11 **Abstract.** We analyze tropical ozone (O₃) and carbon monoxide (CO) distributions in the upper
12 troposphere (UT) for 2005–2020 using Aura Microwave Limb Sounder (MLS) observations and
13 simulations from the Whole Atmosphere Community Climate Model (WACCM) and two
14 variants of the Community Atmosphere Model with Chemistry (CAM-chem), each variant using
15 different anthropogenic CO emissions. Trends and variability diagnostics are obtained from
16 multiple linear regression.

17 The MLS zonal mean O₃ UT trend for 20°S–20°N is $+0.39 \pm 0.28$ %yr⁻¹; the WACCM and
18 CAM-chem simulations yield similar trends, although the WACCM result is somewhat smaller.
19 Our analyses of gridded MLS data yield positive O₃ trends (up to 1.4 %yr⁻¹) over Indonesia and
20 East of that region, and over Africa and the Atlantic. These positive mapped O₃ trends are
21 generally captured by the simulations, but in a more muted way. We find broad similarities (and
22 some differences) between mapped MLS UT O₃ trends and corresponding mapped trends of
23 tropospheric column ozone.

24 The MLS zonal mean CO UT trend for 20°S–20°N is -0.25 ± 0.30 %yr⁻¹, while the
25 corresponding CAM-chem trend is 0.0 ± 0.14 %yr⁻¹ when anthropogenic emissions are taken
26 from Community Emissions Data System (CEDS) version 2. The CAM-chem simulation driven
27 by CAMS-GLOB-ANTv5 emissions yields a tropical mean CO UT trend of 0.22 ± 0.19 %yr⁻¹, in
28 contrast to the slightly negative MLS CO trend. Previously published analyses of total column
29 CO data have shown negative trends.

30 Our tropical composition trend results are contributing to continuing international assessments
31 of tropospheric evolution.

32 **1 Introduction**

33 Tropospheric ozone (O_3) can be influenced by downward transport from the stratospheric ozone
34 layer, but the main O_3 source in the troposphere is in situ photochemical formation through the
35 oxidation of carbon compounds in the presence of (catalyzing) nitrogen oxides ($NO_x = NO + NO_2$)
36 (Crutzen, 1973; Logan, 1985); tropospheric ozone loss is dominated by in situ photochemistry and
37 by deposition at the Earth's surface (Monks et al., 2015). Past studies have also shown that the
38 main sources of tropospheric NO_x are fossil fuel combustion, biomass burning, soil microbial
39 activity, and lightning. Global anthropogenic emissions dominate the natural NO_x sources and
40 biomass burning plays quite a significant role in the tropics. There is evidence from in situ
41 measurements from ozonesondes and commercial aircraft for slow increases in tropospheric and
42 upper tropospheric O_3 abundances (e.g., Cooper et al., 2014; Gaudel et al., 2020; Thompson et al.,
43 2021; Wang et al., 2022). At the surface, regional differences have been noted, for example, a
44 leveling off in ozone increases over western Europe and parts of the United States after the 1990s,
45 including some decreases, depending on the season. Changes in tropospheric ozone precursor
46 emissions (e.g., from NO_x , carbon monoxide – CO, and volatile organic compounds) have been
47 implicated as causes for global tropospheric ozone change over the past few decades (Zhang et al.,
48 2016; Zheng et al., 2018; Liu et al., 2022; Wang et al., 2022). Souri et al. (2017) and Zhang et al.
49 (2016), for example, discussed the existence of decreases in NO_x emissions over developed
50 countries following emission regulations after the turn of the century. In the North Atlantic region,
51 both surface O_3 and CO have decreased; Kumar et al. (2013) showed this for 2001–2011. Such
52 decreases have been attributed to a decline in anthropogenic emissions from North America that
53 more than compensate for emission increases over parts of Asia. Furthermore, after the dramatic
54 reduction in global economic activity following the CoronaVirus Disease 2019 pandemic,
55 significant reductions in northern hemisphere (NH) tropospheric ozone values were observed in
56 2020 and 2021, although the tropical decreases are much smaller (Ziemke et al., 2022; Steinbrecht
57 et al., 2021; Bouarar et al., 2021; Miyazaki et al., 2021).

