16

17 **Abstract.**

18 Secondary organic aerosol (SOA) derived from n-alkanes, as emitted from vehicles and volatile
19 chemical products, is a major component of anthropogenic particulate matter, yet its chemical
20 composition and phase state are poorly understood and hardly constrained in aerosol models.
21 Here we provide a comprehensive analysis of n-alkane SOA by explicit gas-phase chemistry
22 modeling, machine learning, and laboratory experiments to show that n-alkane SOA adopt low
23 viscous semisolid or liquid states. Our study underlines the complex interplay of molecular
24 composition and SOA viscosity: n-alkane SOA with higher carbon number mostly consists of
25 less functionalized first-generation products with lower viscosity, while the lower carbon
26 number SOA contains more functionalized multigeneration products with higher viscosity. This
27 study opens up a new avenue for analysis of SOA processes and the results indicate little kinetic
28 limitations of mass accommodation in SOA formation, supporting the application of
29 equilibrium partitioning for simulating n-alkane SOA formation in large-scale atmospheric
30 models.

31

32 **Introduction**

33 Secondary organic aerosols (SOA) are ubiquitous in the atmosphere, affecting climate, air
34 quality and public health (Pöschl and Shiraiwa, 2015; Jimenez et al., 2009). They are generally
35 formed by multigenerational oxidation of volatile organic compounds (VOCs) emitted by both
36 anthropogenic and biogenic sources followed by condensation of semi-volatile oxidation
37 products into the particle phase (Ziemann and Atkinson, 2012; Kroll and Seinfeld, 2008). As
38 an important class of SOA precursors, there is a growing attention to intermediate volatile
39 organic compounds (IVOCs), which can partition to the gas phase upon dilution of primary
40 organic aerosols after fresh emission sources such as vehicle tailpipes, combustion of fossil and
41 fuel oils, and volatile chemical products (Robinson et al., 2007; McDonald et al., 2018). The
42 inclusion of IVOCs in the model simulations helps to reduce the gap between model simulation
43 and field observation of SOA (de Gouw et al., 2011; Li et al., 2022; Zhao et al., 2016).

44 SOA can adopt different particle phase states (liquid, amorphous semisolid, and glassy
45 solid), depending on their chemical composition, relative humidity and temperature (Virtanen
46 et al., 2010; Petters et al., 2019; Reid et al., 2018; Renbaum-Wolff et al., 2013) and also
47 evolving upon chemical aging and photochemistry (Baboomian et al., 2022). SOA phase state
48 plays an important role in a number of atmospheric multiphase processes (Shiraiwa et al., 2017).
49 The occurrence of glassy SOA in the free troposphere can impact activation pathways of ice
50 crystals and cloud droplets (Knopf and Alpert, 2023). Slow diffusion in viscous particles

51 induces kinetic limitations in heterogeneous and multiphase reactions (Zhang et al., 2018; Zhou
52 et al., 2019; Shiraiwa et al., 2011), affecting long-range transport (Shrivastava et al., 2017; Mu
53 et al., 2018). The timescale of SOA partitioning can be prolonged in viscous particles
54 (Schervish and Shiraiwa, 2023), retarding uptake of semi-volatile compounds and mixing of
55 different particle populations (Ye et al., 2016). Particle phase state also modulates SOA growth
56 to cloud condensation nuclei sizes, affecting cloud life cycle (Zaveri et al., 2022). While the
57 phase states of SOA generated by biogenic VOCs such as terpenes and isoprene have been
58 extensively studied (Virtanen et al., 2010; Petters et al., 2019; Renbaum-Wolff et al., 2013;
59 Baboomian et al., 2022; Zhang et al., 2018), those derived from IVOCs are hardly investigated
60 and remain poorly constrained.

61 Viscosity (η) is a dynamic property that characterizes the particle phase state, which can
62 be derived from the glass transition temperature (T_g) of the constituting species (Koop et al.,
63 2011). Several structure-activity relationships models have been developed to predict the T_g of
64 an organic compound using various molecular properties including molar mass, atomic O:C
65 ratio (Shiraiwa et al., 2017), elemental composition (DeRieux et al., 2018), and volatility (Li et
66 al., 2020; Zhang et al., 2019). A method was developed to predict SOA viscosity from the T_g -
67 scaled Arrhenius plot of fragility by considering Gordon-Taylor mixing rule and hygroscopic
68 growth of SOA particles (DeRieux et al., 2018; Shiraiwa et al., 2017). The T_g compositional
69 parameterizations (CP) and the viscosity prediction method have been applied to high
70 resolution mass spectrometry data of various types of SOA including toluene SOA (DeRieux
71 et al., 2018), SOA generated by diesel fuels (Song et al., 2019), β -caryophyllene SOA (Maclean
72 et al., 2021), and SOA generated by surrogate VOC mixtures by healthy and stressed plants
73 (Smith et al., 2021), agreeing well with viscosity measurements. However, CP substantially
74 overestimated viscosity measurements of indoor surface films which are mostly composed of
75 unsaturated high molar mass compounds such as triglycerides (O'Brien et al., 2021). CP does
76 not consider molecular structure nor functionality explicitly, representing a limitation of this
77 method. Galeazzo and Shiraiwa (2022) overcame this limitation by developing a machine
78 learning-based model, tgBoost, with an application of cheminformatics “molecular
79 embeddings” that retains detailed information on atomic composition, molecular structure and
80 connectivity. The main novel feature introduced by tgBoost is model capability to predict
81 different T_g for structural isomers and high sensitivity of T_g to various functional groups,
82 consistent with viscosity measurements for functionalized compounds (Rothfuss and Petters,
83 2017; Grayson et al., 2017).

