Abstract. While international climate policies now focus on limiting global warming to well below 2 °C, or pursuing 1.5 °C level of global warming, the climate modeling community has not provided an experimental design in which all Earth System Models (ESMs) converge and stabilize at the same prescribed global warming levels. This gap hampers accurate estimations based on comprehensive ESMs of the carbon emission pathways and budgets needed to meet such agreed warming

5 levels, and of the associated climate impacts under temperature stabilization. Here, we apply the Adaptive Emission Reduction Approach (AERA) with ESMs to provide such simulations in which all models converge at 1.5 °C and 2.0 °C warming levels by iteratively adjusting their emissions <u>over time</u>. These emission-driven simulations provide a wide range of emission pathways and resulting atmospheric CO₂ projections for a given warming level, uncovering uncertainty ranges that were previously missing in the traditional CMIP scenarios with prescribed greenhouse gas concentration pathways. Meeting the 1.5 °C warming

- 10 level necessitates requires a 40 % (model full full model range: 7 to 76 %) reduction in multi-model mean CO₂-forcing equivalent (CO₂-fe) emissions from 2025 to 2030, a 98 % (57 to 127 %) reduction from 2025 to 2050, and a stabilization at 1.0 (-1.7 to 2.9) PgC yr⁻¹ from 2100 onward after the 1.5 °C target global warming level is reached. For Meeting the 2.0 °C warming level , emissions require requires a 47 % (8 to 92 %) reduction in multi-model mean CO₂-fe emissions until 2050 and a stabilization at 1.7 (-1.5 to 2.7) PgC yr⁻¹ from 2100 onward. The on-average positive emissions under stabilized global
- 15 temperatures are the result of a decreasing transient climate response to cumulative CO₂-fe emissions over time under stabilized global warming. This evolution is consistent with a slightly negative zero emissions commitment initially assumed zero and leads to an increase in the post-2025 CO₂-fe emission budget by a factor 2.2 (-0.8 to 6.9) by 2150 for the 1.5 °C warming level and a factor 1.4 (0.9 to 2.4) for the 2.0 °C warming level compared to its first estimate in 2025. The median CO₂-only carbon budget by 2150, relative to 2020, is 800 GtCO₂ for the 1.5 °C warming level and 2250 GtCO₂ for the 2.0 °C warming
- 20 level. These median values exceed the median IPCC AR6 estimates by 60% for the 1.5 °C warming level and 67% for 2.0 °C, respectively. Some of the differences may be explained by the choice of the mitigation scenario for non-CO₂ radiative agents. Our simulations highlight shifts in carbon uptake dynamics under stabilized temperature, such as a cessation of the carbon sinks in the North Atlantic and in tropical forests. On the other hand, the Southern Ocean and the northern high-latitude land remain carbon sinks remains a carbon sink over centuries after temperatures stabilize. Overall, this new type of target-based warming
- 25 <u>level-based</u> emission-driven simulations offers a more coherent assessment across climate models and opens up a wide range of possibilities for studying both the carbon cycle and climate impacts, such as extreme events, under climate stabilization.

1 Introduction

Climate goals outlined in international policies, such as the 2015 Paris Agreement (UNFCCC, 2015), primarily focus on global warming targetslevels. The Paris Agreement in particular aims to hold "the increase in the global average temperature to well
below 2°C above pre-industrial levels" and to pursue efforts "to limit the temperature increase to 1.5°C above pre-industrial levels". Global warming levels are chosen in international policies as they are often directly correlated to global and regional impacts of climate change (IPCC, 2018; Seneviratne et al., 2016). Hence, each fraction of avoided warming reduces risks for humans and ecosystems (IPCC, 2022).

The Coupled Model Intercomparison Project (CMIP) provides climate projections of Earth System Models (ESM) for the 21th century and beyond. These projections, however, follow an approach that poses challenges in estimating carbon emission pathways and budgets that are consistent with the goals of the Paris Agreement. In CMIP projections, ESMs have traditionally been driven by prescribed pathways in the concentrations of CO₂ and other radiative agents (O'Neill et al., 2016; Meinshausen et al., 2020), although there is now a push towards more emission-driven scenario designs (Sanderson et al., 2023). For a given greenhouse gas emissions or concentrations trajectory, each ESM simulates different global warming trajectories (e.g., Tebaldi et al., 2021, and see schematic in Fig.1), primarily due to the wide range in climate sensitivity

or and in the transient climate response (e.g. Zelinka et al., 2020; Meehl et al., 2020; Arora et al., 2020). The varying re-

Figure 1. Schematic of the forward vs. backward modelling approach. Black lines indicate the same prescribed variable (emissions for CMIP, global warming level for AERA) in all models. Red lines indicate the resulting range across models in simulated temperature, and the resolved range in emissions in AERA.

sponses of ESMs has have lead to varying estimates for the cumulative CO₂ emissions until a given global warming level is reached (Rogelj et al., 2016; Tokarska et al., 2018). In addition, for the inverse problem, Consequently, it is difficult to estimate the emission pathways that align with stabilizing the climate at specific global warming levels. Instead, the emission pathways and budgets for temperature stabilization were estimated with reduced-form models (Millar et al., 2017), Earth System Models of Intermediate Complexity (Steinacher et al., 2013; Matthews et al., 2017; Goodwin et al., 2018b; Mengis and Matthews, 2020; Matthews et al., 2021), or by the near-linear relationship between anthropogenic global surface warming and cumulative emissions suggested by ESMs (Allen et al., 2009; Matthews et al., 2009; Zickfeld et al., 2009).

50 Numerous studies have confirmed the near-linear response between global temperature increase and cumulative CO_2 emissions, with the slope of this relationship called the Transient Climate Response to Cumulative CO_2 emissions (TCRE). The TCRE has been estimated from observational data (e.g. Millar and Friedlingstein, 2018) and model experiments, and has been

used to estimate the amount of cumulative emissions that could still be emitted before reaching a given global warming target level (Meinshausen et al., 2009; Rogelj et al., 2016, 2019). The amount of cumulative CO_2 emissions up to the point of net zero

- 55 CO₂ emissions is known as the remaining carbon budget (RCB) for a fixed warming level. The RCB from the beginning of year 20232020, for example, has been estimated to be 250-400 GtCO₂ (68-109 PgC) for a 50 % chance of maintaining the global temperature below 1.5 °C of warming, with its uncertainty range being 27 to 136-54 to 204 PgC, for an 83 %-17 % chance (Forster et al., 2023). For the 2.0 °C targetlevel, the RCB ranges from 218 to 545 PgC. 245 to 600 PgC. The uncertainty of the RCB is large due to uncertainties in the TCRE, elimate-carbon feedbacks, climate response to zero emissions, unrepresented
- 60 feedbacks, future warming from non-CO₂ agents (Rogelj et al., 2019), and pathway dependencies (Millar et al., 2017). As the uncertainties in the TCRE, feedbacks, and future warming from non-CO₂ agents will unlikely be significantly reduced in the near future, an iterative and regular update of the RCB is necessary to ensure that the latest scientific understanding is included and to ensure policies can be judiciously implemented to avoid exceeding the given global warming levels. Through an adaptive process aligned with the "pledge and review" mechanism of the Paris Agreement, the RCB and emission pathways
- 65 might be regularly updated at each stocktake period based on the best available science (Otto et al., 2015). The An iterative approach ensures that the emission pathway remains in line with the warming target prescribed warming level and adaptively adjusts to uncertainties in the evolution of the climate response, such as the potential warming or cooling at near-zero CO₂ emissions (Zero Emissions Commitment - ZEC - MacDougall et al., 2020), and the response to mitigation rates in non-CO₂ radiative agents. Such adaptive approaches have been proposed and tested with reduced complexity models running forward
- 70 from present day, and offer promising potential. Goodwin et al. (2018a) introduced the "Adjusting Mitigation Pathways" method using a climate box model. In this approach, the remaining carbon budget to a predefined warming level is estimated by using the near-linear relationship between warming and cumulative carbon emission from a historically forced simulation. Then the remaining budget is distributed in the future and reassessed every ten years. However, limitations, including ideal-ized emission trajectories, disregarding non-CO₂ agents in TCRE and RCB calculations, and challenges in reaching the target
- 75 warming level within the uncertainty range of ± 0.25 °C by 2300, hinder its real-world applicability. Further approaches which do not make use of an adaptive RCB include backwards modelling approaches, like temperature tracking using models of intermediate complexity (EMICs; Matthews and Caldeira (2008); Zickfeld et al. (2009, 2013); Mengis et al. (2018)) or employing impulse-response functions with a simple climate model (Millar et al., 2017) to convert a smooth temperature trajectory into an emission pathway. In contrast, the recently developed Adaptive Emission Reduction Approach (AERA), validated with the
- 80 Bern3D-LPX Earth System Model of Intermediate Complexity (Terhaar et al., 2022a, 2023), offers a less idealized approach and addresses several limitations inherent in previous approaches. AERA-Even though the underlying principles of AERA are similar to the Adjusting Mitigation pathways approach (Goodwin et al., 2018a), AERA provides smoother emission pathways, incorporates non-CO₂ agents, always stabilizes at the warming targets levels within ± 0.2 °C, and can also be applied to run simulations that temporarily overshoot the warming targetlevel. However, as of now, AERA has not yet none of these
- 85 approaches have been implemented in comprehensive fully coupled ESMs.

Here, we implement the AERA introduced by Terhaar et al. (2022a) across a range of fully-coupled CO_2 emission-driven Earth System Models. This new Adaptive Emission Reduction Approach Model Intercomparison Project (AERA-MIP) provides projections that stabilize surface temperature to the same warming level. The AERA-MIP framework enables estimations of the remaining carbon budget, compatible emission pathways, and the ocean and land carbon cycle response to those path-

90 ways within scenarios of stabilized warming levels at 1.5 °C or 2 °C, which we present in this study. Other potential applications of AERA-MIP will be addressed in the Conclusions.

2 Methods

95

The detailed protocol for the simulations of the AERA-MIP is provided in Frölicher et al. (2022). The protocol is a slightly modified version from the method originally proposed of the originally proposed method by Terhaar et al. (2022a). For details, see steps 1 and 3 in section 2.1. The AERA code is distributed as a python module openly available under https://github.

com/Jete90/AERA, with a guided documentation and examples. Below, the protocol is summarized before introducing the participating models, simulations, and carbon stock analysis.

2.1 Adaptive emission reduction approach - AERA

- The goal of the AERA is to quantify successive future trajectories of CO₂-forcing equivalent (CO₂-fe) emissions that stabilize the global surface air temperature (GSAT) at a predetermined level (Terhaar et al., 2022a). The concept of CO₂-fe emissions is used to consider unify the emissions of various radiative forcing agents and precursors using a unified metric into a single metric (Jenkins et al., 2018; Allen et al., 2018; Smith et al., 2021). CO₂-fe emissions of for all non-CO₂ agents represent the quantity of CO₂ emissions that would cause produce the same radiative forcing trajectory as emissions from these non-CO₂ agents (Jenkins et al., 2018; Allen et al., 2018; Smith et al., 2021). Thus, the emissions. While cumulative CO₂
- 105 emissions largely determine anthropogenic warming, non-CO₂ radiative forcing agents such as methane, nitrous oxide and aerosols also play an important role. Quantifying the impact of these non-CO₂ agents on global temperatures is complicated by existing methodologies, which often use conventional Global Warming Potentials or other metrics to convert the non-CO₂ radiative forcing agents into 'CO₂ -equivalent' emissions. The CO₂-fe metric is well-suited emissions framework offers an alternative, well-suited for comparing emissions from different agents in the context of temperature stabilization pathways -
- 110 (Terhaar et al., 2022a). It also offers an opportunity to compare emission reductions of different radiative forcing agents for ecosystem impacts (Terhaar et al., 2023). The CO₂-fe emissions from non-CO₂ agents, *E_{non-CO₂-fe*, are estimated based on the radiative forcing time series of non-CO₂ agents (Smith et al., 2021):}

$$E_{non-CO_2-fe}(t) = \frac{1}{\alpha} \left(\frac{\mathrm{d}F_{non-CO_2-fe}(t)}{\mathrm{d}t} + \rho F_{non-CO_2-fe}(t) \right) \tag{1}$$

where F_{non-CO2} is the radiative forcing of non-CO₂ agents, ρ is the rate of decline in radiative forcing under zero emission
 over decadal to centennial timescales (0.33%), and α is a constant representing the forcing impact of ongoing CO₂ emissions (1.08 Wm⁻² per 1000 GtC). By varying the relative shares of CH₄ and N₂O emissions and radiative forcing from aerosols in the total CO₂-fe emissions, Terhaar et al. (2022a) demonstrated the robustness of the CO₂-fe approach in translating contributions from different radiative forcing agents into CO₂-fe emissions.