58 CO is another important pollutant in the troposphere. Its primary tropospheric sources are
59 incomplete combustion (biomass burning emissions and pollution from industrial and traffic-

60 related emissions), and the oxidation of methane and other hydrocarbons (Logan et al., 1981;
61 Crutzen and Andreae, 1990; Khalil and Rasmussen, 1990); its main tropospheric loss pathway is
62 oxidation by the hydroxyl radical (OH). Lower tropospheric CO anomalies are propagated upward
63 by convection and general ascent to produce a tropical “CO tape recorder” (Schoeberl et al., 2006),
64 primarily as a result of biomass burning episodes near the equinoxes (Duncan et al., 2003, 2007;
65 Logan et al., 2008; Nassar et al., 2009; Livesey et al., 2013; Huang et al., 2016). Further insights
66 into the transport of CO pollution into the upper troposphere and lower stratosphere (UTLS) have
67 been provided by Park et al. (2013), who examined CO and other species from the Atmospheric
68 Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS) and MLS. In the tropics, the
69 clear signature of semiannual maxima centered around April and October were observed, primarily
70 over Africa, Indonesia, and South America, with connections to biomass burning and convection
71 patterns. Park et al. (2021) examined CO pollution transport to the UTLS during and long after the
72 highly enhanced 2015 Indonesian fire season, using a combination of CO satellite data and model
73 simulations (with the CAM-chem model). This model produced underestimates in CO
74 comparisons versus tropical upper tropospheric CO from MOPITT, as well as versus MLS and
75 ACE-FTS CO data in this region; those retrievals compared well with MOPITT CO.

76 In terms of tropospheric CO trends, Worden et al. (2013a) found significant CO column
77 decreases for the 2000–2011 period at a rate of -1.5 \%yr^{-1} over Europe, East Asia, and the United
78 States; this work was based mainly on data from the Measurements of Pollution in the Troposphere
79 (MOPITT) and the Atmospheric Infrared Sounder (AIRS) (see also Warner et al., 2013). Using
80 MOPITT data, Laken and Sahbaz (2014) obtained a significant global CO trend of -0.6 \%yr^{-1} from
81 2000–2012; they also pointed to significant increasing trends over parts of Asia, South America,
82 and Africa. Buchholz et al. (2021) found a similar result using 2002–2018 gridded time series from
83 MOPITT CO, AIRS, and other satellite instruments; the global trend for this period was found to
84 be $-0.5 \pm 0.3 \text{ \%yr}^{-1}$, with a slower decreasing trend during 2010–2018. Hedelius et al. (2021) also
85 discussed MOPITT-inferred decreasing trends in column CO for 2002–2017 and pointed out that
86 decreases in CO emissions, obtained from the Emissions Database for Global Atmospheric
87 Research (EDGAR) version 4.3.2, do not always match column CO trends. Analyses of ground-
88 based in situ surface CO data also point to a slowdown in the rate of decrease of CO after 2010, in
89 comparison to the 2001–2010 decade (Patel et al., 2024). There is also a north-south
90 interhemispheric difference in the CO abundances (and total columns), along with faster rates of

91 decrease in the northern hemisphere. Decreasing CO emissions from anthropogenic and biomass
92 burning sources appear to be the main cause of global tropospheric CO decreases (Jiang et al.,
93 2017, Andela et al., 2017), while secondary CO resulting from methane oxidation is increasing
94 (Gaubert et al., 2017). Some steeper CO decreases have been observed in local extra-tropical near-
95 surface data (Li and Liu, 2011; He et al., 2013; Yoon and Pozzer, 2014; Gratz et al., 2015),
96 apparently because of tighter air quality standards and reduced pollution from industrial and
97 traffic-related emissions.