84 Long-chain linear alkanes (n-alkanes) are representative IVOCs and account for a
85 substantial fraction of non-methane hydrocarbons in urban air as mainly emitted from
86 anthropogenic activities such as vehicle exhausts and incomplete fuel combustion (Li et al.,
87 2022). Gas-phase oxidation of n-alkanes by OH radicals can trigger the formation of SOA with
88 high yields, as observed in laboratory experiments (Aimanant and Ziemann, 2013a; Lim and
89 Ziemann, 2009b; Srivastava et al., 2022) and field observations (Gentner et al., 2012; Li et al.,
90 2022). Gas-phase oxidation pathways of n-alkanes are relatively well understood and
91 successfully simulated by detailed gas-phase chemistry modeling (Aumont et al., 2012; La et
92 al., 2016), but the chemical composition of n-alkane SOA has only been characterized well for
93 the C₁₆ n-alkane (Ranney et al., 2023) and the phase state and viscosity of alkane SOA are
94 unknown. Therefore, the n-alkane SOA system provides an ideal benchmark for the
95 investigation of the interplay of chemical composition, particle phase state and kinetic
96 limitations influencing SOA growth and evolution.

97 In this study, we implemented tgBoost in an explicit gas-phase chemistry model
98 GECKO-A to investigate the complex interplay of chemical composition, kinetic partitioning,
99 and phase state of n-alkane SOA generated under dry and high NO_x conditions. The GECKO-
100 A model is one of the most comprehensive generators of gas-phase chemical schemes to date,
101 as it automatically generates detailed gas-phase chemical mechanisms involving thousands to
102 millions of oxidation products from a given VOC precursor based on established reaction
103 pathways and structure–activity relationships (Aumont et al., 2012; La et al., 2016). The
104 simulations were conducted with variable effective mass accommodation coefficient to
105 consider potential kinetic limitations in amorphous semisolid particles (Shiraiwa and Pöschl,
106 2021). The simulated results were compared with chamber experimental data on SOA yields
107 (Lim and Ziemann, 2009b) as well as new measurements on thermal desorption temperatures
108 and functional group distributions.

109

110 **Methods:**

111 **Model simulations.**

112 We applied the Generator for Explicit Chemistry and Kinetics of the Organics in the
113 Atmosphere (GECKO-A) (Aumont et al., 2012; La et al., 2016) to obtain detailed reaction
114 schemes of gas-phase OH oxidation of n-alkanes along with rate constants. The GECKO-A
115 generator used for the oxidation of linear n-alkanes treats chemistry of peroxy (RO₂) and alkoxy
116 (RO) radicals. Under high NO_x conditions, RO₂ radicals mainly react with NO and NO₂, to
117 form closed-shell compounds or RO radicals, which undergo reaction with O₂, unimolecular

118 decomposition (i.e. C-C bond breaking) or isomerization, generating stable compounds and/or
119 to new RO₂ radicals. The detailed protocol for such mechanism generation is available in
120 previous studies (Aumont et al., 2013; Aumont et al., 2005; Aumont et al., 2012; La et al.,
121 2016). In this study, the generated chemical schemes include the description of the formation
122 of organic species up to four generations. Species with vapor pressure below 10⁻¹³ atm are
123 assumed to be of low enough volatility to completely partition to the condensed phase and their
124 gas phase chemistry is then not generated in the mechanism to reduce the mechanism (La et al.,
125 2016). The number of species treated in the model was ~10⁴ species for dodecane (C₈H₁₈) that
126 increases to ~10⁵ species for heptadecane (C₁₇H₃₆).

127 The latest structure-activity relationships are treated for the chemistry of organic
128 compounds with OH radical (Jenkin et al., 2018b, a; Jenkin et al., 2019), the bimolecular
129 reactions of peroxy radicals (Jenkin et al., 2019), as well as alkoxy radical decomposition and
130 H migration reaction rates (Vereecken and Peeters, 2009; La et al., 2016). The vapor pressures
131 of semi-volatile species were estimated by using Nannoolal's group contribution method
132 (Nannoolal et al., 2008) implemented in GECKO-A, as described in detail in Valorso et al.
133 (2011). The model treats unimolecular particle-phase reactions including cyclization of
134 hydroxyketones and dehydration of cyclic hemiacetals to form dihydrofurans (La et al., 2016).
135 The model does not treat autoxidation and dimerization in the gas phase, but these processes
136 should be minor pathways during n-alkane oxidation in the presence of high NO_x as the reaction
137 of peroxy radicals with NO_x should be dominant (Praske et al., 2018; Pye et al., 2019); thus,
138 their absence from GECKO-A chemical schemes should not have major impacts on the
139 simulated results.

140 These explicit chemical mechanisms were implemented into a box model to simulate
141 the multigenerational oxidation of n-alkanes, partitioning of oxidation products into the particle
142 phase based on their vapor pressures, and vapor wall loss to mimic chamber experiments (La
143 et al., 2016). We replicated the experimental conditions used in Lim and Ziemann (2009b) to
144 generate SOA from OH oxidation of C₈-C₁₇ n-alkanes at high NO_x conditions in the presence
145 of non-volatile dioctyl sebacate (DOS) seed particles with particle radius of 150 nm and mass
146 loading of 200 μg m⁻³. Temperature was held constant at 295.15 K, pressure was set at 1 atm
147 and RH was fixed at 0.5%. Photolysis frequencies were calculated based on the cross sections,
148 quantum yields as described in Aumont et al. (2005) and the photonic flux of blacklight lamps.
149 Each simulation ran for 1 hour and the time evolution of species concentration were computed
150 through a two-step method that solves stiff ordinary differential equations (Verwer, 1994;
151 Verwer et al., 1996). To investigate effects of mass concentrations, we also simulated

152 experiments of n-alkane photooxidation under high NO_x conditions with low mass loadings by
 153 Presto et al. (2010). The number concentration of seed particles with particle diameter of 200
 154 nm was ~5000 cm⁻³, corresponding to the mass concentration of ~20 μg m⁻³. Initial mixing
 155 ratios of n-alkane and NO_x were in the range of 3 – 99 ppb and 1 – 5 ppm, respectively, as
 156 reported in Presto et al. (2010) and these conditions were applied in the model.

