24.83 hours). Possibly, for the first time, we find a lunar terdiurnal component (MK₃, period 8.18 hours) which is named the shallow water terdiurnal tide. The MK₃ component rises to 5% in SSW years. It is evident that all lunar components in Figure 6 have periods at the periods of ocean tides (Li, 2022). Due to the interannual variability of the tidal components, the standard error σ of the FFT spectra is often of the same size as the enhancements during SSW years. Figure 6 also shows a spectral peak at about 30 days which is close to the synodic period of the Moon cycle (29.53 days). At the frequency 0.5 cpd, we can see a significant peak of the two day-oscillation during no SSW years while the peak turns into a valley during SSW years.

2.1.1 Discussion

The attribution of ionospheric effects to individual major SSWs is a difficult task at Okinawa which is close to the border between low latitude and mid-latitude ionosphere. The case study of the SSW on 6 January 2013 suggested that the semidiurnal cycle of NmF2 might be amplified after the SSW onset. Indeed, we find an increased peak of the semidiurnal amplitude on 16 January 2013 which is coincident with the amplified semidiurnal pattern in vertical ion drift and TEC above the magnetic

Figure 4. Composite of the relative amplitude of the semidiurnal cycle of NmF2 at Okinawa in SSW years (red) and no SSW years (blue). The curves are averaged with a 14 days-moving average. The thin lines denote the standard errors. In total, the composite consist of 29 SSW events from 1973 to 2022.

Figure 5. Time evolution of the maximum relative amplitude of the semidiurnal cycle of NmF2 at Okinawa in SSW years (red) and no SSW years (blue). The maximum is taken from two weeks before the central date to two weeks after the central date of a major SSW.

equator from 15 to 19 January 2013 reported by Goncharenko et al. (2013). The plasma fountain in the equatorial ionosphere may slightly modulate the ionosphere above Okinawa though Okinawa is a bit northward of the equatorial ionization anomaly (EIA). The result of an increased amplitude of the semidiurnal cycle of NmF2 at Okinawa was confirmed by a coincident amplitude increase observed by the nearby ionosonde station at Wuhan in China.

175 Since the ionospheric SSW effects are possibly smaller at Okinawa than at the magnetic equator, it makes sense to perform a composite analysis of 29 SSW events since 1972. The composite analysis describes the average behaviour of the ionosphere before, during and after SSW onsets. Moreover, we divided the observations into SSW years and no SSW years and calculated composites for both cases. This idea is powerful for a critical assessment of SSW effects in spite of high ionospheric variability

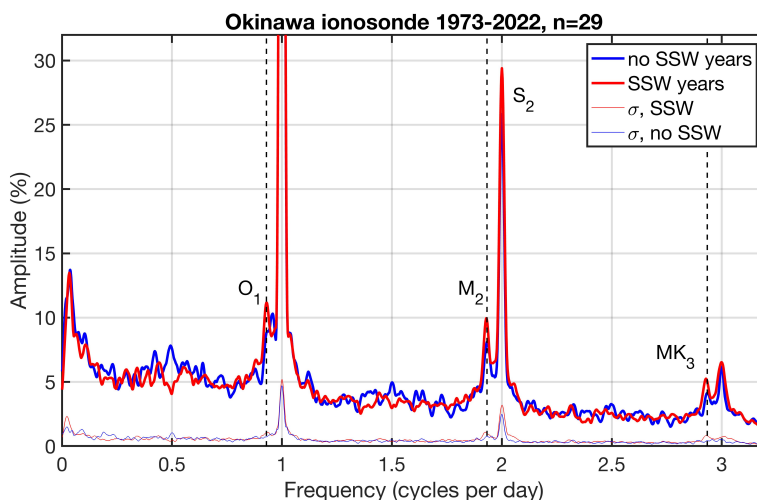

Figure 6. Composite of FFT spectra (time interval: five weeks before SSW to five weeks after SSW) for SSW years (red) and no SSW years (blue). The lunar components O_1 , M_2 and MK_3 are indicated by the vertical dashed lines at the periods 25.82 hr, 12.42 hr and 8.18 hr. The solar and lunar components in the ionosphere above Okinawa are enhanced during SSW years (composite of 29 SSW events). Please see the text for information about the S_1 peaks. The standard errors of the spectra σ are shown by the thin lines at the bottom.

due to other sources such as solar and geomagnetic variability or variability of atmospheric waves from below. The composite
180 analysis showed that there is a peak of the semidiurnal cycle of NmF2 which occurs at the epoch time 0 (SSW onset). This
result is supported by the composite of the no SSW years which showed no peak at epoch time 0. This result is important since
a peak might be due to the winter maximum of the amplitude of the semidiurnal cycle (Zolotukhina et al., 2011). Our data
analysis clearly shows that the peak cannot be explained by the seasonal variation since the SSW induced ionospheric peak
185 amplitude does not occur in no SSW years. However, it is also a finding that the SSW effect is not so strong (relative amplitude
in SSW years is 38.2% and in no SSW years 32.9%).