98 The upper troposphere is a complex region where production of NO_x by lightning (Schumann
99 and Huntrieser, 2007; Murray et al., 2014), aircraft NO_x emissions (Hoor et al., 2009; Brasseur et
100 al., 2016; Lee et al., 2021; Wang et al., 2022), and stratosphere-troposphere exchange (STE) (Sudo
101 et al., 2003; Collins et al., 2003; Hegglin and Shepherd, 2009; Hess and Zbinden, 2013; Neu et al.,
102 2014) can significantly impact ozone concentrations; STE plays a larger role in the extra-tropics
103 than in the tropics (Hsu and Prather, 2014). Upper tropospheric trend analyses of in situ CO data
104 from commercial aircraft participating in the In-service Aircraft for a Global Observing System
105 (IAGOS, see Petzold et al., 2015) measurements have indicated decreasing trends from 1995 to
106 2013 in northern midlatitude UT CO, with some larger (and statistically robust) trends as high as
107 -2 to -3 % yr⁻¹ over eastern Asia (Cohen et al., 2018). The UT ozone trends from the latter analyses
108 were found to range between 0.25 to 0.45 ppbv yr⁻¹; this reflects changes of order 0.4–0.8% yr⁻¹.
109 In terms of variability, there are interannual composition changes in the troposphere and in the
110 UTLS associated with ENSO (Chandra et al., 1998; Ziemke and Chandra, 2003; Nassar et al.,
111 2009; Oman et al., 2011, 2013) and related sea surface temperature and pressure changes. It has
112 long been known that this important mode of climate variability that originates in the Pacific
113 Ocean, with alternating warm (El Niño) and cold (La Niña) phases, leads to disruptions in global
114 circulation patterns, and has impacts on fire and wetland emissions that affect tropospheric
115 composition (Feely et al., 1987; Jones et al., 2001; Sudo and Takahashi, 2001; Duncan et al., 2003;
116 Doherty et al., 2006; Calvo et al., 2010; Voulgarakis et al., 2015; Rowlinson et al., 2019).

117 How do changes in the upper troposphere relate to changes in the lower troposphere, such as
118 changes in emissions? There have not been many such studies in the past, in large part because of
119 the lack of well-sampled long-term data in the upper reaches of the troposphere, where ozone is of
120 radiative significance. While this region is not directly connected to surface pollution, fast
121 convection episodes in the tropics imply that there might well be some correlations between lower

122 tropospheric and upper tropospheric abundances, and even for long-term trends. Long-range
123 transport of pollution can, however, extend into the UT, and also back downward with cross-
124 continental impacts on surface pollution levels. Constraints on chemistry climate models are one
125 important goal for studies of long-term measurements of upper tropospheric composition. Such
126 studies are also expected to contribute to continuing assessments of pollutant trends in the
127 troposphere, such as the Tropospheric Ozone Assessment Report Phase II (TOAR-II), while
128 related model simulations are of interest to continuing assessments of chemistry climate models
129 (e.g., CMIP-7).

130 Tropical upper tropospheric profiles of O₃ and CO have been measured on a continuous daily
131 basis by the Microwave Limb Sounder on the Aura satellite, from a near-polar sun synchronous
132 orbit since late 2004. Here, we present results of trends and variability analyses of these data sets
133 (from 2005–2020), along with a similar treatment of UT O₃ and CO time series from two chemistry
134 climate models, “specified dynamics” versions of the Whole Atmosphere Community Climate
135 Model version 6 (WACCM6) and the Community Atmosphere Model with chemistry (CAM-
136 chem), both of which are configurations of the Community Earth System Model version 2.2
137 (CESM2.2). When using regression fits, as done here, to analyze broad-scale atmospheric time
138 series, one should pay attention to likely drivers (e.g., ENSO) of variability in that region, since a
139 better fitting of such variability can reduce the resulting trend uncertainties. Altogether, we use
140 one WACCM simulation as well as two separate CAM-chem simulations (the latter two having
141 different anthropogenic emission inputs for CO), as described in Sect. 2, where we provide more
142 details about the MLS data and these model simulations. Section 3 focuses on the trend analysis
143 methodology. In Sect. 4, we discuss the analysis results for O₃, and then for CO; we review the
144 UT climatologies for these species and some differences versus model simulations, and discuss
145 results from zonal mean and mapped trend analyses. We also place our results in the context of
146 past analyses. We then finish with some brief conclusions in Section 5.