157 The box model accounts for mass transfer kinetics of organic species between gas and
 158 particle phases. Partitioning follows Raoult's law at equilibrium and partitioning kinetics is
 159 described by the gas-particle mass transfer coefficient with the Fuchs-Sutugin approach
 160 (Seinfeld and Pandis, 2016). For the base case scenario, we fixed the mass accommodation
 161 coefficient (α) to be 1 based on molecular dynamics simulations (Julin et al., 2014), assuming
 162 particles being low viscous liquids without kinetic limitations of bulk diffusion. To account for
 163 potential kinetic limitations in viscous particles, we applied an effective mass accommodation
 164 coefficient (α_{eff}) that is a function of volatility and bulk diffusivity (Shiraiwa and Pöschl, 2021):

$$165 \quad \alpha_{\text{eff}} = \alpha_s \frac{1}{1 + \frac{\alpha_s \omega C^0 r_p}{4 D_b \rho_p} \frac{10^{-12} \text{ g cm}^{-3}}{\mu\text{g m}^{-3}}} \quad (1)$$

166 where α_s is the surface accommodation coefficient assumed to be 1, ω (cm s⁻¹) is the mean
 167 thermal velocity of the organic compound in the gas phase, r_p (cm) is the particle radius, ρ_p (g
 168 cm⁻³) is the particle density, and C^0 (μg m⁻³) is the pure compound saturation mass
 169 concentration. D_b (cm² s⁻¹) is bulk diffusivity as simulated by conversion of viscosity as detailed
 170 below. α_{eff} values are shown as a function of D_b and vapor pressure p^0 in Fig A3a. We
 171 accounted for a reversible gas-to-chamber wall partitioning of gases and assumed a fixed first-
 172 order deposition rate constant of 5×10^{-4} s⁻¹ based on experimental observations and previous
 173 modeling studies (Krechmer et al., 2016; La et al., 2016; Lim and Ziemann, 2009b). A
 174 desorption rate constant from wall to the gas phase was derived by using a parameter of
 175 $C_w/M_w \gamma_w$ of 9 μmole m⁻³ for n-alkanes and 120 μmole m⁻³ for oxidation products based on
 176 chamber observations (Matsunaga and Ziemann, 2010), as discussed in La et al. (2016).
 177 Potential concentration gradients in the particle phase are not resolved explicitly and SOA
 178 particles are assumed to be homogeneously well-mixed implicitly.

179 The glass transition temperatures (T_g) of organic compounds were predicted by the
 180 machine learning-based model tgBoost (Galeazzo and Shiraiwa, 2022) and the
 181 parameterization based on elemental composition (DeRieux et al., 2018; Li et al., 2020). The
 182 implementation of the compositional parametrization into the GECKO-A box model was done
 183 in Galeazzo et al. (2021) with a thorough description of all the equations, assumptions and steps

184 adopted for the implementation of this viscosity estimation method. In this study, we
185 implemented tgBoost, a newly developed machine learning model for better predictions of T_g .
186 tgBoost is a powerful model that can discern compositional isomers by functionality and predict
187 the glass transition temperature of an organic compound i ($T_{g,i}$) with an uncertainty of ± 18.3 K
188 using the canonical SMILES notation of a molecule (Galeazzo and Shiraiwa, 2022). We have
189 implemented a pipeline (i.e., gecko2vec) into GECKO-A to predict T_g of compounds from the
190 chemical mechanism in a fast and computationally efficient manner. Gecko2vec executes three
191 main steps: first, it translates the IDs of the compounds of interest of the GECKO-A mechanism
192 into the respective canonical SMILES notations (translation step); second, it transforms the
193 canonical SMILES notations into the respective molecular embeddings (i.e., unique 300-
194 dimensional numerical representations of molecules; embedding step); and finally, the
195 pretrained tgBoost model and its weights are loaded and used to predict T_g of each species
196 (prediction step). Within the box model, the T_g of total SOA particles ($T_{g,org}$) resulting from the
197 combination of its organic component and water mixture is computed using the Gordon–Taylor
198 equation (Dette et al., 2014; Koop et al., 2011; Zobrist et al., 2008). $T_{g,org}$ can be converted to
199 viscosity based on the Vogel-Tammann-Fulcher approach assuming the fragility parameter of
200 10 (DeRieux et al., 2018). Viscosity is further converted into bulk diffusivity using the
201 fractional Stokes-Einstein equation with a fractional parameter of 0.93 and an effective
202 molecular radius of 0.5 nm (Evoy et al., 2019). For both model simulations with CP and
203 tgBoost, the particle number concentration is assumed to remain constant (coagulation is not
204 treated), while the particle radius evolves following the partitioning of organic compounds.

205

206 **Laboratory experiments.**

207 SOA particles were generated from OH oxidation of C₈-C₁₇ n-alkanes in a 5.9 m³ Teflon
208 environmental chamber filled with clean air under high NO_x conditions in the presence of non-
209 volatile dioctyl sebacate (DOS) seed particles, as described in detail elsewhere (Lim and
210 Ziemann, 2009b). Briefly, 1 ppm of n-alkane, 10 ppm of methyl nitrite, and 10 ppm of NO were
211 added to the chamber from a glass bulb, and ~200–400 μg m⁻³ of seed particles were added
212 from an evaporation-condensation apparatus. Relatively high mass concentrations of seed
213 particles were used so that semi-volatile compounds would condense to particles, minimizing
214 vapor deposition to chamber walls (Zhang et al., 2014; Matsunaga and Ziemann, 2010).
215 Blacklights covering two of the chamber walls were then turned on for 60 min to form OH
216 radicals by methyl nitrite photolysis (Atkinson et al., 1981). The amount of n-alkane reacted
217 was measured by collecting Tenax[®] samples before and after the experiment and analyzing by

218 gas chromatography with flame ionization detection (GC-FID). Aerosol volume concentrations
219 were measured using a scanning mobility particle sizer (Docherty et al., 2005) and converted
220 to an SOA mass formed using a density of 1.06 g cm^{-3} . SOA mass yields (mass of SOA
221 formed/mass of n-alkane reacted) were calculated from the measured SMPS mass (corrected
222 for particle wall loss using the $\sim 20\% \text{ h}^{-1}$ decay in mass after the lights were turned off) and the
223 GC-FID analyses. The final SOA mass concentrations were in the range of $\sim 300 - 6000 \text{ } \mu\text{g m}^{-3}$
224 3 depending on precursors (Lim and Ziemann, 2009b). The SOA yields measured in these
225 experiments were reported previously (Lim and Ziemann, 2009b), but in light of a recent
226 comparison of the accuracy of our SMPS measurements with filter sampling the values reported
227 here are higher by a factor of 1.24 (Bakker-Arkema and Ziemann, 2021).