AERA achieves the temperature stabilization at a predetermined warming level by estimating future CO₂-fe emissions based on the estimated TCRE-fe (the transient climate response to cumulative CO₂-fe emissions). The TCRE-fe in turn is derived from simulations of past annual GSAT, past fossil fuel and land-use change CO₂ emissions, and CO₂-fe emissions from non-CO₂ forcing agents calculated from their radiative forcing estimates (Jenkins et al., 2021).

The AERA consists of three steps, which are repeated every five years, mirroring the stocktaking mechanism implemented in the Paris Agreement (Terhaar et al., 2022a).

- AERA estimates the anthropogenic warming ΔT from the simulated GSAT time series (relative to 1850-1900). The past anthropogenic warming is here estimated by applying a 31-year running mean with a linear extrapolation for the last 15 years, assuming constant warming rate based on the last 31 years. This is in contrast to the original AERA method, which employs an impulse response function on radiative forcing and temperature estimates to determine anthropogenic warming (Otto et al., 2015). The simple running mean method was applied here as it yields more robust results in cases where the model's radiative forcing is unknown (as is the case for most ESMs), and after reaching the temperature targetlevel.
 - 2. The anthropogenic warming calculated in step 1 is then divided by the cumulative CO₂-fe emissions since 1850 to determine the TCRE-fe. Using this TCRE-fe metric, we compute the amount of CO₂-fe emissions that can still be emitted before reaching the target temperature temperature level. This remaining CO₂-fe emission budget, referred to as REB, is derived by dividing the remaining warming until the temperature target level is reached ($\Delta T_{remaining}$) by the TCRE-fe value:

$$REB = \frac{\Delta T_{remaining}}{TCRE - fe} \tag{2}$$

3. The REB from step 2 is then distributed in the future using a cubic polynomial function. The parameters of the function are chosen to limit an overshoot in temperature and maintain minimal year-to-year changes in CO_2 -fe emissions (see Terhaar et al. (2022a) for details). In contrast to Terhaar et al. (2022a) and to prevent large oscillations in the emissions in the ESMs when the warming levels are reached, we modified the minimum and maximum length (both now variable and depending on the REB and the annual emissions) of the cubic polynomial that distributes the CO_2 -fe emissions over the future years.

2.2 Earth System Models

135

140

- 145 Thirteen models have participated in the AERA-MIP: ten fully coupled Earth System Models (ACCESS-ESM1-5, CESM2, EC-Earth3-CC, NASA-GISS-E2-1-G-CC, GFDL-ESM2M, GFDL-ESM4, IPSL-CM6-LR-ESMCO2, MIROC-ES2L, MPI-ESM1-2-LR and NorESM2-LM), two models of intermediate complexity (Bern3D-LPX and UVic-ESCM-2.10), and one atmosphere-ocean general circulation model coupled to a carbon cycle emulator (HadCM3-FaIR2, see Appendix A for a description of the configuration). Nine of the fully-coupled ESMs have participated in the sixth phase of the coupled model intercomparison
- 150 project (CMIP6), and GFDL-ESM2M has participated in CMIP5. Table A1 lists the models, their abbreviation used in this

6

paper, as well as the corresponding references, the simulated time period and the number of ensemble members. A summary of their components has been already provided in several multi-ESM studies (e.g., Séférian et al., 2020; MacDougall et al., 2020; Arora et al., 2020; Canadell et al., 2021).

Small initial condition ensembles were provided by two participating ESMs to estimate the uncertainty associated with 155 internal variability (Table A1). EC-Earth provided a three-member and GFDL-ESM2M a five-member ensemble. Ideally, larger ensemble simulations for every ESM would have been more ensemble members are necessary to properly quantify the internal variability of each model (Lehner et al., 2020). However, even the small number of ensemble members available here provide a first-order estimate of internal variability.

The ACCESS-ESM1-5 is the only model that does not converge to the target before 2200. model is somewhat an outlier.

- 160 It also converges to both prescribed temperature levels, but substantially later than all other models. The model most likely does not converge converges later due to a strong mismatch between the estimate of non-CO₂ radiative forcing used in the AERA to estimate CO_2 -fe emissions (from the RCP/SSP database, see below) and the non-CO₂ radiative forcing simulated in the model based on the prescribed atmospheric non-CO₂ radiative agents. Hence, results from ACCESS were excluded from subsequent multi-model statistics but are still shown for transparency in Fig. 2. However, the inclusion of the ACCESS model
- 165 in the ensemble modifies our results only slightly (Fig. B1).

2.3 Simulations

The simulations of the AERA-MIP are performed until at least 2150 (except for HadCM3-FaIR2 until 2100) and up to 2300 to allow for enough time to reach the temperature target level and stabilize global surface warming (Table A1). Simulations have been conducted for both the 1.5 °C and 2.0 °C temperature targets levels. To remove biases in simulated warming over

- 170 the historical period relative to observations, we use the concept of a relative temperature target level (Millar et al., 2017; Goodwin et al., 2018a; Terhaar et al., 2022a). Under this concept, the remaining allowable warming in 2020 is first estimated from observations. In a second step, the AERA adds this observation-based remaining allowable warming to the models' anthropogenic warming in 2020 to calculate the absolute temperature target level in each model (see Frölicher et al., 2022a). (see Frölicher et al., 2022a). Thus, each model estimates the emission trajectory for the same remaining
- 175 allowable warming in 2020, which is here estimated to be 0.28 °C for the 1.5 °C target_warming level and 0.78 °C for the 2.0 °C targetlevel. These values were derived from the observation-based estimated warming of 1.22 °C in 2020 (Terhaar et al., 2022a). Each initial condition ensemble member has its own anthropogenic temperature in year 2020, resulting in very small differences in absolute temperatures for that year (maximum differences across GFDL ESM2M ensemble members of 0.067°C).
- All-Following a similar simulation strategy as in Terhaar et al. (2022a), all simulations branch off an emission-driven simulation (*esm-hist*) over the historical period following the CMIP6 protocol. After the end of the CMIP6 historical period in 2014, fossil fuel CO₂ emissions follow observed emissions until 2020 (Friedlingstein et al., 2020; Le Quéré et al., 2021) and projected emissions from the Nationally Determined Contributions (NDCs; Climate Action Tracker: https://climateactiontracker.org/global/temperatures/, last accessed December 2021) from 2021 to 2025. Starting at the end of year 2025, fossil-fuel CO₂

- 185 emissions prescribed to the model are obtained every five years from AERA (see below and schematic in Fig. B2) by subtracting CO₂-fe emissions from prescribed non-CO₂ radiative agents and land use land cover change from the AERA-derived total CO₂-fe emission curve. Non-CO₂ agents as well as land use and land cover change are prescribed as in the SSP1-2.6 scenario after 2015. This low emission high mitigation scenario is often used in related climate stabilization approaches (e.g. Millar et al. (2017); Mengis et al. (2018)). An exception is the CMIP5-type GFDL-ESM2M which follows the CMIP5 protocol for the his-
- 190 torical period as well as the RCP2.6 scenario instead of the SSP1-2.6 scenario for the non- CO_2 forcing agents and land use and land cover change. After 2100, no further changes occur in non- CO_2 forcing agents, land use and land cover. A schematic is provided in Fig. B2, summarising the feedback loop between the AERA module and the ESM during the post-2025 period of the simulations.
- As the AERA calculates the total CO₂-fe emissions, it requires information about emissions from non-CO₂ forcing agents 195 (E_{non-CO_2-fe}) and CO₂ emissions from land use and land cover change (E_{LUC} ; referred to as land use change emissions for simplicity from now on) to estimate the past TCRE-fe, on top of the past fossil fuel CO₂ emissions (E_{FOS}). Moreover, the future E_{FOS} prescribed to the model after each stocktake are calculated as the difference between the CO₂-fe emission curve ($E_{total-fe}$) from Step 3 of AERA, and the estimated future CO₂-fe emissions from land use change and non-CO₂ forcing agents:

$$200 \quad E_{FOS} = E_{total-fe} - E_{LUC} - E_{non-CO_2-fe} \tag{3}$$

As most models do not directly output the radiative forcing of non-CO₂ agents (required to derive E_{non-CO_2-fe}), we estimate this time series from the radiative forcing given by the RCP/SSP database for both the historical period and SSP1-2.6 scenario. Some models, however, have provided an estimate of the simulated effective radiative forcing for all non-CO₂ radiative agents (see Table A2, and Fig. ??4d). For these models, the internally calculated effective radiative forcing estimates were used to derive the CO₂-fe emissions from the non-CO₂ forcing agents (Smith et al., 2021). Similarly, some models (see Table A2 and Fig. A1a4c) have conducted additional simulations to estimate E_{LUC} (Lawrence et al., 2016; Liddicoat et al., 2021). In that case, the model-specific E_{LUC} is prescribed to AERA instead of the default E_{LUC} estimate stemming from the Bern3D-LPX model that was scaled to align with the Global Carbon Budget estimates from 1850 to 2020. The default E_{non-CO_2-fe} and E_{LUC} time series as well as the model-specific emissions for those who were able to estimate them are shown in Figs. ?? and

210 A1a4 and A1.

205

Although the future E_{LUC} and E_{non-CO_2-fe} are prescribed in AERA to enable the extraction of future E_{FOS} as input to the models (Fig. B2), the future CO₂-fe emission curve $E_{total-fe}$ is largely insensitive to the chosen land use and non-CO₂ forcings (see tests in Terhaar et al. (2022a)).

Further details on the configuration of the AERA simulations in the models are provided in Appendix A.

215 2.4 Remaining emission budget over time

While the TCRE is commonly considered approximately constant, recent studies suggest a potential variability in TCRE when CO₂ emissions are reduced, owing partly to a non-zero ZEC (Frölicher and Paynter, 2015; Steinacher and Joos, 2016; Nicholls

et al., 2020; MacDougall et al., 2020). This indicates that the REB originally estimated at the end of 2025 may evolve over time, with the additional effect of potential non-linearities in the response of non- CO_2 forcing agents. To illustrate the temporal

evolution of the REB from a fixed starting point, we reconstruct the CO₂-fe emission budget from beginning of year 2026 (EB_{2026}) at each stocktake by summing the REB (i.e. all future emissions) calculated at the end of the stocktake year (t_{st}) and the already emitted CO₂-fe emissions between 2026 and that year:

$$EB_{2026}(t_{st}) = REB(t_{st}) + \int_{2026}^{t_{st}} E_{total-fe}(t)dt$$
(4)

 $EB_{2026}(2025)$ is by definition REB(2025).

225 2.5 Distribution of carbon in the Earth System

Within individual ESMs, all sources and sinks of the carbon mass balance are known and we can write:

$$E_{FOS} = G_{ATM} + S_{OCEAN} + (S_{LAND} - E_{LUC}) \tag{5}$$

 E_{FOS} are the prescribed global fossil fuel CO₂ emissions during the historical period and calculated by AERA post 2025. G_{ATM} indicates the simulated atmospheric CO₂ growth rate in PgC yr⁻¹ by using the conversion factor of 2.123 PgC ppm⁻¹

230 (Enting et al., 1994). S_{OCEAN} is the net ocean carbon sink derived from the CO₂ flux into the ocean (CMIP6 variable *fgco2*). S_{LAND} - E_{LUC} denotes the net CO₂ flux into land and is derived from the net biosphere production (CMIP6 variable *nbp*). It The net biosphere production includes the gross land carbon sink S_{LAND} minus emissions from land use and land cover change, E_{LUC} .