147 **2 Observations, model simulations, and trend analysis methods**

148 For both MLS and the chemistry climate models, we analyze monthly averaged zonal mean
149 time series as well as monthly-averaged longitude/latitude binned time series. The models have
150 been designed to capture key dynamical and chemical processes well enough to be usefully
151 compared to the observations. We focus on a region that is somewhat below the tropopause, to

152 minimize potential effects from stratosphere-troposphere exchange and to avoid results that might
153 depend more on lower stratospheric rather than tropospheric change.

154 **2.1 Observations**

155 The Aura MLS observational dataset considered here is taken from sixteen full years (2005
156 through 2020) of global composition measurements, with about 3500 vertical profiles per day per
157 measured species. The MLS antenna performs scans of the atmospheric limb ahead of the Aura
158 satellite in its near-polar sun-synchronous orbit. MLS measures daytime and nighttime thermal
159 emission using microwave radiometers operating at frequencies near 118, 190, 240, and 640 GHz;
160 a 2.5 THz module measured OH during the early part of the mission. The 240 GHz radiometer
161 provides the standard O₃ and CO measurements. For an overview of the MLS measurement
162 technique, the reader is referred to Waters et al. (2006). Read et al. (2006) gave a description of
163 the simulated MLS forward model and related spectra. The MLS retrievals (Livesey et al., 2006)
164 use the optimal estimation approach (Rodgers, 2000); there is no assumption of atmospheric
165 homogeneity along the line of sight (see Livesey and Read, 2000), and the retrievals make use of
166 the MLS antenna's views along overlapping tangent rays during consecutive scans of the Earth's
167 limb. The specifics of MLS data characterization and data quality, along with estimated errors and
168 related information can be found in the documentation by Livesey et al. (2022).

169 Here, we have used the latest data version from MLS, labeled version 5.0 or v5. More
170 specifically, we use the binned MLS Level 3 data sets, with a latitude grid that includes the
171 equatorial bin (-2° to +2°) and the 44 other adjacent 4°-wide bins. In this work, we use monthly
172 mean time series based on zonal averages as well as latitude bands divided into 12 longitude bins.
173 The typical number of MLS profiles in a monthly zonal mean 4° bin is of order 2400, and about
174 200 for each of the 12 mapped (monthly) longitude/latitude bins. Prior to averaging the MLS data,
175 the standard MLS data quality screening criteria (Livesey et al., 2022) have been applied to all the
176 O₃ and CO Level 2 profiles; this screening removes only a very small fraction (typically 1–3%) of
177 the retrieved profiles. In the troposphere and stratosphere, the MLS O₃ retrieval grid is defined by
178 a subset of the pressure levels given by $p(n) = 1000 \times 10^{-n/12}$ hPa, where n is the pressure level index
179 number; for CO, the grid is twice as coarse, meaning that $n/6$ is used as an exponent in the above
180 equation, rather than $n/12$. The bottom recommended levels for the O₃ and CO retrievals are at 261
181 and 215 hPa, respectively. Our tropical analyses will focus on results between 215 and 147 hPa,

182 in order to largely obtain upper tropospheric results, as more influence from the stratosphere occurs
183 as one gets closer to 100 hPa in the tropics. In the upper troposphere, the vertical resolution of the
184 O₃ and CO products is about 3 km and 5 km respectively (Livesey et al., 2022). In this region, the
185 single-profile precision (1 σ random uncertainty) is 20–30 ppbv (meaning ~35-50%) for O₃ and
186 15–20 ppbv (~20–30%) for CO. For our analyses of monthly MLS averages, the relevant precision
187 for O₃ and CO reduces to ~0.5 ppbv (~1%) for 4° zonal means and ~2 ppbv (~4%) for the gridded
188 data using 30° longitude by 4° latitude bins. In addition, the methodology used by the MLS team
189 to assess the aggregate effects of estimated errors in various input parameters, coupled with
190 validation results (see Livesey et al., 2022), leads to systematic uncertainty estimates (1 σ) of 5–12
191 ppbv (~10–20%) and 15–25 ppbv (~20–35%) for tropical upper tropospheric O₃ and CO,
192 respectively.