228 A temperature-programmed thermal desorption (TPTD) method was also used to
229 measure thermal desorption temperatures of DOS that was present as seed particles in n-alkane
230 SOA. Particles were sampled directly from the chamber into a thermal desorption particle beam
231 mass spectrometer (Tobias et al., 2000), where they were formed into a beam inside an
232 aerodynamic lens, transported into a high vacuum chamber, and impacted on a copper rod
233 vaporizer that was coated with a non-stick polymer and cooled to -40°C . Note that compounds
234 with vapor pressure $< 10^{-5}$ Torr is estimated to undergo negligible evaporation with the residence
235 time of $\sim 0.2 \text{ s}$ in the aerodynamic lens (Tobias et al., 2000). After sampling for 30 min, the
236 vaporizer was warmed by room air to -5°C and then heated at 2°C min^{-1} to 200°C . Compounds
237 desorbed according to volatility and entered a quadrupole mass spectrometer, where they were
238 ionized by 70 eV electrons prior to mass analysis. In one recent n-hexadecane experiment, the
239 composition of nitrate, hydroxyl, carbonyl (ketone + aldehyde), carboxylic acid, ester, and
240 peroxide functional groups in SOA was measured using derivatization-spectrophotometric
241 methods, with the amount of $-\text{CH}_2-$ groups calculated by difference (Ranney et al., 2023). We
242 note that in that experiment the SOA yield measured by filter sampling was nearly identical to
243 the one we measured previously after applying the above correction.

244

245 **Results and discussion**

246 **SOA yields and viscosity.**

247 Figure 1 shows comparisons of measurements and modeling for (a) SOA yields, (b)
248 functional group distributions, (c) N:C ratios, and (d) O:C ratios. Figure 1(a) shows the
249 measured yields of SOA generated from the oxidation of n-alkanes ($\text{C}_n\text{H}_{2n+2}$; $n = 8 - 17$) (Lim
250 and Ziemann, 2009b). The model base case (black line) with mass accommodation coefficient
251 of 1 for all species represents no kinetic limitations in the particle phase and the results are

252 similar to previous simulations performed by La et al. (2016). Vapor wall loss was considered
253 based on experimental observations and previous modeling studies (Krechmer et al., 2016; La
254 et al., 2016; Lim and Ziemann, 2009b), which is important to account for as no wall loss would
255 lead to a significant overestimation of SOA yields, as shown in the black dotted line and was
256 discussed in detail in La et al. (2016). Both experimental and simulated SOA yields increase
257 with an increase of n , reflecting the decrease in volatility of the precursor and its oxidation
258 products (Shiraiwa et al., 2014). The observed SOA yield trend is consistent with measurements
259 by a thermal desorption particle beam mass spectrometer, showing that n-alkane SOA are
260 composed of less oxidized products with lower volatility for precursors with higher n (Lim and
261 Ziemann, 2009b, a).

262 The overall good agreement suggests that multigenerational chemistry in the gas phase
263 and partitioning of semi- and low-volatile products, as explicitly treated by GECKO-A box
264 modeling, are the dominant pathway of n-alkane SOA formation under these conditions. It also
265 suggests that peroxy radicals (RO_2) mainly react with NO_x , minimizing auto-oxidation and
266 gas-phase dimerization by $\text{RO}_2 + \text{RO}_2$ reactions. Good model agreement also suggests that
267 particle-phase oligomerization chemistry is not a dominant process, while particle-phase
268 unimolecular reactions including cyclization of hydroxyketones and dehydration of cyclic
269 hemiacetals forming dihydrofurans are treated in the model as they are important for the further
270 oxidation due to the presence of a double bound in the dihydrofurans (Lim and Ziemann, 2009a;
271 La et al., 2016). Thus, the GECKO-A model seemingly treats all essential processes for
272 simulations of n-alkane SOA formation under high NO_x conditions. Note that a very recent
273 study suggested that cyclic hemiacetals form acetal dimers in the particle phase for SOA formed
274 from the reaction of n-hexadecane SOA and OH/NO_x (Ranney et al., 2023). In addition,
275 particle-phase chemistry was shown to be substantial in n-alkane SOA formation under low
276 NO_x conditions through peroxyhemiacetal and oligomer formation (Shiraiwa et al., 2013;
277 Ziemann and Atkinson, 2012). The impact of such particle-phase chemistry may warrant further
278 investigations by future model development and experimental studies.

279 To explore the potential impacts of particle phase state on SOA formation and
280 partitioning, we implemented an effective mass accommodation coefficient (α_{eff}) which can
281 effectively consider kinetic limitations of bulk diffusion and also account for the effect of vapor
282 pressure on partitioning kinetics for species with various volatilities (Shiraiwa and Pöschl,
283 2021). Bulk diffusivity evolves upon SOA formation, which can be derived by viscosity and T_g
284 as predicted from the machine learning-based tgBoost model (dashed green line in Fig. 1a) and
285 the compositional parametrization (CP, dashed orange line in Fig. 1a). The simulated SOA

286 yields with tgBoost are very similar to the base case scenario with $\alpha = 1$, while the application
287 of the CP leads to smaller SOA yields for $n = 15-17$. These results indicate that α_{eff} is close to
288 1 with little kinetic limitations of bulk diffusion for most cases, except some limitations are
289 predicted by CP for large precursors. Deviations of tgBoost and CP stem from the difference in
290 phase state and viscosity predicted by the two methods.