For the eight models that estimate their E_{LUC} term, we can quantify the gross land carbon sink S_{LAND} (Figure A1 and 235 Appendix A), by adding the two diagnostics $nbp + E_{LUC}$. Thus, by rearranging Equation 5, we can separate net sources and sinks of CO₂:

$$E_{FOS} + E_{LUC} = G_{ATM} + S_{OCEAN} + S_{LAND} \tag{6}$$

As opposed to earlier studies (Liddicoat et al., 2021; Koven et al., 2022), atmospheric CO₂ is freely evolving and not prescribed, whereas E_{FOS} is prescribed and does not need to be diagnosed.

From Equation 6, we derive the cumulative airborne ($CAFC_{AE}$), ocean-borne fraction ($COFC_{OE}$) and land-borne fraction (CLF): C_{LE}):

$$\underline{CAF}_{CAF}(t) = \frac{\int G_{ATM}}{\int (G_{ATM} + S_{OCEAN} + S_{LAND})} \frac{\int G_{ATM}(t)dt}{\int (G_{ATM}(t) + S_{OCEAN}(t) + S_{LAND}(t))dt}$$
(7)

$$\underline{COFC_{OF}(t)} = \frac{\int S_{OCEAN}}{\int (G_{ATM} + S_{OCEAN} + S_{LAND})} \frac{\int S_{OCEAN}(t)dt}{\int (G_{ATM}(t) + S_{OCEAN}(t) + S_{LAND})(t))dt}$$
(8)

$$\underline{CLF}\underline{C_{LF}(t)} = \frac{\int S_{LAND}}{\int (G_{ATM} + S_{OCEAN} + S_{LAND})} \frac{\int S_{LAND}(t)dt}{\int (G_{ATM}(t) + S_{OCEAN}(t) + S_{LAND})(t))dt}$$

with the \int sign representing the time integral from 1850. Here we use $G_{ATM} + S_{OCEAN} + S_{LAND}$ instead of $E_{FOS} + E_{LUC}$ as the denominator of the cumulative fractions to avoid minor budget closure errors. These errors are negligible in most models, represent maximum a few percents (not shown), in which case they are very likely due to missing diagnostics.

(9)

250

245

For some models, the E_{LUC} term prescribed to AERA was either the default estimate from the adjusted Bern3D-LPX time series, or presented some errors. In the carbon stock analysis, we corrected these terms (see Appendix A).

3 Temperature, CO₂-fe emission and atmospheric CO₂ pathways

3.1 Convergence towards the prescribed temperature targetlevel

The AERA effectively stabilizes the simulated GSAT around the target in ESMs around the prescribed warming level within
an uncertainty of ±0.2 °C (Fig. 2a,b). The uncertainty of ±0.2 °C corresponds to the uncertainty with which anthropogenic warming can be determined from observations (Haustein et al., 2017; Jenkins et al., 2022a). Only the The IPSL model temporarily leaves the 1.5 °C uncertainty rangeand MIROC very shortly °C uncertainty range, and MIROC briefly leaves the 2.0 °C °C uncertainty range. In the 1.5 °C simulation(Fig. 2a)°C simulation, the multi-model mean GSAT anomaly (black thick line) enters the target temperature enters the warming level uncertainty range in 2026, i.e., the year when the first AERA period begins . The temperature (black thick line in Fig. 2a). The temperature anomaly first peaks at 1.43 °C in 2043 (min-max model range: 1.20 °C to 1.57 °C), temporarily drops to 1.40 °C (1.23 °C to 1.50 °C) in 2069, and stabilizes around 1.44 °C (1.25 °C to 1.64 °C) between 2100 and 2150. In the 2.0 °C simulation (Fig. 2b), the multi-model mean GSAT anomaly enters the uncertainty envelope in 2061, and stabilizes at around 1.90 °C (1.77 °C to 2.09 °C) between 2100 and 2150.

The convergence to the temperature target level here shows that the AERA approach works for both intermediate complexity models, as shown previously (Terhaar et al., 2022a), as well as for fully-coupled ESMs. This is the case despite differences in E_{LUC} and E_{non-CO_2-fe} prescribed to the AERA framework and in the models themselves. An exception is the ACCESS model that only converges to the respective targets warming level by the late 22nd century after an overshoot of 0.3-0.5 °C (larger overshoot for the 1.5 °C targetwarming level; see Methods for more details).

3.2 Compatible CO₂-fe emission pathways

For the 1.5 °C warming targetlevel, CO₂-fe emissions decrease strongly and immediately after 2025 for all models, albeit with a large inter-model spread (Fig. 2c; Table 1). By 2030, CO₂-fe emissions drop to 8.1 (min-max range: 3.1 to 11.9) PgC yr⁻¹, a 40 % (7 % to 76 %) decline compared to 2025 levels of 13.7 (11.0 to 18.9) PgC yr⁻¹. During this strong decline phase, CO₂-fe emissions reach a maximum reduction of -2.0 (-0.4 to -3.6) PgC yr⁻². Afterwards, the emissions reach a temporary minimum at nearly zero in 2050 (0.2 PgC yr⁻¹; range: -3.6 to 5.0 PgC yr⁻¹), corresponding to a 98 % (57 % to 127 %) decline

Figure 2. Simulated temperature anomaly and CO₂-fe emissions for the 1.5 °C and 2.0 °C warming levels. Panels a) and b) display the 31-year running mean of the global surface air temperature (GSAT) anomaly, aligned with the observed value in 2020. Panels c) and d) illustrate CO₂-fe emissions. The multi-model mean, excluding the ACCESS model, is displayed by the black thick line, with the grey shading indicating the min-max spread. The ensemble mean is shown for models that have several ensemble members. The vertical dotted line at year 2026 marks the beginning of the AERA simulations. The horizontal shading in (a) and (b) indicates the uncertainty with which anthropogenic warming can be determined (\pm 0.2 °C).

275 from 2025 levels, before peaking at 1.9 (-0.2 to 4.2) PgC yr⁻¹ in 2077. This bounce in the CO₂-fe emission curve could be explained by the very rapid mitigation of non-CO₂ forcing agents in the early decades of the SSP1-2.6 scenario, causing slightly negative forcing-equivalent emissions approximately from 2030 to 2100 (*E_{non-CO₂-fe*, see Fig. ??4d). Because this decline in *E_{non-CO₂-fe* is not accounted for in the first estimate of the REB at the end of year 2025, the emission budget is re-evaluated and increases in the stocktake years around 2050 relative to its 2025 estimate (Fig. 5a), leading to the on-average increase in emissions between 2050 and 2077. Subsequently, CO₂-fe emissions decrease again to 1.0 (-1.7 to 2.9) PgC}}

 yr^{-1} between 2100 and 2150 when global mean temperatures have been stabilized. Until the end of the 22nd century, CO₂fe emissions remain slightly positive on average. The positive emissions <u>but and</u> large model spread during the temperature stabilization phase are consistent with the overall negative but highly uncertain multi-decade zero emissions commitment (i.e., global surface temperature change after setting temperature response after zero CO₂ emissions to zero and keeping emissions

285 at zero thereafter) highlighted by MacDougall et al. (2020) and Jenkins et al. (2022b) across a range of EMICs and ESMs (MacDougall et al., 2020; Jenkins et al., 2022b). In 4 out of 13 models (GFDL-ESM4, IPSL, MPI, UVic), negative CO₂-fe emissions are not necessary to stabilize at the 1.5 °C warming level.

Achieving the 2.0 °C target-warming level also requires strong CO₂-fe emission reductions, albeit less drastic than for the 1.5 °C targetlevel. By 2030, multi-model mean CO₂-fe emissions decrease to 13.0 (10.9 to 17.1) PgC yr⁻¹, a 5.2 % (-1 % to 16 %)

- 290 reduction from 2025 levels. By 2050, they further drop to 7.2 (1.3 to 11.4) PgC yr⁻¹, a 47 % (8 % to 92 %) decrease compared to 2025, and stabilize at 1.7 (range: -1.5 to 2.7) PgC yr⁻¹ between 2100 and 2150. The maximum reduction rate between 2026 and 2100 is -0.7 (range: -2.3 to -0.1) PgC yr⁻². Only two models, EC-Earth and CESM2, exhibit temporary negative CO₂-fe emissions before 2150.
- Several models simulate decadal-scale oscillations in emissions trajectories after reaching the temperature targetsprescribed temperature level. These fluctuations partly stem from the challenge faced by AERA's anthropogenic warming estimation, utilizing an extended 31-year running mean, in distinguishing entirely between multi-decadal internal variability and anthropogenic trends in atmospheric temperature. In particular in NorESM2, large multi-decadal temperature variations due to Atlantic Meridional Overturning Circulation (AMOC) decline and subsequent recovery have been shown to occur when emissions are phased out (Schwinger et al., 2022). However, these oscillations lead to temperature fluctuations that remain within the ±
- 300 0.2°C range around the temperature targetlevel, except for a small undershoot simulated in the IPSL model, which takes a few decades to recover towards the warming targetlevel. This slow evolution of GSAT could be partly related to the large low-frequency internal variability exhibited in this model (Bonnet et al., 2021).

Beyond 2200, a time period for which only three models provide results, CO_2 -fe emissions necessary for maintaining temperature stabilization are still projected to evolve slightly. For example, GFDL-ESM2M shows a slower reduction in CO_2 -

- 305 fe emissions during the 21^{st} century compared to other models due to its low TCRE and a negative temperature response to zero emissions on decadal timescales. However, by the mid- 22^{nd} to 23^{rd} century, CO₂-fe emissions in this model become slightly negative and will remain so for several centuries in response to a time-varying ZEC and continued warming in this model on multi-centennial timescales under zero emissions (Frölicher et al., 2014; Frölicher and Paynter, 2015). On the other hand, the Bern and MIROC models simulate continuous (albeit small) positive emissions on these timescales, reflecting continued
- 310 cooling in these models under zero CO_2 emissions (negative ZEC) on multi-centennial timescales (MacDougall et al., 2020). This time dependency of the ZEC response following a period of CO_2 emissions erodes the value of the remaining budget concept as a fixed estimate beyond the first several decades around net zero.

The simulated uncertainty range in CO_2 -fe emission pathways across the models is not solely caused by model differences but also by internal variability (as diagnosed by the range across individual ensemble members of one model; Table 1, Figs.

315 3b and B3b). The internal variability uncertainty range diagnosed here represents a lower bound of the true internal variability

Figure 3. Comparison between model uncertainty and a lower bound for internal variability uncertainty in simulated temperature, CO_2 -fe emissions and atmospheric CO_2 pathways for the 2.0 °C warming level. Similar to Fig. 2b,d, but the panels show the multi-model min-max range in grey, and the inter-member min-max range of EC-Earth (3 members) in yellow and GFDL-ESM2M (5 members) in blue. The inter-member ensemble ranges are centered on the multi-model mean. For the 1.5 °C warming level, refer to Fig. B3.

uncertainty from ESMs as only a few ensemble members are available. Across the 3 ensemble members of EC-Earth and 5 ensemble members of GFDL-ESM2M, the min-max range in CO₂-fe emissions in 2050 is 3.9 PgC yr⁻¹ for the 1.5 °C target level and 0.7 PgC yr⁻¹ for the 2.0 °C target level, corresponding to 45 % and 7 % of the multi-model range, respectively. These numbers rise to 66 % and 53 % between 2100 and 2150, respectively. The EC-Earth 3-member ensemble represents 33 % and 53 % of the multi-model range CO₂-fe emissions in 2050 for the 1.5 °C and 2.0 °C levels, and respectively 34 % and 29% between 2100 and 2150. The inter-member spread decreases during the temperature stabilization period. For example, in the 2.0 °C target warming level ensemble by GFDL-ESM2M, the inter-member range decreases from 2.7 PgC yr⁻¹ in 2100-2150 to 1.1 PgC yr⁻¹ in 2250-2300 (Fig. B33b). As for the maximum reduction rate in CO₂-fe emissions between 2026 and 2100, the GFDL-ESM2M ensemble members range from -1.3 to -0.1 PgC yr⁻² for the 2.0 °C target warming level, corresponding to

325 56 % of the spread across all models.