193 Following validation work on UT MLS O₃ and CO in the early few years since the Aura launch
194 (Livesey et al., 2008), studies of UT MLS O₃ by Livesey et al. (2013) focused on seasonal and
195 interannual variability and comparisons versus ozonesonde data. Despite sampling differences
196 between these measurement systems, the temporal patterns evident in the MLS UT O₃ data were
197 found to be generally well correlated with the *in-situ* data over different low latitude regions.
198 Distinct seasonality was evident in O₃ and CO (as well as MLS-derived ice water content) over
199 South America and South Africa. Other patterns such as the “wave-one” pattern in tropical O₃ (see
200 Thompson et al., 2000, 2003, Wang et al., 2006) and double peaks in O₃ variability over eastern
201 equatorial Africa (with enhancements around May/June and September to November) were
202 discussed; for MLS UT CO, distinct seasonal behavior was found, for example, in the northern
203 hemisphere tropics, over Eastern Asia and across the Pacific (see also Huang et al., 2012). Livesey
204 et al. (2013) and Huang et al. (2014) discussed the connection between emissions from intense
205 fires over Indonesia in 2006 (following the El Niño-related drought) and dramatic concomitant
206 enhancements in UT CO (from MLS data) over this region. This work has been expanded upon in
207 analyses by Park et al. (2013, 2021) of the significant and long-lasting impacts of more recent El
208 Niño-related droughts and wildfires on tropospheric and lower stratospheric CO abundances.

209 Regarding MLS ozone, previous work has shown vertical oscillations in zonal mean MLS
210 UTLS O₃ profiles (e.g., see Livesey et al., 2022). There are also some biases in MLS tropical UT
211 ozone values, which tend to be on the high side (by 10–20%) with respect to ozonesonde data (see
212 Hubert et al., 2016, Fig. 6), but the above issues are systematic in nature. While we think that

213 neither these biases nor the small vertical oscillations (a few % in magnitude in the region of
214 interest here) would play a major role in changing our MLS UT trend results, given the trend
215 uncertainties (discussed later), any time-dependent effect, if it exists, would be quite difficult to
216 characterize, or provide a fix for.

217 We also compare the CO simulations to CO data from Terra/MOPITT, obtained from
218 multispectral retrievals (V9J) Level 3 dry air total column data, or X_{CO} in ppbv (Deeter et al.,
219 2022). The simulated CO values are smoothed by using the MOPITT a priori columns as well as
220 the 10 layers a priori and averaging kernel profiles, as recommended for a quantitative comparison
221 of modelled and MOPITT X_{CO} .

222 **2.2 Model simulations**

223 We use the Whole Atmosphere Community Climate Model version 6 (WACCM6) and the
224 Community Atmosphere Model with Chemistry (CAM-chem), both of which are components of
225 the CESM2.2 (Danabasoglu et al., 2020). WACCM6 uses the “high-top” set of 70 model levels
226 between the surface and the lower thermosphere (~140 km), while CAM-chem uses 32 layers
227 (“low-top”) that stop in the middle of the stratosphere (~40 km). Both configurations run on a
228 horizontal resolution that is 0.95° latitude x 1.25° longitude and share the same vertical grid in the
229 troposphere, with a vertical resolution in the upper troposphere of about 1.2 km. Both CAM-chem
230 and WACCM6 include the same representations of boundary layer processes, shallow convection,
231 liquid cloud macrophysics, and cloud microphysics (Gettelman et al., 2019). Each model employs
232 the same chemical mechanism processes (labeled TS1). The chemical scheme includes the O_x ,
233 NO_x , HO_x , ClO_x , and BrO_x families, along with CH_4 and its degradation products, as well as
234 primary non-methane hydrocarbons and related oxygenated organic compounds (Emmons et al.,
235 2020). Reaction rates follow the JPL Publication 19-5 recommendation (Burkholder et al., 2019).
236 TS1 includes a total of 231 species and 583 chemical reactions broken down into 150 photolysis
237 reactions, 403 gas-phase reactions, 13 tropospheric, and 17 stratospheric heterogeneous reactions.
238 The photolytic reactions are based on both inline chemical modules and a lookup table approach
239 (Kinnison et al., 2007). Secondary organic aerosols are represented through the Volatility Basis
240 Set approach (Tilmes et al., 2019). Comparisons of oxidants during the Korea–United States Air
241 Quality (KORUS-AQ) experiment in South Korea led to a revision of the heterogeneous aerosol