291 Figure 2(a) shows the simulated viscosity and corresponding bulk diffusivity of n-
292 alkane SOA. Remarkably, the two models predict contrasting trends. The simulated glass
293 transition temperature ($T_{\text{g,org}}$) of SOA is presented in Fig. A1. The CP predicts a decrease in
294 $T_{\text{g,org}}$ for C_{8-12} with the lowest $T_{\text{g,org}}$ of ~ 250 K, which is likely due to a decrease of O:C ratio
295 (Fig. 1d) as lower O:C ratio can lead to a decrease of T_{g} (DeRieux et al., 2018; Shiraiwa et al.,
296 2017), followed by an increase of $T_{\text{g,org}}$ with n to reach ~ 270 K with C_{17} . These values
297 correspond to viscosity of $10^4 - 10^6$ Pa s, indicating that n-alkane SOA adopts viscous semisolid
298 phase state. The increase of viscosity for larger precursors is apparently reasonable, as their
299 oxidation products would have higher molar mass which would generally correspond to higher
300 $T_{\text{g,org}}$ (Koop et al., 2011; Shiraiwa et al., 2017). Based on the Stokes-Einstein relation, bulk
301 diffusivity would be in the range of $3 \times 10^{-15} - 10^{-12}$ $\text{cm}^2 \text{s}^{-1}$. The characteristic timescale of bulk
302 diffusion in an average particle diameter of 300 nm can be as low as ~ 2 hours (Shiraiwa et al.,
303 2011), which is longer than experimental timescale of one hour. These low diffusivities and
304 long diffusion timescale can induce concentration gradients in the particle bulk, reducing α_{eff}
305 to cause significant kinetic limitations to retard SOA growth, which is not consistent with the
306 measured SOA yields.

307 tgBoost predicts the opposite trend, predicting a monotonic decrease of $T_{\text{g,org}}$ and
308 viscosity with an increase of n , suggesting that SOA phase state shifts from an amorphous
309 semisolid state ($10^2 < \eta < 10^5$ Pa s) towards a liquid-like phase state ($\eta < 10^2$ Pa s). These
310 results are counter-intuitive as T_{g} values of n-alkanes increases with an increase of n , which can
311 be reproduced with great precision by tgBoost (Galeazzo and Shiraiwa, 2022). The
312 determinants explaining this unexpected trend are chemical composition and molecular
313 structure of the oxidation products as discussed below. The characteristic timescale of bulk
314 diffusion is less than one second in a low viscous state and high bulk diffusivity (Shiraiwa et
315 al., 2011) and SOA particles are expected to be homogeneously well-mixed. Hence, α_{eff} remains
316 very close to 1 with little kinetic limitation of bulk diffusion.

317 Unfortunately, no direct viscosity measurements of n-alkane SOA generated under high
318 NO_x conditions are available to date, while there are two studies for n-alkane SOA generated

319 under NO_x-free conditions. Saukko et al. (2012) (Saukko et al., 2012) observed that n-
320 heptadecane (C₁₇H₃₆) SOA with low O:C ratio did not bounce from an impactor plate. It
321 indicates that these particles adopted a liquid-like state, as indicated by the violet shading in
322 Fig. 2(a), which is consistent with the tgBoost prediction. Shiraiwa et al. (2013) estimated bulk
323 diffusivity of n-dodecane (C₁₂H₂₆) SOA generated without NO_x to be 10⁻¹² cm² s⁻¹ using a
324 kinetic multilayer model to simulate evolution of particle size distribution. While these two data
325 points cannot be directly compared with the viscosity predictions of high NO_x n-alkane SOA,
326 they serve as reference data points for now and direct viscosity or bulk diffusivity
327 measurements of high NO_x n-alkane SOA are warranted in future studies.

328 Figure 2(b) shows the thermal desorption profiles of DOS that was present as seed
329 particles within the SOA formed from oxidation of the n-alkanes. Since DOS desorption
330 involved diffusion through the SOA prior to escape into vacuum, these profiles provided a
331 means for probing the SOA viscosity. The peaks in the DOS profiles for the C₈₋₁₃ and C₁₄₋₁₇ n-
332 alkanes are closely grouped, with vaporizer temperature at ~80 °C and ~65 °C, respectively,
333 with the peak for pure DOS occurring in between at ~72°C. The observed decrease in desorption
334 temperatures from low to high carbon numbers suggests an increase in effective volatility of
335 DOS in SOA generated from larger n-alkanes. In addition, Lim and Ziemann (2009) have
336 observed that C₁₀ n-alkane SOA generated under high NO_x conditions evaporate at higher
337 temperatures compared to C₁₂ and C₁₅ n-alkane SOA based on total ion thermal desorption
338 measurements (Lim and Ziemann, 2009b). Volatility and T_g were shown to exhibit clear
339 anticorrelation (Li et al., 2020); hence, these results strongly indicate that C₈₋₁₃ SOA have higher
340 T_g and viscosity compared to C₁₃₋₁₇ SOA. It is remarkable to note that the C₁₃ profile is bimodal
341 with peaks at ~80 °C and ~65 °C (Fig. 2b), which is in line with tgBoost prediction that the
342 viscosity of C₁₃ alkane SOA is at the edge of amorphous semi-solid and liquid phase states (Fig.
343 2a). These results indicate that n-alkane SOA generated by larger precursors adopt low viscous
344 liquid-like states, while n-alkane SOA generated by smaller precursors adopt viscous semisolid
345 states, in agreement with tgBoost predictions. The major strength of tgBoost is that it considers
346 molecular structure and functionality for T_g predictions, while the compositional
347 parameterization does not account for this effect, leading to intuitive but erroneous predictions.

348

349 **Chemical composition of SOA.**

350 Figure 1 also shows the simulated (c) N:C and (d) O:C ratios of SOA with $\alpha = 1$ (black
351 line) and $\alpha = \alpha_{\text{eff}}$ with T_g determined with tgBoost (green line) or the compositional

352 parameterization (orange line). The N:C ratio is very similar among all simulations being ~ 0.2
353 for C_8 and decreasing progressively to ~ 0.03 with each addition of a carbon atom in the
354 precursor. O:C ratios were calculated in two different ways by treating a nitrate ($-ONO_2$) group
355 to contain either three (solid lines) or one (dashed lines) oxygen atoms. One oxygen atom is
356 also considered because O:C ratios reported from aerosol mass spectrometer measurements
357 generally treat a nitrate group the same as a hydroxyl group, since they have the same effect on
358 oxidation state (Farmer et al., 2010). Similar to the N:C ratio, there is a constant decrease in
359 O:C of SOA with increasing n , which is consistent with previous measurements for n -
360 pentadecane ($C_{15}H_{32}$) SOA (Aimanant and Ziemann, 2013a) and n -hexadecane ($C_{16}H_{34}$) SOA
361 in this study, even though the simulated values are $\sim 45\%$ and 15% lower than the measured
362 N:C and O:C ratios, respectively. The discrepancies are likely due to errors on modeling gas-
363 wall partitioning and gas-particle partitioning. The difference may also be caused by missing
364 processes in the model such as reactive uptake of oxidants and particle-phase chemistry.