320

3.3 Emissions from fossil fuel, non-CO₂ agents and land use change

3.4 Fossil fuel emissions

Fossil fuel emissions (E_{FOS} , see Equation 3) closely track the evolution of the CO₂-fe curve (Fig. 2e,f4a,b). In the 1.5 °C scenario, the multi-model mean emissions remain slightly positive throughout the simulation, reaching a minimum in 2046 of

330 0.9 (-2.7 to 6.6) PgC yr⁻¹, peaking in 2069 at 1.7 (-1.0 to 5.4) PgC yr⁻¹, and gradually declining towards zero by the end of the 22nd century. Although the multi-model mean suggests that E_{FOS} can remain positive if emission reductions are fast and strong, negative emissions may still be necessary as five models simulate negative E_{FOS} , reaching -4.5 to -1.6 PgC yr⁻¹ before 2050.

Table 1. Simulated CO ₂ -fe emissions in 2025, 2030, 2050 and averaged between 2100-2150 in the 1.5 °C and 2.0 °C warming level simulations. The last column
indicates the minimum of the derivative of the CO2-fe curve, between 2026 and 2100. For models that performed several ensemble members, the ensemble mean is
ndicated, as well as the minimum to maximum range in the brackets.

Multi-model mean	13.7	8.1	13.0	0.2	7.2	1.0	1.7	-2.0	- 0.7
Multi-model range	(11.0 to 18.9)	(3.1 to 11.9)	(10.9 to 17.1)	(-3.6 to 5.0)	(1.3 to 11.4)	(-1.7 to 2.9)	(-1.5 to 2.7)	(-3.6 to -0.4)	(-2.3 to -0.1)

In the 2.0 °C simulation, the multi-model mean reaches 8.2 (1.4 to 11.9) PgC yr⁻¹ in 2050, stabilizes at 1.3 (-1.7 to 3.2) PgC yr⁻¹ between 2100 and 2150, and slightly declines thereafter. In this scenario, only two models (CESM2 and EC-Earth) simulate non-negligible negative fossil fuel emissions before 2150, reaching -1.5 to -2.0 PgC yr⁻¹. A temporary increase in

335

 E_{FOS} occurs post 2025 in the 2.0 °C simulation due to rapid reductions in non-CO₂ emissions (E_{non-CO_2-fe}) as prescribed in the SSP1-2.6 scenario (Fig. **??**4d).

The prescribed CO₂-fe emissions from non-CO₂ agents based on SSP1-2.6 (Fig. 4d; colored lines for models that were able

- 340 to estimate their internal radiative forcing; black line for the others; see Methods) exhibit a rapid decrease after year 2026, reaching maximum negative emissions around year 2054 of -1.4 PgC yr⁻¹ and stabilizing at slightly positive levels of 0.2 PgC yr⁻¹ after 2100 for the default prescribed emissions (black line). The simulated CO₂ emissions based on prescribed land use change from SSP1-2.6 (Fig. 4c) generally remain slightly positive throughout the 21st century, except in the NASA-GISS, EC-Earth and ACCESS models, where they are temporarily negative. Post-2100, the land-use change CO₂ emissions prescribed
- to AERA stabilize around zero, consistent with the constant land use area forcing. For the UVic and MPI simulations, the values prescribed to AERA post-2100 in *E_{LUC}* were kept positive and constant, although this does not correspond to the land use forcing. These time series were corrected in the remaining emissions budgets reported in Section 4 and in the carbon stock analysis of Section 6 (see Appendix A). Both the non-CO₂ and the land-use change CO₂-fe emissions, follow identical trajectories for the 1.5 °C and 2.0 °C global warming level simulations, as they follow the SSP1-2.6 scenario for both warming levels.

The simulated model-specific CO_2 emissions from land use change and CO_2 -fe emissions from non- CO_2 agents are not available as output from all models. Nevertheless, negative CO_2 -fe emissions from non- CO_2 radiative forcing agents are only possible if the radiative forcing from these agents is decreasing. However, the radiative forcing agents follow the SSP1-2.6 or RCP2.6 scenario and after 2100 they are set to constant values for all models suggesting that substantial negative non- CO_2

- 355 radiative forcing is unlikely post-2100. In addition, land use area is also set to be constant after 2100. Considering that CO₂ emissions from both land use change and non-CO₂ agents are likely to be zero or slightly above zero after temperature stabilization, it is reasonable to conclude that the positive CO₂-fe and fossil fuel CO₂ emissions after stabilizing warming are more likely a consequence of the overall negative zero emissions commitment rather than net negative forcing from non-CO₂ forcing or from land use change.
- 360 The uncertainty across models found here in residual emissions fossil fuel emissions (Fig. 4a,b) compatible with temperature stabilization appears to be in agreement with the results from Jenkins et al. (2022b), who diagnosed compatible emissions with halting warming after 1pctCO2 and 1.5°C-compatible CO₂ emission-driven experiments. They calculate these emissions based on a theoretical framework (defining the RAZE parameter rate of adjustment to zero emissions), results from the ZECMIP simulations, and a climate emulator. In their scenario in which non-CO₂ forcing agents follow SSP1-1.9 and CO₂ emissions
 365 linearly decrease to zero between 2021 and 2050, the best estimate of CO₂ emissions compatible with halting warming after
- 2050 is given at 0.66 PgC yr⁻¹ (2.2 GtCO₂ yr⁻¹), with a 5th-95th percentile range of -2.2 to 1.9 PgC yr⁻¹. In their formulation of the multi-decade ZEC response, this equates to a small negative RAZE parameter whose uncertainty spans zero. On the other hand, Mengis et al. (2018) find that net negative fossil fuel CO₂ emissions are necessary to stabilize global surface temperature

at 1.5 °C in an observation-constrained carbon cycle perturbed-parameter ensemble of the UVic model. In their study, they

used RCP2.6 non- CO_2 forcing extended to the year 2200, which in total causes positive radiative forcing between the first time the temperature is reached in 2055, and the period of stabilisation until 2200. They discuss that this is a likely cause for the net-negative CO_2 emissions.

3.4 Consequences for atmospheric CO₂

Since the simulations are CO₂ emission-driven, atmospheric CO₂ evolves dynamically (Fig. 2g,h4e,f). The multi-model mean
atmospheric CO₂ reaches 420 ppm in 2020, slightly higher than the observed 412 ppm (Lan et al., 2023). In both temperature target stabilization simulations, the multi-model mean exhibits a peak and subsequent decline behavior. Atmospheric CO₂ peaks at 438 ppm in 2031 for the 1.5 °C scenario and at 499 ppm in 2070 for the 2.0 °C scenario, subsequently decreasing to 410 ppm in the 1.5 °C scenario and to 480 ppm in the 2.0 °C scenario by 2150. Thus, atmospheric CO₂ should start to decrease around 2030 to reach the 1.5 °C targetlevel, according to the multi-model mean. Some models do not simulate such a smooth peak and decline behavior, and simulate in addition a (temporary) rise in atmospheric CO₂ due to a temporary rise in CO₂ emissions during or after the decline -(Fig. 4a).

The different CO₂ emissions and the strength of the land and ocean carbon sinks lead to large differences in atmospheric CO₂. The model min-max range in atmospheric CO₂ of 53 ppm in <u>year</u> 2025 originates from different ocean and land carbon sinks and E_{LUC} emissions during the historical period (Hoffman et al., 2014) as all models have identical prescribed E_{FOS}

- 385 fossil fuel CO₂ emissions (Fig. 2e4a,b; note HadCM3-FaIR2 differs due to the emissions being diagnosed and not prescribed, see Appendix A). After year 2025, the spread in atmospheric CO₂ is also driven by the divergent E_{FOS} pathways and thus strongly increases, as E_{FOS} evolves also with the model-dependent AERA calculation every five years. The model min-max range expands to 105 ppm (1.5 °C simulation) and 55 ppm (2.0 °C) by year 2050, 125 ppm (1.5 °C) and 139 ppm (2.0 °C) by year 2100, and 123 ppm (1.5 °C) and 141 ppm (2.0 °C) by year 2150.
- ³⁹⁰ Part of these large uncertainties may stem from internal variability (Fig. 3c and B3c). GFDL-ESM2M's 5 ensemble members show a min-max range of 54 ppm (1.5 °C) and 49 ppm (2.0 °C) by 2100, approximately 43 % and 40 %, respectively, of the multi-model range. EC-Earth's 3 ensemble members represent 29 % and 27 % of the model range in 2100. GFDL-ESM2M's range tends to decrease over the 23rd century, reaching 24 ppm (1.5 °C) and 41 ppm (2.0 °C) by 2300. Sensitivity simulations with the Bern model, covering the IPCC AR6 likely range of TCRE, exhibit an inter-member spread in atmospheric CO₂
- 395 levels that is as large as the inter-model spread, persisting during stabilization (not shown). Thus, while internal variability certainly plays an important role by 2100, differences in TCRE among the models remain the primary driver for the substantial model uncertainties in simulated atmospheric CO₂. Additional processes may be at play in explaining the model spread, not explained by differences in TCRE, such as the sensitivity to evolving non-CO₂ agents and the representation of land use land cover changes in the models. For example, the MIROC model has a low TCRE and negative ZEC (MacDougall et al., 2020),
- 400 and yet it exhibits the lowest levels of atmospheric CO₂ already at the end of the historical period (Fig. $\frac{2g,h4e,f}{2g,h4e,f}$).

Figure 4. Simulated fossil fuel CO_2 emissions, emissions from land use change and non- CO_2 forcing agents, and atmospheric CO_2 . The multi-model mean, excluding the ACCESS model, is displayed by the black thick line, with the grey shading indicating the min-max spread. The ensemble mean is shown for models that have several ensemble members. The vertical dotted line at the year 2026 marks the beginning of the AERA simulations. In panels c and d, the black line shows the default AERA input for both warming levels, whereas the colored lines show the diagnosed land-use change or non- CO_2 forcing equivalent emissions for models that do not use AERA default values. The (c) non- CO_2 and the (d) land-use change CO_2 -fe emissions follow identical trajectories for both warming levels.

4 The remaining emission budget from 2020 to 2150

The AERA simulations provide actual emissions data both during the period of model stabilization to the prescribed warming level and beyond. We compare these numbers with the remaining carbon budget (RCB) estimates from the IPCC AR6 Working Group I (WGI; IPCC (2021)). For consistency with IPCC data, we convert our results from GtC into GtCO₂, and round up the

- 405 numbers to the nearest 50 GtCO₂. For the 1.5 °C warming level, our median estimate of cumulative total CO₂-fe emissions between 2020 and 2150 is 900 GtCO₂, with a 17th-83rd percentile model range of 450 to 1800 GtCO₂ (Table 4). This includes 700 (250 to 1450) GtCO₂ from fossil fuel CO₂, 150 (50 to 300) GtCO₂ from land use changes, and 10 (-10 to 20) GtCO₂ from non-CO₂ forcing agents. Note the sum of the individual median estimates are not exactly equal to the total CO₂-fe emissions because the median is not linear, and because of rounding. The CO₂ only budget from both fossil fuel and land use change
- 410 emissions is 800 (250 to 1800) GtCO₂. In comparison, the IPCC AR6 WGI estimate of the remaining carbon budget (CO₂ only) from year 2020 is 500 (300 to 900) GtCO₂ for a 50 % (83 to 17 %) likelihood of limiting global warming to 1.5 °C. The methodological update from Forster et al. (2024) slightly lowers the budget to 400 (200 to 750) GtCO₂ (Table 2). Our new median remaining carbon budget (CO₂ only) estimate from year 2020 for the 1.5 °C warming level is therefore 60 % larger than the median IPCC AR6 estimate.
- For the 2.0 °C warming level, the AERA simulations estimate median $(17^{th}-83^{rd} \text{ percentile range})$ total CO₂-fe emissions between 2020 and 2150 at 2150 (1600 to 2900) GtCO₂. 2050 (1350 to 2600) GtCO₂ is from fossil fuels, 150 (50 to 300) GtCO₂ from land use changes, and 10 (-10 to 20) GtCO₂ from non-CO₂ forcing agents (note the land use change and non-CO₂ emissions are not warming level dependant in the AERA protocol). This gives a total CO₂-only budget of 2250 (1350 to 2900) GtCO₂, compared to 1350 (900 to 2350) GtCO₂ from the IPCC AR6 RCB, and 1300 (900 to 2200) from Forster et al. (2024).
- 420 Our new median remaining carbon budget (CO_2 only) estimate from year 2020 for the 2.0 °C warming level is therefore 67 % larger than the median IPCC AR6 estimate.