The long-term series of ionosonde observations are very valuable for studying the SSW effects of historical SSW events, and
we found that the SSW of 31 December 1984 generated a relative amplitude of 162% in the semidiurnal cycle of the relative
NmF2 variations at Okinawa. In addition, we find that the amplitude increase in no SSW years also can be quite strong which
should be regarded if one is analysing the ionospheric effects of individual SSW events.

190 The most important result of our study is contained in the composites of the FFT spectra of the 29 SSW events. The solar
(S_2) and lunar tidal components of NmF2 are increased during SSW years compared to no SSW years. We find strong diurnal
(O_1), semidiurnal (M_2) and terdiurnal (MK_3) components of the moon. The periods of the lunar components are at the place of
ocean tides. In addition, the amplitudes are about 10% for O_1 and M_2 and 5% for MK_3 . This is totally different to the results
which we obtain for the Kokubunji ionosonde in Tokyo (not shown here) where we do not find significant lunar components.
195 Past studies of Forbes and Zhang (2019) and Pedatella (2014) reported about lunar diurnal and semidiurnal tides in ionospheric
electron density of up to 5%. In SSW years, we find the double of this value at Okinawa. An explanation might be a strong

non-migrating lunar tidal components which are excited by ocean tides at the ocean-atmosphere boundary. The strong lunar tides only occur in the winter season at Okinawa. Perhaps, there exist, especially in SSW winters, special vertical propagation conditions for solar and lunar tides. The breaking or dissipation of tides in the upper mesosphere and lower thermosphere induce a tidal signal in the neutral and ion temperature at these heights which is immediately transferred by heat conduction to the ionospheric F_2 region. These tidal variations in the ion temperature induce tidal variations of the ionospheric plasma and the peak electron density NmF_2 (Zolotukhina et al., 2011).

It is interesting that the two day-oscillation in NmF_2 is strong in no SSW years while it is missing in SSW years (Figure 6). It can be do to interactions of the tides with the quasi two day wave (QTDW) (Yue et al., 2016) or to different propagation conditions of the two day-wave from below in SSW years and no SSW years. A composite shows a peak of the QTDW in NmF_2 in the no SSW years in winter while the peak disappears in SSW winters (not shown in the present study). The synodic period of the Moon (29.53 days) has strong peaks in both FFT spectra. Since the data segment was relatively short (10 weeks), a longer time interval is needed for a better distinction between the spectral peaks of the synodic period of the Moon and the 27 day-solar rotation cycle.

Vokhmyanin et al. (2023) reported that enhanced solar activity leads to a higher occurrence rate of SSWs. Indeed, the SSW years from 1973 to 2023 have an average $F_{10.7}$ index of 122 s.f.u. while the no SSW years have an average value of 111 s.f.u.. This may explain that NmF_2 at Okinawa was increased in the SSW years by 26% compared to the no SSW years (not shown in the present study). A further indication is that there were no SSWs from 1990 to 1997, and a solar minimum occurred in 1994/1995. However, the flat composites of solar or geomagnetic activity in SSW years cannot explain the peak in stratospheric temperature or the peak of the ionospheric semidiurnal amplitude (Figure 4) at the SSW onset time. On the other hand, it is interesting to better understand why the mean state of the ionosphere is different in SSW years compared to no SSW years, correlated changes in ENSO and QBO may also play a role (Vokhmyanin et al., 2023).

3 Conclusions

We find a clear SSW effect in the foF_2 series at Okinawa (Figure 3). In the composite of 29 SSW events, the amplitude of the semidiurnal cycle of foF_2 shows a peak at the SSW onset time in SSW years. This peak is certainly not due to seasonal effects since the peak disappears in the composite of no SSW years. In so far, our analysis method is powerful for a critical assessment and attribution of SSW effects in the highly variable ionosphere. Composites of solar and geomagnetic activity showed no relevant variations at the SSW onset time, but the solar activity was generally higher in the SSW years than in the no SSW years. The composite of the relative NmF_2 variations also shows a significant peak of the semidiurnal amplitude at the SSW onset time in the SSW years (Figure 4).

The evolution of the amplification of the semidiurnal amplitude of the relative NmF_2 variations in winter is shown from 1972 to 2023 (Figure 5). It is evident that the amplification of the semidiurnal amplitude also can occur in no SSW years. Thus, the major SSWs cannot be the sole reason for a sudden amplification of the semidiurnal amplitude in the ionosphere above

Okinawa. Other processes such as minor sudden stratospheric warmings or variability of the mesospheric polar vortex may
230 play a role in the years without major SSWs.

The solar and lunar tidal components at Okinawa are slightly enhanced during SSW years compared to no SSW years
(Figure 6). For the first time, we find a lunar terdiurnal component with a relative amplitude of about 5% in SSW years. The
lunar diurnal and semidiurnal components have relative amplitudes of about 10% in SSW years. The periods of the lunar
ionospheric tidal variations are at the periods of ocean tides. Our study showed that the long-term series of foF2 and NmF2
235 from ionosondes are valuable for learning about ionospheric effects of historical SSWs and the study of lunar tides which are
excited in the ocean-atmosphere system.