365 We measured functional group distributions in n -hexadecane SOA using derivatization-
366 spectrophotometric methods described in Aimanant and Ziemann (2013b), as shown in Fig.
367 1(b) and summarized in Table A1. Experimental measurements report high presence of $-CH_2-$
368 (13.81) and $-ONO_2$ (0.91), followed by ROH (0.41), $RC(=O)$ (0.38), and $RC(=O)OR$ (0.28),
369 with the average measured number of groups per C_{16} molecule in parenthesis. Figure 1(b)
370 includes simulation results by GECKO-A with CP and tgBoost, showing overall satisfactory
371 agreement. The simulated results with tgBoost show excellent agreement for hydroxyl and
372 methylene groups, while the simulated nitrates and carbonyls (ketones + aldehydes) are lower
373 than the measurements. The simulation by CP has also a similar trend, but with significantly
374 lower presence of nitrates, carbonyls, and esters.

375 Figure 3(a) shows the top 15 oxidation products in the particle phase formed by the
376 oxidation of n -hexadecane simulated by GECKO-A box model with tgBoost. Note that
377 positional isomers are lumped into one species and that the five species in the first row
378 constitute majority ($\sim 86\%$) of SOA mass. The simulated SOA is composed mostly by 1st
379 generation products including alkyl nitrates, hydroxynitrates, and hydroxyketones. There is also
380 a significant presence of 2nd and 3rd generation products such as esters and dinitrates. We also
381 found multi-functionalized decomposition products including smaller chain hydroxy nitrates
382 and alkyl lactones as well as particle-phase products from cyclization of hydroxyketones and
383 dehydration of cyclic hemiacetals to form dihydrofurans. A very recent study by Ranney et al.
384 (2023) measured n -hexadecane oxidation products under high NO_x , finding that alkyl nitrates,
385 hydroxyl nitrates, hydroxyl carbonyls, cyclic hemiacetals, and cyclic hemiacetal nitrates are

386 major products. These compounds are indeed major products as shown in Fig. 3a, confirming
387 that GECKO-A simulated n-alkane oxidation very well. There are notable differences in
388 molecular composition for SOA simulated by CP (Fig. A2): the major compounds are 1st
389 generation single and multi-functionalized products, followed by some 2nd and 3rd generation
390 products, without decomposition products in the top species.

391 The simulated T_g by both methods for each compound are listed in Fig. 3. Overall
392 tgBoost predicts T_g to be 157 – 221 K which are much lower compared to CP, especially with
393 significant differences for organic nitrates and multi-functionalized species. As tgBoost
394 considers the molecular structure, functional group and atomic interconnectivity of a molecule,
395 it should make better predictions for multi-functionalized compounds based on the presence of
396 different functional groups. CP is based on elemental composition and it predicts high T_g for
397 compounds with high molar mass, predicting same T_g for isomers. In addition, the CP for
398 CHON compounds was developed based on T_g values mainly estimated from their melting
399 points, as there are limited number of CHON compounds with measured T_g available. T_g of
400 organic nitrates are especially scarce and future T_g measurements for organic nitrates are desired
401 to improve T_g parameterizations. For these reasons, CP overestimates T_g for oxidation products
402 of n-alkane with long chain on average by ~66 K compared to tgBoost, overpredicting SOA
403 viscosity as shown in Fig. 2(a).

404 Figure 3 also lists α_{eff} values, showing that they are very close to 1 for tgBoost, with
405 SOA to be low viscous liquid with little kinetic limitations in mass accommodation. Additional
406 oxidation products with lower concentrations are listed in Fig. A3 and their α_{eff} remain also
407 close to 1. In contrast, as CP predicts the SOA phase state to be viscous amorphous semisolid,
408 α_{eff} values for semi-volatile compounds become significantly smaller to kinetically limit mass
409 accommodation. This decrease of α_{eff} is larger for compounds with higher volatility, as such
410 compounds have higher re-evaporation rate on viscous particles with lower rate of bulk
411 diffusion (Shiraiwa and Pöschl, 2021) (Fig. A3). α_{eff} for lower volatility compounds remain
412 high, as they exhibit much lower desorption rates and are less likely to re-evaporate, even if
413 their diffusion into the bulk is slow. Consequently, SOA simulated with CP mainly consists of
414 later generation products with higher functionalization and molar masses.

415 Figure 3(b) shows top 15 oxidation products of n-decane ($\text{C}_{10}\text{H}_{26}$) as predicted by
416 GECKO-A with tgBoost. SOA is mostly composed of 2nd and 3rd generation products with
417 multiple functional groups including nitrates, ketones, and alcohols. These highly oxidized
418 products have T_g in the range of 225 – 304 K, with similar predictions by CP and tgBoost. This

419 is consistent with previous studies that demonstrated successful applications of CP to predict
420 the measured viscosity of SOA derived from biogenic and other relatively small precursors
421 (DeRieux et al., 2018; Smith et al., 2021; Baboomian et al., 2022). These results are consistent
422 with total ion thermal desorption profiles of n-alkane SOA formed in the presence of NO_x (Lim
423 and Ziemann, 2009b): C₁₀ SOA was observed to have a broad single peak around ~75 °C,
424 indicating the presence of low volatility multigenerational products; in contrast, C₁₂ and C₁₅
425 SOA exhibited two peaks with one larger peak at lower temperature, corresponding to 1st
426 generation products and another smaller peak for multigenerational products. The phase state
427 of n-decane SOA is predicted to be semisolid, but kinetic limitations are not strong as α_{eff} values
428 for most compounds are only slightly reduced from 1.