The AERA simulations show larger CO_2 emission budgets for both 1.5 °C and 2.0 °C warming levels compared to the IPCC AR6 RCBs, although the large model range encompasses the uncertainty distribution from AR6. The methodologies are different and part of that gap could be due to the choice of non-CO₂ scenario. In the AERA simulations, the remaining

- 425 total CO₂-fe emission budget calculated in step 2 of the AERA is independent of the future pathway of non-CO₂ forcing agents. Nonetheless, the partition between future CO₂ and non-CO₂ emissions is scenario-dependent, with a very small amount distributed to non-CO₂ emissions here (median estimate of 10 GtCO₂), constrained by the SSP1-2.6 scenario in our modelling protocol. Similarly, the AR6 estimate is also scenario-dependent regarding future additional non-CO₂ warming until net-zero CO₂ emissions. The median estimate for this non-CO₂ warming is 0.1-0.2 °C (Canadell et al., 2021), corresponding to 220-440
- 430 GtCO₂ following the median TCRE, much more than our median estimate of 10 GtCO₂. The scenario uncertainty in the AR6 estimate represents variations of at least ± 220 GtCO₂. Thus, when adding up CO₂ and non-CO₂ contributions (although estimated using different approaches), the median 1.5 °C remaining emission budget is in fact very similar between the AR6 estimate and the AERA simulations (around 800 GtCO₂). This does not hold for the 2.0 °C remaining emission budget, which is still larger in the AERA simulations, even when accounting for the differences in non-CO₂ emission budget.

Table 2. Estimates of the remaining emission budget for 1.5 °C and 2.0 °C warming levels, considering the AERA-MIP simulations from the beginning of year 2020 until the end of year 2150. Reported here is the multi-model median, as well as the 17^{th} - 83^{rd} percentile model range in the brackets, for each term. The ACCESS and HadCM3 models are excluded from the model statistics (ACCESS simulations do not converge to the given warming level in time, see text; HadCM3 simulations stop in 2100). In this table, we use the default time series prescribed to AERA for E_{LUC} and for E_{non-CO_2-fe} for the models which do not have their own internal estimate (see Methods and Appendix). For a few models, we use the corrected E_{LUC} time series (see Appendix A). All values are given here in GtCO₂ (a factor 3.67 compared to PgC), and rounded to the nearest 50 GtCO₂ (except for E_{non-CO_2-fe} since the range is smaller than 50 GtCO₂), for direct comparison with IPCC AR6 WGI estimates of the remaining carbon budget, as well as the update from Forster et al. (2024). For those two references, the reported numbers correspond to a 50 % (83 % to 17 %) likelihood of limiting global warming to the temperature limit.

	Warming level	Total CO ₂ -fe	FF+LUC CO ₂	FF CO ₂	LUC CO ₂	non-CO ₂
		$E_{FOS} + E_{LUC} + E_{non-CO_2-fe}$	$E_{FOS} + E_{LUC}$	E_{FOS}	E_{LUC}	E_{non-CO_2-fe}

- Another source of difference can stem from the uncertainty in the response to CO_2 emissions. Interestingly, the median TCRE (CO_2 -only) from the models participating in AERA and sampled in Table 2 (1.60 °C / 1000 PgC) is very close to the IPCC AR6 median TCRE estimate (1.65 °C / 1000 PgC), indicating that model sampling bias alone cannot explain the differences. In addition, the RCB calculation in AR6 relies on the assumption that TCRE remains constant over time. The numbers from the AERA simulations provided in Table 2 on the other hand retrospectively count the simulated emissions until
- 440 temperature is stabilized and beyond. This makes AERA a valuable tool for exploring how TCRE and the estimated emission budget evolve as the climate responds to mitigated emissions and temperature stabilization. Next, we explore the evolution of the remaining CO₂-fe emission budget.

5 The evolving remaining emission budget

AERA calculates the simulated remaining CO₂-fe emission budget (REB) every five years based on the remaining allowable warming and the TCRE-fe relationship (see Equation 2 in Methods). At the beginning of year 2026, the start of the AERA period, the multi-model mean REB is 99 (47 to 204) PgC for the 1.5 °C target warming level and 409 (248 to 581) PgC for the 2.0 °C target level (Table 3). These REBs translate to 7 (3 to 14) years of CO₂-fe emissions sustained at mean 2020 levels (14.1 PgC yr⁻¹) for the 1.5 °C target warming level and 29 (18 to 41) years for the 2.0 °C target level before reaching the respective temperature target. Based on the model distribution, the REB from the beginning of year 2026 for a 50 % chance of staying

450 below 1.5 °C is 93 PgC and for staying below 2.0 °C is 412 PgC. For a 66 % chance, the REB decreases to 84 PgC for the 1.5 °C target and to 372 PgC for the 2.0 °C target. level

To compare these model-based estimates to other REB estimates from the beginning of year 2021 (Jenkins et al., 2021; Terhaar et al., 2022), we combine the CO_2 -fe cumulative emissions of 70 PgC on average from 2021 to 2025 with the REB from beginning of year 2026, which yields a mean REB of 169 (113 to 264) PgC from the start of 2021 for the 1.5 °C target warming level and 479 (309)

455 to 640) PgC for the 2.0 °C targetlevel. Our model-estimated REB range encompasses the AERA-based REB calculations from observations of 167 PgC for 1.5 °C and 472 PgC for 2.0 °C (Terhaar et al., 2022a). The model's estimated REB also aligns with observation-constrained estimates by Jenkins et al. (2021) of 128-237 PgC for an 83 %-17 % probability of limiting warming to 1.5 °C (also based on total CO₂-fe emissions).

As the TCRE-fe evolves over time (see Fig. B4), so does the REB (Fig. 5), by definition (the two time series are almost

- 460 perfectly anti-correlated). In our simulations, the multi-model mean REB as estimated at the beginning of year 2026 (EB_{2026}) is smaller than the emissions that are actually emitted until temperature stabilization. Or in other words, the actual EB is larger than the REB estimated at the beginning of 2026 (Table 3). Between 2100 and 2150, the multi-model mean estimate of EB_{2026} (calculated as the sum of the REB in the respective year and the already emitted emissions between 2026 and that year, see Methods for details) reaches 217 (-40 to 475) PgC for 1.5 °C and 552 (297 to 778) PgC for 2.0 °C. These updated emission
- 465 budgets correspond to 15 years (-3 to 34) of sustained mean CO₂-fe emissions at 2020 levels for 1.5 °C and 39 years (21 to 55) for 2.0 °C. Based on the model distribution, this results in a remaining emission budget from beginning of 2026 of 116 PgC (474 PgC) for a 66 % chance of staying below 1.5 °C (2.0 °C). Thus, the simulated remaining emissions until temperature stabilization are 2.2 times larger than estimated at the beginning of 2026 for the 1.5 °C target warming level and 1.4 times larger for 2.0 °C. This increase in the *EB*₂₀₂₆ between the beginning of the AERA period and the end of the simulations
- 470 corresponds to a decrease in the TCRE-fe (Fig. B4), which is qualitatively consistent with a slightly negative multi-decade zero emissions commitment (and RAZE parameter) (MacDougall et al., 2020; Jenkins et al., 2022b) and the resulting residual positive emissions found on average across models during the stabilization phase (Fig. 2). However, this relationship does not hold for all models, pointing to other dominant processes that may be at play, such as the evolution of physical feedbacks, heat uptake by the ocean, carbon uptake by the ocean and land sinks, and the fraction of radiative forcing explained by CO₂
- 475 compared to non-CO₂ agents (e.g. Williams et al., 2017, 2020).

Table 3. Remaining CO₂-fe Emission Budget (REB) from beginning of year 2026, calculated at the first stocktake (end of year 2025; $EB_{2026}(2025)$), and recalculated and averaged between 2100 and 2150, taking into account the emissions actually seen by the models since 2026 ($EB_{2026}(2100-2150)$); see Eq. 4).

Models	REB at fir	st stocktake	EB ₂₀₂₆ average	EB_{2026} averaged between stocktakes 2100-2150		
	$EB_{2026}(2$	025) (PgC)	EB_2	026(2100-2150) (PgC)

Multi-model range	(47 to 20)	(248 to 581)	(-40 to 475)	(297 to 778)		

When summed from 1850 to 2150, the total CO₂-fe emissions amount to 1063 (750 to 1461) PgC for the 1.5 °C target warming level and 1380 (1087 to 1785) PgC for the 2.0 °C target level. The lower end of the multi-model distribution encompasses the estimate of 817 PgC, respectively 1090 PgC found by Mengis and Matthews (2020) under a 1.5 °C and 2.0 °C stabilisation scenario with the UVic model.

480

Similar to residual emissions compatible with temperature stabilization, the spread across models in EB_{2026} and its evolution is very large. For the 1.5 °C target, this range spans from a decrease of a factor of -1.2 to an increase of a factor of 6.9 between 2025 and 2100-2150. The largest decrease in absolute value is simulated by CESM2, for which EB2026 is initially estimated at 100 PgC, but decreases drastically to 6 PgC by 2100-2150 for the 1.5 °C target. The largest increase is simulated by GFDL-ESM4, for which EB2026 is initially 111 PgC but increases sharply to 475 PgC. For the 2 °C target, the factor spans from 0.8 to 2.4.

485

This large range in EB_{2026} reflects the uncertainties in the non-linear evolution of the TCRE, in the response to non-forcing agents but also in, which does not only reflect model differences but also uncertainties due to internal climate variability. The range in EB_{2026} , when estimated at the end of year 2025, across the ensemble members of GFDL-ESM2M, represents 41 % (24 %) of the total model range for the 1.5 °C (2.0 °C) target warming level (Fig. B5). For EC-Earth, the ensemble range

- 490 amounts to 28 % (11 %) of the total model range. These differences in EB_{2026} are predominantly caused by differences in GSAT anomaly across members estimated anthropogenic warming in 2020 due to the difference in internal variability in each ensemble member. If a perfect fit to GSAT for anthropogenic warming existed, which could remove all internal variability, these differences would vanish. This shows how sensitive the emission budget is to the estimate of global warming (Tokarska et al., 2020). When EB_{2026} is re-estimated later in the simulations and averaged between 2100 and 2150, the GFDL-ESM2M
- 495 range is 41 % (44 %) of the model range and the EC-Earth ensemble amounts to 24 % (31 %). The model spread in the change of EB_{2026} over time is also large. For the 1.5 °C warming level, the model range spans from a EB_{2026} decrease by a factor of -1.2 to an increase of a factor of 6.9 between 2025 and 2100-2150. The largest decrease in absolute value is simulated by CESM2, for which EB_{2026} is initially estimated at 100 PgC, but decreases drastically to 6 PgC by 2100-2150 for the 1.5 °C warming level. The largest increase in absolute value is simulated by GFDL-ESM4, for which
- EB_{2026} is initially 111 PgC but increases sharply to 475 PgC. For the 2 °C warming level, the factor spans from 0.8 to 2.4. 500 These differences in the evolution of the emission budget reflect uncertainties in the non-linear evolution of the TCRE-fe, in the response to non-CO₂ forcing agents but also partly in internal climate variability. Within the GFDL-ESM2M 5-member ensemble, the increase in EB_{2026} ranges from a factor 1.2 to 2.4 for the 1.5 °C warming level, and from a factor 1.1 to 1.7 for the 2 °C warming level.
- As the evolution in the remaining emission budget is crucial for achieving goals defined in the Paris Agreementgoals, we 505 here test if this evolution can be explained by standard climate metrics, such as the (effective) Equilibrium Climate Sensitivity (ECS), the Transient Climate Response (TCR) and the (CO₂-only) Transient Climate Response to cumulative CO₂ emissions (TCRE). These metrics, reported by various studies (Arora et al., 2020; Meehl et al., 2020; MacDougall et al., 2020) are analyzed alongside the 2025 estimate of the TCRE-fe including all CO₂-fe emissions. For the 2.0 °C target warming level,
- there is no significant strong relationship between those metrics and the differences in EB_{2026} between the 2100-2150 average 510