429

430 **Effects of mass loadings on viscosity.**

431 The use of higher mass loadings in chamber experiments than ambient conditions
432 assured that the condensation of semi-volatile vapors to suspended particles is a dominant
433 process over vapor wall deposition (Zhang et al., 2014; Matsunaga and Ziemann, 2010).
434 Chamber experiments of n-alkane photooxidation at high NO_x were also conducted with lower
435 mass loading by Presto et al. (2010), who measured temporal evolution of SOA yields as shown
436 in Fig. 4(a). SOA yields are increased with an increase of SOA mass concentrations, which is
437 consistent with SOA absorptive partitioning theory (Pankow, 1994). The oxidation of larger
438 precursors leads to higher SOA yields, in agreement with Lim and Ziemann (2009b) as
439 presented in Fig. 1a. As shown with solid lines, the GECKO-A box model simulated
440 experimental observations of SOA yields very well.

441 Figure 4(b) depicts the simulated SOA viscosity. We observed the same trend as Fig.
442 2(a) with lowering of viscosity upon an increase of carbon number n . SOA phase state is
443 predicted to be semisolid for low carbon n , while it is expected to be liquid for high n . The
444 predicted viscosity is about one order of magnitude higher compared to Fig. 2(a). Lower mass
445 loadings suppress partitioning of higher volatility compounds, resulting in higher viscosity as
446 condensation would be dominated by lower volatility compounds with higher T_g (Jain et al.,
447 2018; Champion et al., 2019; Grayson et al., 2016; DeRieux et al., 2018).

448

449 **Atmospheric Implications.**

450 The phase state and viscosity of SOA formed by IVOCs have been largely unknown
451 and unexplored. We demonstrated in this study that SOA derived from small and middle size
452 n-alkane (C₁₂ and smaller) mostly consists of multigenerational oxidation products to adopt an

453 amorphous semisolid state, while larger n-alkane SOA are mainly composed of first generation
454 lightly oxidized products to adopt a low viscous liquid state. This result is counter-intuitive, as
455 it has been established that higher molar mass would lead to higher glass transition temperature,
456 and hence, higher viscosity (Koop et al., 2011; Shiraiwa et al., 2017). In fact, the viscosity of
457 biogenic SOA follows this trend: the viscosity of isoprene (C₅H₈) SOA is reported to be lower
458 than monoterpene (C₁₀H₁₆, such as α -pinene and limonene) SOA (Renbaum-Wolff et al., 2013;
459 Zhang et al., 2019), while oxidation products of sesquiterpene (C₁₅H₂₄) increase viscosity of
460 SOA (Smith et al., 2021), which is captured by empirical parameterizations based on elemental
461 composition (DeRieux et al., 2018; Li et al., 2020). In contrast, n-alkane SOA exhibits an
462 opposite trend, as indicated by thermal desorption measurements that show that DOS in SOA
463 formed by oxidation of large n-alkanes has higher volatility. Hence, the SOA has lower
464 viscosity, due to the enhanced presence of less functionalized first-generation products (Li et
465 al., 2020; Zhang et al., 2019). This trend is successfully predicted by GECKO-A combined with
466 machine learning-based model tgBoost, which emphasizes the importance of consideration of
467 functionality and molecular structure in accurate predictions of T_g . The relationship between
468 viscosity and composition is also reflected in the atomic O:C and N:C ratios of n-alkane SOA,
469 which decrease monotonically upon an increase of carbon number of the n-alkane, since higher
470 oxidation state and functionalization can increase T_g (DeRieux et al., 2018; Koop et al., 2011;
471 Shiraiwa et al., 2017; Saukko et al., 2012).

472 IVOCs have gained growing attention for better characterization of urban air quality, as
473 they represent an important source of SOA as shown by chamber experiments (Aimanant and
474 Ziemann, 2013a; Lim and Ziemann, 2009b) and as observed in field observations (Gentner et
475 al., 2012; Li et al., 2022; Robinson et al., 2007; McDonald et al., 2018). While a few large-scale
476 aerosol models treat IVOC SOA to achieve better agreement with ambient measurements (de
477 Gouw et al., 2011; Li et al., 2022; Zhao et al., 2016), IVOC SOA is still highly uncertain in
478 terms of chemical composition and particle phase state and model parameters and treatments
479 for SOA formation and partitioning are poorly constrained. Our study provides critical insights
480 for these aspects, showing that n-alkane SOA formation under high NO_x conditions (as usually
481 the case for ambient urban air) is dominated by gas-phase chemistry followed by partitioning.
482 As the generated SOA particles adopt a low viscous state, there is little kinetic limitations of
483 mass accommodation and bulk diffusion, which supports the application of equilibrium SOA
484 partitioning in the boundary layer. While the experiments and modeling were conducted for dry
485 conditions in this study, the phase state and viscosity of ambient n-alkane SOA would be
486 expected to be even lower under humid conditions due to hygroscopic growth and water acting

487 as plasticizer. Note that further experiments and model simulations are required for different
488 conditions for middle and upper free troposphere, as viscosity is expected to become higher
489 under low temperatures.

490 It is highly remarkable that the combination of tgBoost and GECKO-A box model
491 accurately simulates SOA yields, functional group distributions and phase state. This new
492 model represents a unique and comprehensive tool for simulating formation, partitioning and
493 chemical evolution of SOA, opening up a new avenue for analyzing complex interplay of gas-
494 phase chemistry and particle-phase processes and composition in SOA for detailed analysis and
495 interpretation of laboratory experiments and field observations. In addition, we propose to
496 pursue the application of this model as a basis for the development of a detailed master
497 mechanism of multiphase aerosol chemistry as well as for the derivation of simplified but
498 realistic parameterizations for air quality and climate models. In regional and global air quality
499 models, it is challenging and computationally very expensive to treat complex SOA multiphase
500 processes. Thus, such processes should be treated in efficient but effective way and the new
501 model shall serve as benchmark for the development of simplified SOA descriptions.

845 **Appendix.**

846

847 **Table A1:** Experimental and simulated functional group distributions, O:C and N:C ratios of
 848 SOA generated from C16 oxidation by OH in presence of high NO_x.

FG/C16 molecule	Experimental	Simulated (tgBoost)	Simulated (CP)
Nitrate	0.91	0.65	0.54
Carbonyl	0.38	0.26	0.15
Hydroxyl	0.41	0.43	0.45
Carboxyl	0.09	0.0	0.0
Ester	0.28	0.2	0.07
Peroxide	0.12	0.01	0.0
Methylene	13.81	12.12	12.07
O:C	0.28	0.25	0.25
N:C	0.06	0.04	0.03
H:C	1.85	/	/
MW	294	/	/
Density (g cm ⁻³)	1.10	1.06	1.06

849

850

851

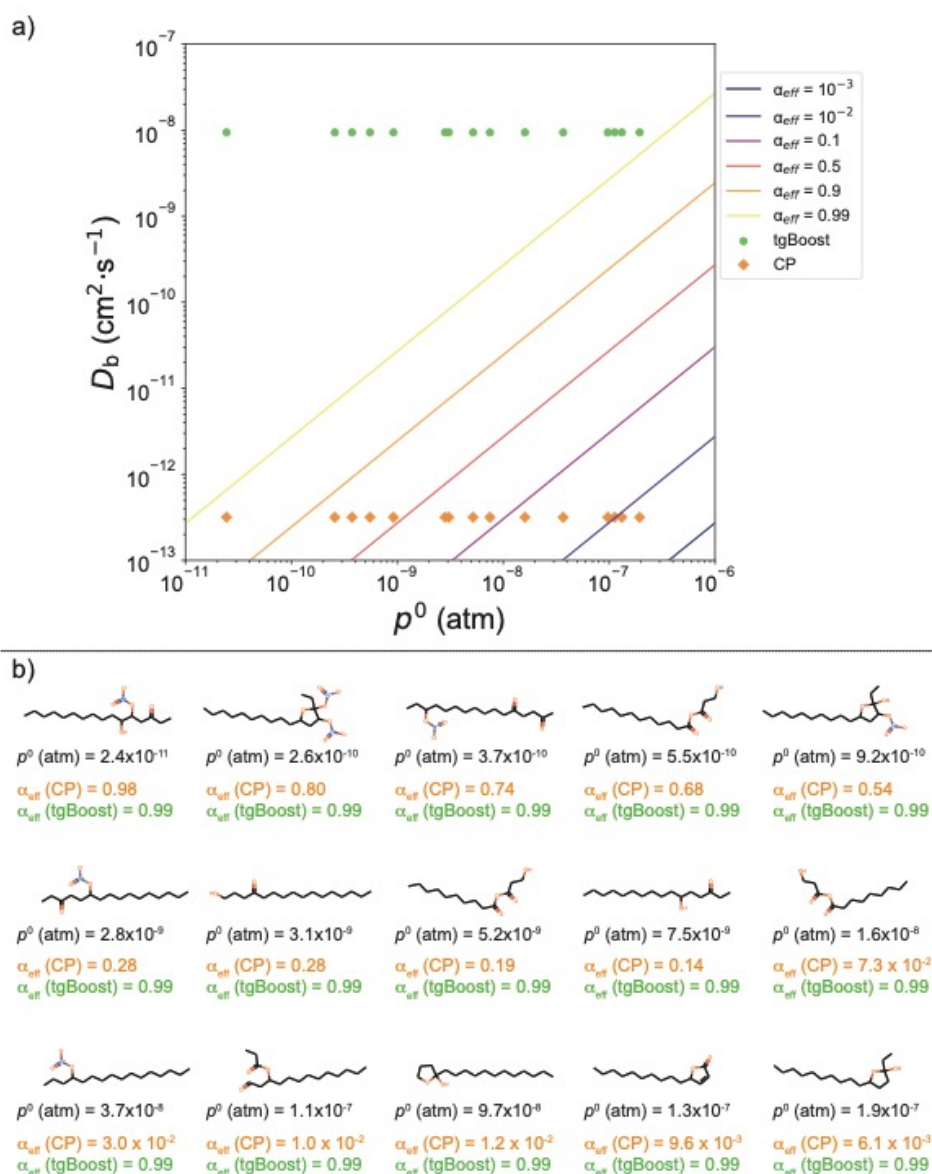

852

853 **Figure A1:** Predicted $T_{g,org}$ of SOA generated from n-alkanes as computed by the GECKO-A
 854 box model with the T_g compositional parametrization (orange line) and tgBoost (green line) at
 855 the last step of the simulations ($t = 3600$ s).
 856

857
 858 **Figure A2.** Top 15 species with highest concentrations in oxidation products of n-hexadecane
 859 ($C_{16}H_{34}$) under high NO_x conditions simulated by GECKO-A with effective mass
 860 accommodation coefficient (α_{eff}) with the compositional parameterization. The species are
 861 reported in descending concentrations from left to right and from top to bottom. Listed values
 862 are T_g as calculated by tgBoost and CP and α_{eff} values at the end of simulation (3600 s) in
 863 brackets. Types of compounds are also noted (1st, 2nd, and 3rd generation products,
 864 decomposition products).
 865

866

867 **Figure A3.** a) α_{eff} isolines as a function of bulk diffusivity D_b and saturation vapor pressure
 868 p^0 of semi-volatile species. b) Selection of various representative SOA contributors produced
 869 during the oxidation of n-hexadecane. The species are ordered by decreasing vapor pressure.
 870 The reported α_{eff} values for each SOA contributor are calculated for D_b estimated with tgBoost
 871 ($D_b = 1 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$) and CP ($D_b = 3 \times 10^{-13} \text{ cm}^2 \text{ s}^{-1}$). The values of α_{eff} for the selected species
 872 are reported as points in the top panel. It shows that for the liquid-like state estimated with the
 873 tgBoost configuration, α_{eff} tend towards 1 for all species. This behavior is not observed in the
 874 amorphous semi-solid state estimated using the CP model configuration for species with p^0
 875 above 10^{-9} atm. For the simulated conditions, species with p^0 between 10^{-8} and 10^{-6} atm are of
 876 enough low volatility to partition between the particle and gas phases at equilibrium. For species
 877 in that volatility range, no mass transfer limitation is observed with the tgBoost configuration,
 878 unlike the CP configuration. Using the CP configuration, the most volatile SOA contributors
 879 are subjected to substantial mass transfer limitation and are therefore mainly eliminated by gas-
 880 phase oxidation or wall deposition.