2026 CO₂-fe Emission Budget (EB₂₀₂₆)

Figure 5. Remaining CO₂-fe Budget recalculated from the beginning of year 2026 at each stocktake (denoted as EB_{2026} in the text) in the 1.5 °C (a) and 2.0 °C (b) warming level simulations. The ensemble mean is shown for models that have several ensemble members. The multi-model mean is displayed by the black thick line and the grey shading covers the min-max spread.

and the first estimate at the end of 2025 (Fig. 6). The IPSL model stands out as being a highly sensitive model (Boucher et al., 2020), thus with a very low initial estimate of the EB_{2026} compared to other models. However, as emissions rapidly decrease during the AERA simulations, the linearity of the TCRE-fe relationship breaks in this model and positive emissions become necessary to keep warming the model at the target temperature prescribed warming level. This could be due either to large negative ZEC (which needs to be confirmed by dedicated ZECMIP simulations), and/or to strong sensitivity to non-CO₂ 515 greenhouse gases which are heavily mitigated in the SSP1-2.6 scenario. When the IPSL model is removed from the analysis, a clearer relationship emerges. Models with higher sensitivity (e.g., high ECS/TCR/TCRE/TCRE-fe) tend to exhibit a lower increase or even a slight decrease in the EB_{2026} , while less sensitive models show a more substantial increase. It is noticeable that the relationship between the different configurations of the Bern model (small pink dots) aligns particularly well with 520 the slope of the linear regression between models excluding IPSL (red line). This relationship aligns with previous findings illustrating a positive correlation between the zero emissions commitment (implying decreases in EB over time) and TCR or TCRE across multiple models (MacDougall et al., 2020). Additionally, this correlation is evident between the zero emissions commitment and ECS within parameter-perturbed ensembles of a single model (MacDougall et al., 2020), as also shown here for the Bern model. Nevertheless, this relationship is not true for all models as shown in Fig. 6 and the range remains large. For 525 example, NASA-GISS has a low sensitivity but a decreasing EB_{2026} . As pointed out by MacDougall et al. (2020), the evolution

23

of the surface temperature and thus the evolving amount of emissions needed to stabilize warming is a balance between large quantities controlled by heat and carbon dynamics, and thus not expected to scale particularly well with these climate metrics.

Figure 6. Simulated changes in the EB_{2026} , i.e., the estimate averaged over 2100-2150 minus the first estimate at the end of year 2025, plotted against ECS (a), TCR (b), CO₂-only TCRE (c) and TCRE-fe at the end of year 2025 (d). Here only the 2.0 °C simulation is shown. Results for the 1.5 °C simulation are displayed in Fig. B6. The black line indicates the linear regression including all models, and the red line excluding the IPSL model. The 9 parameter-perturbed configurations of the Bern model are displayed by the small pink dots but the regression is calculated based on the ensemble mean (larger pink dot).

6 Where does the carbon go?

6.1 Global response

- 530 Atmosphere, ocean and land carbon fluxes exhibit peak and decline patterns, albeit with distinct differences between all three sinks (Fig. 7). In this section, our emphasis is on the 2.0 °C scenario. HoweverIn addition, the analysis for the 1.5 °C scenario is shown in the Appendix (Fig. B7), and the numbers for the cumulative emissions and sinks are reported for both scenarios in Tables 4 and 5.
- The atmospheric CO₂ growth rate, G_{ATM} , initially mirrors fossil fuel emissions, reaching 4.7 (3.5 to 5.7) PgC yr⁻¹ in 2020 (Fig. 7a), consistent with the observation-based estimate of 5.0 ± 0.2 PgC yr⁻¹ (Friedlingstein et al., 2022). As emissions decrease, G_{ATM} deviates from fossil fuel emission trends, turning negative and reaching -0.5 (range: -2.7 to 1.7) PgC yr⁻¹ between 2100-2150 due to continued carbon uptake by the ocean and land. The ocean remains a consistent carbon sink, with multi-model mean uptake decreasing from 2.9 (2.2 to 3.3) PgC yr⁻¹ in 2020 to 1.2 (0.2 to 1.9) PgC yr⁻¹ by 2100-2150 (Figs. 7c). Conversely, the net land carbon sink (S_{LAND} - E_{LUC}) undergoes a transition from a net source to a sink between 1850-1950.
- 540 The net land carbon sink peaks at 2.1 (0.5 to 4.1) PgC yr⁻¹ in 2020 and remains a net sink or neutral until 2200 (Fig. 7g). Notably, the land sink reaches a neutral state faster than the ocean sink, even temporarily shifting to a small carbon source

2.0ºC warming level

Figure 7. (a) Atmospheric CO₂ growth rate (G_{ATM}), (c) net ocean sink (CO₂ flux into the ocean; S_{OCEAN}), (e) gross land sink (S_{LAND}), (g) net land sink (CO₂ flux into land; S_{LAND} - E_{LUC}), cumulative (b) airborne, (d) ocean-borne and (f) land-borne fractions, in the 2.0 °C simulation. The multi-model mean is displayed by the black thick line and the grey shading covers the min-max spread. Apart from the cumulative fractions, all time series have been smoothed with a 31-year running mean to remove short-term internal variations for visual purposes. The numbers are reported in the text without the 31-year average to be comparable with the Global Carbon Budget estimates.

by the end of the 22nd century. The simulated ocean and land carbon uptake in 2020 align well with the observation-based estimates: 3.0 ± 0.4 PgC for ocean carbon uptake and 2.0 PgC yr⁻¹ ($S_{LAND} = 2.9 \pm 1.0$ PgC yr⁻¹ minus $E_{LUC} = 0.9$ \pm 0.7 PgC yr⁻¹) for land carbon uptake (Friedlingstein et al., 2022). Among the models providing land use change emissions

545

estimates, the gross land carbon uptake S_{LAND} emerges as a larger sink than the net land carbon flux $S_{LAND} - E_{LUC}$ (Fig. 7e), trending towards neutrality or even displaying a source tendency on longer timescales in GFDL-ESM2M. SLAND in NASA-GISS, which lies at the lower end of the model range, is small because its sensitivity to CO₂ fertilization is damped: while the model simulates enhanced photosynthetic uptake of CO₂, its vegetation structure remains fixed and the extra carbon is instead allocated to the soil where it can still be respired back to the atmosphere. Also, it the NASA-GISS model does not 550 capture regrowth from secondary forest. These together lead to a relatively smaller cumulative land-borne fraction (Fig. 7df) and larger cumulative ocean-borne fraction by compensation (Fig. 7d).

The net ocean carbon flux initially has a narrow spread across models during the historical period, with a min-max range of 0.8 PgC yr⁻¹ over 2000-2020. However, this spread notably widens after 2025, reaching 1.5 PgC yr⁻¹ over 2040-2060 and 1.7 PgC yr⁻¹ over 2100-2150. Pre-2025 differences among models are mainly due to various representations of ocean circulation 555 and biogeochemistry in ESMs (Terhaar et al., 2022b). Post-2025, the widening spread results also from differing emission pathways. In contrast, the land carbon flux exhibits a much wider spread during the historical period, reaching 4.0 PgC yr⁻¹ over 2000-2020. This range only increases slightly after 2025 to 5.0 PgC yr⁻¹ over 2040-2060, reverting to 4.0 PgC yr⁻¹ over 2100-2150. The substantial spread in land carbon flux, not entirely depicted in Fig. 7 due to a 31-year average for visual clarity, arises from the diverse representations of land carbon processes across models (Canadell et al., 2021).

- 560 From 1850 to 2020, 294 (PgC (ranging from 236 to 354) PgCof the PgC) of the total cumulative CO₂ emissions from fossil fuel fuels (462 PgC, Table 4) and land use change (170 PgC) stayed remained in the atmosphere, while. During the same period, the ocean has taken up 173 (PgC (ranging from 128 to 208) PgCPgC), and the land absorbed 168 (PgC (ranging from 79 to 254)PgCPgC) (Table 5). This partitioning translates to a cumulative airborne fraction of 0.48 (0.41 to 0.53), an ocean-borne fraction of 0.27 (0.24 to 0.31) and a land-borne fraction of 0.26 (0.16 to 0.33). These values are similar to observation-based
- estimates for 1850-2020 of 0.26 for the ocean sink and 0.30 for the land sink (Friedlingstein et al., 2022). Over the simulation 565 period, the cumulative airborne fraction steadily decreases alongside declining emissions after 2025, signifying the gradual uptake of anthropogenic carbon by the ocean and the land (Fig. 7b,d,f). By the year 2150, the cumulative airborne fraction decreases to 0.34 (0.26 to 0.42), with an average of 416 (284 to 354) PgC of anthropogenic carbon still remaining in the atmosphere. Concurrently, the ocean-borne fraction consistently rises, emerging as the dominant fraction by the end of the
- 570 simulations. In 2150, the ocean-borne fraction increases to 0.36 (0.30 to 0.45), surpassing both the land-borne fraction of 0.30(0.13 to 0.44) and the airborne fraction. The cumulative ocean sink by 2150 amounts to 426 (330 to 556) PgC, while the land has taken up 370 (113 to 540) PgC. Nonetheless, substantial variability persists among model estimates for each fraction.

Regional distribution 6.2

The continuous ocean carbon uptake until the end of the simulations is limited to specific regions (Fig. 8a,c,d). While the ocean carbon sink increases almost everywhere from the early 20th century to the mid-21st century, it only continues to take up 575

carbon after temperature stabilization at the end of the 21^{st} century in the Southern Ocean and the low latitude regions close to the equator. Especially the Southern Ocean around 60°S remains a prominent and enduring carbon sink post temperature stabilization, a consistent feature across models (no stippling in Fig. 8a,d). Cumulatively, the Southern Ocean south of 30°S, representing 35 % of the ocean area, takes up 42 % (35 % to 46 %) of the global ocean carbon uptake by 2020, rising to 46 %

- (35 % to 57 %) by 2150 in the 2.0 °C simulation shown here. This region remains a sink until 2300 for the models that have run long simulations (GFDL-ESM2M, MIROC, Bern, not shown). Another strong present-day carbon sink (panel c), the subpolar North Atlantic, ceases to absorb carbon when the surface temperature stabilizes (panel d). The subpolar North Atlantic north of 40°N (and using the northern boundary of Fay and McKinley (2014)) represents 3 % of the ocean area, but takes up 7 % (3 % to 11 %) of global ocean carbon uptake by 2020, a fraction that decreases to 5 % (1 % to 11 %) by 2150. The prevalence of
- 585 the Southern Ocean carbon sink is consistent with results from CMIP5 and CMIP6 simulations for the historical period and for idealized 1pctCO₂ experiments (Frölicher et al., 2015; Terhaar et al., 2021; Williams et al., 2023). The pronounced long-term steady carbon sink in the Southern Ocean can be attributed to the high carbon concentration feedback and efficient surface to deep export of anthropogenic carbon shown in earlier studies (Tjiputra et al., 2010; Roy et al., 2011). In the mid-latitude subtropics, some models even simulate less carbon uptake or outgassing due to the accumulation of anthropogenic carbon near 590 the surface layers (Couespel and Tjiputra, 2024; Rodgers et al., 2020).

The land carbon uptake also persists only in particular regions during temperature stabilization (Fig. 8b,e,f). Some strong and robust carbon sink regions in the present era (2011-2030), particularly in tropical areas like South America, central Africa and part of Indonesia, experience a complete cessation of carbon uptake after 2100. However, strong terrestrial carbon uptake persists in the Northern Hemisphere during temperature stabilization, including regions like Central America, temperate and boreal forests in Eastern North America and Eurasia.

595

Compared to the ocean carbon uptake, the land carbon uptake has locally a larger uncertainty across models, although much of this uncertainty is located in regions where no carbon exchange is found during the pre-industrial period (e.g. desertic regions), and is thus an artefact of the method and therefore not indicated by stipples on the maps (see caption in Fig. 8).

The land and ocean carbon sink patterns look qualitatively similar as previous results based on low emission scenarios 600 (Canadell et al., 2021). The novelty of these simulations is a quantification of these sinks for a given temperature target level and the representation of carbon cycle dynamics beyond the 21st century under strong mitigation scenarios. For example, here we show that the North Atlantic ocean sink vanishes during and after stabilization while the Southern Ocean remains an active sink. The divergence in carbon uptake between these regions can be attributed to distinct ocean circulation patterns. The Southern Ocean is the region where old, anthropogenic CO₂-poor circumpolar deep waters are being upwelled (e.g. Mikaloff Fletcher

- et al., 2006), even during global surface climate stabilization. This upwelling results in continuous carbon uptake due to the positive air-sea gradient in anomalous pCOpCO₂ (Frölicher et al., 2015). On the other hand, when global temperature stabilizes, the Atlantic Meridional Overturning Circulation (AMOC) is expected, at least in some models, to recover after an initial decrease (e.g. Manabe and Stouffer, 1994; Sigmond et al., 2020; Frölicher et al., 2020; Schwinger et al., 2022; Bonan et al., 2022), a phenomenon associated with a recovery of deep convection in the subpolar North Atlantic, enhanced mixing of
- anthropogenic CO₂-rich waters previously sequestered at depth, and a consequently lower ocean carbon uptake in this region.

Figure 8. Multi-model mean ocean (top, S_{OCEAN}) and land (bottom, $S_{LAND} - E_{LUC}$) carbon flux anomalies in the 2.0 °C simulation relative to 1850-1900. In panels (a) and (b) the fluxes are zonally-integrated and smoothed with a 31-year running mean, while panels (c)-(f) display maps averaged between 2011-2030 and 2100-2150. Stipples indicate where less than 80 % of the models agree on the sign of the anomaly. Stippling is not shown where carbon fluxes during the 1850-1900 period are lower than 2.5 gC m⁻² yr⁻¹.

A stronger AMOC would also transport more warm surface waters with high anthropogenic carbon concentrations to the high latitudes where the anthropogenic carbon would be outgassed during cooling (Siegenthaler and Joos, 1992; Völker et al., 2002; Tjiputra et al., 2010), a phenomenon already simulated for the present time in the Arctic Ocean while atmospheric CO₂ is still increasing (Terhaar et al., 2020). The exact drivers of the vanishing Atlantic Ocean carbon sink under temperature stabilization will be the subject of future dedicated studies using the AERA-MIP simulations.

7 Discussion

The AERA-driven simulations achieve temperature stabilization with realistic CO_2 -fe and CO_2 emission pathways across an ensemble of comprehensive Earth System Models. However, applying the AERA with ESMs is more complex than traditional concentration-driven simulations and comes with its caveats and limitations.

620

We robustly quantify a decrease in CO_2 -fe emissions towards very low emissions for the selected 1.5 °C and 2.0 °C warming targetslevels. To which extent reductions in CO_2 -fe emissions are realized by reductions in emissions of fossil fuel CO_2 vs. other agents depends on scenario choices. We opted for the low emission high mitigation scenario SSP1-2.6 for all greenhouse gases except CO_2 , and for anthropogenic aerosols. While the scenario choice does not impact initial estimates of the REB and

CO₂-fe emission pathways (Terhaar et al., 2022a), it the choice does affect fossil fuel CO₂ emissions, atmospheric CO₂ and the

625 land and ocean carbon sinks (Terhaar et al., 2023). Thus, the quantitative estimates presented here for the carbon distribution budget in Section 4, carbon distribution in the Earth System and atmospheric CO₂ offer a likely pathway under low emissions and high mitigation but may not encompass all uncertainties. These estimates may change if alternative trajectories for non CO_2 radiative agents and land use change are pursued in the future (Terhaar et al., 2023). Nevertheless, qualitative statements remain robust, such as the necessity to substantially reduce fossil fuel CO_2 emissions for temperature stabilization and the continuous carbon uptake by the Southern Ocean even under temperature stabilization.

630

635

640

The choice of the scenario for non-CO₂ radiative agents can also lead to unwanted trajectories of the CO₂ emission curve if the prescribed non-CO₂ scenario is not ideal for the chosen temperature targetlevel. In the case of the 2 °C target, warming level, fossil fuel CO₂ emissions increase from 2025 to 2030 and start to decrease strongly afterwards (Fig. 2f4b). The temporal increase in fossil fuel CO₂ emissions is a result of a strong decline in CO₂-fe emissions from declining non-CO₂ radiative agents under SSP1-2.6, which exceeds the necessary total CO₂-fe emission decline calculated by the AERA in 2025. As a result, fossil fuel CO₂ emissions increase to compensate for the strong decline in CO₂-fe emissions from declining non-CO₂ radiative agents. Such unwanted effects could be avoided by adjusting the SSP1-2.6 scenario so that mitigation efforts of non-CO₂ agents and land use start later, as already applied by Millar et al. (2017), or simply by choosing the best fitting non-CO₂ SSP scenario for each temperature targetlevel. Another possibility which might be offered in the future when ESMs develop an emission-driven mode for non-CO₂ agents is to scale the CO₂ and non-CO₂ emissions, as already applied in Terhaar et al. (2022a) with an EMIC.

The non- CO_2 and land use change emissions do not only add uncertainties to the carbon budget but also add uncertainties to the AERA at each stocktake. At each stocktake, the AERA needs information about the CO_2 -fe emissions from non- CO_2 radiative agents and from land use change. Unfortunately, most models do not provide emissions from land use change or

- the non-CO₂ radiative forcing from which the corresponding CO₂-fe emissions can be estimated. As a result, the CO₂-fe emissions from land use change and from non-CO₂ agents provided to AERA are estimated from another source other sources (see Methods), which lead to discrepancies between the real CO₂-fe emissions in the model and the estimated CO₂-fe emissions seen by the AERA. This discrepancy affects the estimate of the TCRE-fe and the future CO₂ emission curve, which is estimated as the difference between the AERA-derived CO₂-fe emission curve and the CO₂-fe emissions from land use change and non-
- 650 CO₂ radiative agents. Fortunately, the simulations provided here with an ensemble of ESMs demonstrate that the re-evaluation of the TCRE-fe and the future CO₂-fe emission curve every 5 years allows all models but one to reach the temperature target prescribed temperature level without any larger divergence (Fig. 2). For future simulations, possibly within CMIP7, diagnosing each models' effective radiative forcing of non-CO₂ agents and land use change (Smith, 2020; Zelinka et al., 2023) would likely lead to even more precise results, as shown-described in more detail for the IPSL model in Appendix A. This is particularly
- 655 important for the aerosol radiative forcing, which is the most uncertain component, with important repercussions for the ability to reach climate goals (Watson-Parris and Smith, 2022).

Not only the implementation of the AERA with ESMs introduces uncertainties, but the ESMs comprehensive emission-driven, fully coupled Earth system models themselves also have limitations. Potential feedbacks such as thawing permafrost (MacDougall and Fried , peat land area and carbon evolution (Müller and Joos, 2021), ocean circulationchanges due to ice melt from Greenland or

660 Antarctica (Bronselaer et al., 2018; Lago and England, 2019; Li et al., 2023), feedbacks between warming, nitrous oxide and methane (Stocker et al., 2013; Battaglia and Joos, 2018; IPCC, 2021), and, on longer timescales than considered in this study , feedbacks associated with the potential melting and disintegration of polar ice sheets are currently missing from most ESMsFor example, the models do not include changes in freshwater input from melting ice sheets and the associated impacts on ocean circulation. This additional freshwater input can modulate global and regional temperature and carbon cycle responses (e.g.,

- 665 Bronselaer et al. (2018); Li et al. (2023)). However, ice sheet changes are expected to occur on timescales over many centuries, potentially beyond the time horizon of largest reduction in CO₂-fe emissions. Nevertheless, the AERA approach would adjust allowable emissions in response to emerging, unforeseen feedbacks when applied to real-world emission and temperature data (Terhaar et al., 2022a). Additionally, most models in our study either neglect or poorly represent permafrost dynamics and often underestimate soil carbon stocks in the northern high latitudes (MacDougall et al., 2015; Burke et al., 2017; Gasser et al., 2018; Lowe and I
- 670 . Permafrost thaw due to global warming has the potential to release a substantial amount of carbon stored in soil for millennia into the atmosphere over a relatively short period (e.g., Schuur et al. (2015)). Therefore, CO₂-fe emission pathways that account for the release of permafrost soil carbon may differ from those shown here, potentially requiring more stringent emissions reduction to achieve the prescribed global warming levels. Future model studies incorporating permafrost soil carbon are necessary to quantify this effect and fully capture the uncertainty in land and ocean carbon-warming feedbacks. Another caveat
- 675 is the large uncertainties in the non-CO₂ GHG warming feedbacks (Stocker et al., 2013; Battaglia and Joos, 2018; IPCC, 2021) , which are currently not represented in our approach with prescribed non-CO₂ forcing. These feedbacks would potentially reduce the emission budget over time and potentially make negative emissions over long time periods necessary to maintain a stable temperature (Palazzo Corner et al., 2023). Another limitation of Earth System Model lies in the long equilibration timescales, resulting in potential drift in carbon fluxes, amongst other variables. A correction is often applied by removing the
- 680 pre-industrial trend, but this is not taken into account in the current version of the AERA, as it would add another layer of complexity to the simulation setup.

Using CMIP6 models, Arora et al. (2020) demonstrated that models that included a representation of the terrestrial nitrogen cycle typically show lower carbon uptake than those without, because of widespread nitrogen limitation of the vegetative carbon sink. This finding has been corroborated by the ZECMIP analysis (MacDougall et al., 2020). A lower terrestrial carbon sink in

- 685 models with a terrestrial nitrogen cycle implies stronger reductions in total CO₂-fe emissions in those models. This is indeed simulated in both the 1.5 °C and 2.0 °C global warming level scenarios (see Figure B8). For example, under the 1.5 °C global warming scenario, the multi-model mean CO₂-fe emissions in 2050 for the six models including a terrestrial nitrogen cycle are -1.6 PgC yr⁻¹, compared to 2.0 PgC yr⁻¹ for the 5 models without it. Averaged between 2100-2150, the CO₂-fe emissions are 0.8 PgC yr⁻¹ for models with a terrestrial nitrogen cycle and 1.5 PgC yr⁻¹ without. The minimum CO₂-fe emissions in the
- 690 1.5 °C scenario between 2026 and 2150 are -1.6 PgC yr⁻¹ in the models with a nitrogen cycle, and 1.3 PgC yr⁻¹ in the models without. The emission budget between 2020 and 2150 is also affected when partitioning the models into these two groups. The CO₂ only budget is 550 (250 to 950) GtCO₂ for the models with a nitrogen cycle in the 1.5 °C scenario (median and 17th-83rd percentile range), and goes up to 1500 (1000 to 1850) GtCO₂ for the models without. In the 2.0 °C scenario, the budget is 1850 (1250 to 2500) GtCO₂ for the models with a nitrogen cycle and 2300 (2000 to 3100) GtCO₂ for the models without. The
- analysis indicates that part of the spread in CO_2 -fe emission pathways and budgets can potentially be attributed to whether models account for the nitrogen limitation in the terrestrial carbon sink. However, the model spread in CO_2 -fe emissions also

emerges due to other model differences, such as in ocean carbon uptake (e.g., Terhaar et al. (2022b)) or climate sensitivity (Cox et al., 2018).

8 Conclusions

- 700 This study presents multi-ESM emission-driven projections compatible with internationally-agreed climate goals. We showed that the Adaptive Emission Reduction Approach (AERA) proposed by Terhaar et al. (2022a) works not only for EMICs but also for more complex, higher-resolution fully-coupled ESMs. The temperature targets prescribed temperature levels are reached even when the simulated non-CO₂ radiative forcing and land use change emissions are not fully known, with the exception of one ESM. The success of the AERA-MIP simulations across a large group of modeling centres shows that the AERA can be
- visual results results and results results results and results

Unlike the standard CMIP scenarios that simulate different warming levels for the same prescribed CO_2 concentration or emission pathways (Tebaldi et al., 2021), all models converge to a given warming level. The convergence to a common warming level with varying emissions now allows to quantify the diversity of model responses in terms of emission <u>budgets</u>

- 710 and pathways compatible with these warming levels, as well as resulting atmospheric CO_2 levels, carbon cycle responses, and their effect on ecosystems, such as ocean acidification (Terhaar et al., 2023). While globally integrated results are qualitatively similar to previous results with EMICs (Terhaar et al., 2022a, 2023; Goodwin et al., 2018b), the ESM simulations here allow to explore a more quantitative and regional focus, to better quantify uncertainties, and especially to quantify the importance of internal climate variability.
- To limit warming to 1.5 °C or 2.0 °C (i.e., an allowable warming of 0.28 °C and 0.78 °C from year 2020 forward), drastic reductions in greenhouse gas emissions are necessary. If such immediate and drastic emission reductions of around -1 to -2 PgC yr⁻² were implemented, both CO₂-fe and fossil fuel CO₂ emissions may even be allowed to stay positive (on the order of 1 PgC yr⁻¹ upon stabilization). However, the amount of allowed continuous CO₂-fe emissions after the temperature is stabilized is strongly model-dependent, with a large spread found across ESMs. The large spread is mainly caused by varying
- 720 zero emissions commitments and responses to non-CO₂ forcing agents across the model ensemble. Importantly, the negative multi-model mean zeroemissions commitment might have a bias towards low values because of important feedback processes missing in most ESMs (e. g., the release of carbon from thawing permafrost).

The Unlike the remaining carbon budget concept, which assumes constant TCRE and a constant ZEC centered around zero, the AERA simulations provide the realized emission budget until the temperature reaches the prescribed warming level and

725 stabilizes. This modelling exercise is a powerful tool to explore the evolution of the TCRE and the associated budgets as the climate responds to emissions mitigation. Indeed, the spread in the zero emissions commitment in combination with a non-constant TCRE-fe also results in an initially biased estimate of the remaining emission budget. On average across models, the REB that was estimated in 2025 could change by a factor of 1.4 to 2 (Table 3). The direction of change mainly depends on the ZEC, with a negative ZEC allowing for more emissions. Here, the REB was on average underestimated in line with a slightly

negative multi-model mean ZEC (MacDougall et al., 2020). However, there are large uncertainties around the ZEC and hence 730 the development of carbon and emission budgets with time.

A few ensemble simulations pointed to a significant role of internal variability, potentially explaining 30 % to over 50 % of the inter-model spread in compatible emissions, atmospheric CO_2 levels and emission budgets. The origin of this uncertainty partly lies in the estimate of the anthropogenic warming, which in practise differs among members and can lead to large

735 differences in the emission budgets, as also pointed out by Tokarska et al. (2020). This indicates necessary caution that caution is required when interpreting remaining budgets estimates, and planning for a margin of error in mitigation pathways to avoid overshooting the warming target desired warming level.

In addition to the "relative targetwarming level" simulations presented here (i.e., same amount of remaining warming for all models after 2020 based on observations), the AERA can also be used to make simulations with an "absolute target warming

740 level" (i.e. all models are set up to warm by the same amount relative to 1850-1900) or with an overshoot. Absolute target warming level simulations allow to explore climate impacts of global surface temperature stabilization at different warming levels across Earth System Models (King et al., 2021), which will be the focus of future dedicated studies. Temperature overshoot simulations with the AERA allow to define the magnitude and length of the overshoot by varying temperature targets prescribed temperature levels over time, e.g., a first temperature target warming level of 2.0 °C until 2050 followed by 745

a step-wise reduction of that target-level every 5 years to 1.5 °C in 2100 (Terhaar et al., 2022a).

The AERA framework proposed here only accounts for targets in accounts for prescribed global surface temperature levels, aligned with international climate agreements. However, other climate change impacts, such as ocean acidification, sea level rise, interior ocean changes, terrestrial productivity, regional extremes, pose important risks for ecosystem and human societies. Extending the AERA to other targets, and towards avoiding crossing some of the Earth's planetary boundaries (Rockström

750

et al., 2009), as proposed by Steinacher et al. (2013); Seneviratne et al. (2016); Avrutin et al. (2023), would enable to constrain the emission budget and pathways towards a safer world.

The success of the AERA-MIP simulations across a large group of modeling centres shows that the AERA can be used in subsequent model intercomparison projects, such as CMIP7, with many applications for these temperature stabilization simulations.

755 Code and data availability. The AERA code is distributed as a python module openly available under https://github.com/Jete90/AERA, with a guided documentation and examples. The AERA-MIP model outputs used in this study are available under Silvy et al. (2024). The Python code used to produce the figures of this paper will be made openly available upon final publication.

Appendix A: Further details on the AERA configuration of the participating models

All participating models are listed in Table A1. Both HadCM3-FaIR2 and MPI performed the AERA simulations with a 760 previous version of the AERA code using an impulse response function to the radiative forcing to estimate anthropogenic temperature instead of the 31-year running mean (as in Terhaar et al. (2022a)). The HadCM3-FaIR2 configuration is described in details in Lee et al. (in review). Briefly, it uses the Hadley Centre Coupled Model version 3 (HadCM3, Collins et al. (2001)), with 29 members from a physics perturbed parameter ensemble (Sparrow et al., 2018). Because HadCM3 runs in concentration-driven mode and does not solve the carbon cycle, it is coupled to the Finite amplitude Impulse Response (FaIR)

- 765
- version 2 (Leach et al., 2021) at each AERA stocktake. The FaIR parameters are chosen to fit each member of the HadCM3 ensemble based on the 1881-2025 simulation period. The carbon cycle component of FaIR is used both to derive the CO_2 -fe emissions from non- CO_2 agents, and to convert the CO_2 emissions given by AERA to CO_2 concentration to prescribe to HadCM3 every 5 years.

Table A1. Earth System Models of full and intermediate complexities participating in AERA-MIP.

The time series prescribed to AERA (default or model-estimated E_{LUC} and E_{non-CO_2-fe}) are listed in Table A2. To estimate their own simulated E_{LUC} , most models compare land-air carbon fluxes between two concentration-driven simulations following historical+SSP1-2.6 CO₂ concentrations (1850-2100), one with land use change activated and another without (Lawrence et al., 2016; Liddicoat et al., 2021). This difference is then smoothed with a 21-year running mean to remove large interannual variations. Eight models prescribed their internally-estimated E_{LUC} to AERA. The NASA-GISS model underestimates E_{LUC} as it estimated the emissions from land use change due to crop cover change only, but did not include the transport of crop harvest from land, and did not include the deforestation component of E_{LUC} . UViC used an estimate based on the carbon flux

from vegetation burning only. The time series of all E_{LUC} estimates prescribed to AERA are shown in Fig. A1a -(same as Fig. 4c).

In the analysis of carbon distribution (Equation 6) presented in the paper, we corrected and re-estimated some of these E_{LUC} time series, to obtain the best estimate possible of the internally-simulated E_{LUC} . These time series are shown in Fig. A1b. GFDL-ESM2M performed a posteriori the concentration-driven simulations with and without land use change activated, providing its estimate of E_{LUC} for the carbon analysis from 1861 to 2100. We then extended the time series to 2300 by applying a linear decay to zero emissions from 2100 to 2150, and maintaining the emissions at zero afterwards. We similarly corrected the MPI estimate between 2100 and 2150 by linearly decaying the emissions to zero. Dedicated UVic simulations were additionally performed to better estimate E_{LUC} emissions within the AERA simulations. For CESM2, we were able to estimate E_{LUC} for the historical period, using the available concentration-driven *hist* and *hist-nolu* simulations available on the Earth System Grid Federation and the method described above (Lawrence et al., 2016). However, the extension for the SSP1-2.6 scenario was not available. Nonetheless, the E_{LUC} term during the historical period matched the default E_{LUC} forcing from the Bern model adjusted time series (not shown), so we used the default estimate for the carbon distribution analysis.

790

The simulated effective radiative forcing from non- CO_2 agents was diagnosed in dedicated simulations for IPSL, but only for CH_4 , N_2O and aerosols, which have major climate impacts amongst non- CO_2 forcing agents. For other agents, we used the estimates from Smith et al. (2023) for the historical period and from Smith (2020) for the SSP1-2.6 scenario period post-2022.

For the IPSL model, one <u>additional</u> set of simulations were performed by prescribing the <u>default_internally-calculated</u> E_{non-CO_2-fe} and E_{LUC} forcings to AERA, while another set of simulations were performed with the internally-calculated

795 emissions(Table A2)emissions, enabling us to test the effect of the mismatch in E_{non-CO_2-fe} and E_{LUC} between the default time series and the internally-simulated emissions. The member with the internally-calculated emissions allowed for a shorter

Figure A1. E_{LUC} diagnosed in the models and default AERA input. Panel a) shows the time series prescribed to AERA and panel b) the corrected time series used in the carbon distribution analysis of this paper (see text for details of the corrections).

temperature undershoot in the 1.5 °C simulation, and a better temperature stabilisation within the 2.0 °C uncertainty range in the associated simulation. However, minor differences in emission budget and cumulative fossil fuel emissions were found overall between these two ensemble members, due to compensating effects between CH₄ and N₂O in the estimated and the internally-calculated radiative forcing, and between E_{non-CO_2-fe} and E_{LUC} . As an indication, the $EB_{2026}(2025)$ (i.e., the REB from beginning of year 2026 estimated at the first stocktake) differs by 3 PgC for the 1.5 °C target-warming level and by 15 PgC for the 2.0 °C target-level between the two ensemble members. The differences increase to 52 PgC, respectively 48 PgC, for $EB_{2026}(2100 - 2150)$.

The simulations performed with the Bern3D-LPX model correspond to the configuration in Terhaar et al. (2023), where two parameters (ocean heat uptake efficacy and feedback parameter) were varied to obtain 9 values of Earth Climate Sensitivity (ECS) spanning the range 2.23 °C to 4.63 °C. Since Bern3D-LPX does not represent atmospheric variability on GSAT, a synthetic noise was added on the GSAT output read by AERA for each of these 9 ECS values, providing 8 synthetic ensemble members per configuration, hence a total of 72 ensemble members. This Bern3D-LPX range across members is thus more representative of parametric uncertainty, and not comparable to the perturbed initial-condition ensembles of EC-Earth and GFDL-ESM2M.

Appendix B: Additional figures

Author contributions. TLF, JT and FJ designed the AERA-MIP protocol. YS, FAB, FL and JT participated in the testing and validation of the protocol. YS gathered and analyzed the simulations. YS, JT and TLF wrote the first draft of the manuscript. JT performed the Bern3D-LPX

2.0°C warming level

CO₂-fe emissions (E_{total - fe})

Figure B1. Simulated multi-model mean CO₂-fe emissions for the 1.5°C and 2.0°C warming levels with and without including the ACCESS model.

simulations. FAB and FL performed the GFDL-ESM2M simulations. JRB performed the CESM2 simulations. RF, VL and ET performed the EC-Earth3-CC simulations. PC performed the IPSL-CM6-LR-ESMCO2 simulations. MD and TL performed the ACCESS-ESM1-5 simulations. GG performed the MPI-ESM1-2-LR simulations. TH and MK performed the MIROC-ES2L simulations. NYK, PL and AR performed the NASA-GISS-E2-1-G-CC simulations. DL performed the HadCM3-FaIR2 simulations. NM and EAM performed the UVic-ESCM-2.10 simulations. JS and JTJ performed the NorESM2-LM simulations. ES performed the GFDL-ESM4 simulations. DP provided the GFDL-ESM2M radiative forcing from non-CO₂ radiative agents. All authors contributed to discussions and final writing of the manuscript.

820 TLF led the revision of the paper and YS performed the additional analyses.

Competing interests. All authors declare no competing interests.

Figure B2. Schematic of the feedback loop between the Earth System Model and the AERA module. Steps 1 to 4 are performed at each stocktake year, starting at the end of 2025.

Figure B3. Same as Fig. 3 but for the 1.5 °C warming level.

TCRE-fe

Figure B4. Solid lines show TCRE-fe calculated by AERA at each stockake year. Dotted lines indicate the TCRE-fe calculated a posteriori with the final ("true") estimate of the 31-year running mean time series of GSAT. The deviation between the solid and dotted lines occurs because the temperature fit becomes less accurate when the temperature increase slows toward stabilization. As the warming rate decreases, the 31-year mean will also decrease. Therefore the "true" estimate of the 31-year mean will be smaller than the estimate at each stocktake. Consequently, the TCRE will be smaller than estimated at the stocktake during periods of slowing down temperature increases. In addition, the reconstructed TCRE-fe (dotted lines) is less variable than the TCRE-fe calculated by AERA, which calculates ΔT based on the last year of the extended 31-year running mean time series until each stocktake year, which introduces some noise compared to the true final estimate.