242 uptake of hydroperoxyl radicals (HO_2) to produce H_2O instead of H_2O_2 and a reduction of the
243 coefficient (γ) from 0.2 to 0.1 (Gaubert et al., 2020).

244 To accurately represent weather conditions as well as the Quasi-Biennial Oscillation (QBO)
245 and to reproduce various modes of middle atmospheric variability, both simulations are run in the
246 ‘specified dynamics’ (SD) mode. The model dynamical constraints are taken from meteorological
247 fields provided by the Modern-Era Retrospective Analysis for Research and Applications version
248 2 or MERRA-2 (Gelaro et al., 2017). Contrary to the previous SD approach, the MERRA-2 fields,
249 here the zonal and meridional winds and temperature, are first regridded to the model horizontal
250 and vertical grids. The model nudging (Davis et al., 2022) is updated at every (30 min) time step
251 using the closest 3-hourly MERRA-2 fields; nudging timescales are set at 6 hours for the CAM-
252 chem simulations and at 12 hours for WACCM6. The 11-year solar cycle variability is taken from
253 the Naval Research Laboratory’s (NRL) solar model, namely the NRL Solar Spectral Irradiance
254 version 2 (NRLSSI2; Coddington et al., 2016). Volcanic SO_2 emissions (used in sulfate aerosol
255 density calculations) are derived for significant volcanic eruptions using the Neely and Schmidt
256 (2016) database updated through the year 2020. The model scenario used here is based on historical
257 forcings (and recent updates) from the Climate Model Intercomparison Project – Phase 6
258 (Meinshausen et al., 2017). The forcings include greenhouse gases (CH_4 , N_2O , and CO_2) and
259 organic halogens. After 2014, the greenhouse gas and organic halogen inputs follow the CMIP6
260 SSP5-8.5 scenario that projects inputs beyond 2014 (O’Neill et al., 2016; Riahi et al., 2017;
261 Meinshausen et al., 2020).

262 The emissions used here are taken from CAMS-GLOB-ANT_v5.1 in the simulation we refer
263 to as CAM-chem-CAMS (CAMS is the Copernicus Atmosphere Monitoring Service) and CAMS-
264 GLOB-ANT_v5.3 in the WACCM simulation (labeled WACCM-CEDS) for all surface
265 anthropogenic emissions (Soulié et al., 2024). CO anthropogenic emissions were found to be too
266 low in South Asia and China (Gaubert et al., 2023), so these emissions were replaced by the
267 Community Emissions Data System (CEDS) v2, presented in McDuffie et al. (2020), for the CAM-
268 chem-CEDS simulation also analyzed here, and for the only WACCM simulation used here. The
269 CO anthropogenic emissions from the aforementioned versions 5.3 and 5.1 are almost identical;
270 version 5.3 only includes updates to shipping emissions for years after 2017. As there are no
271 differences in the NO_x or volatile organic compounds (VOC) emissions in all three simulations,
272 we can exclude a change in CO trends between these simulations as a result of differences in CO

273 chemical formation or sink. Daily biomass burning emissions are obtained from the Quick-Fire
274 Emissions Dataset (QFED) 2.5 (Darmenov and da Silva, 2014) in all three simulations.

275 The lightning NO_x production and its role in ozone formation is reviewed by Verma et al.
276 (2021). This study showed that most lightning activity occurs within deep convective clouds in the
277 tropical and subtropical region. In our study, the emission of NO from lightning is based on the
278 Price parametrization (Price and Rind, 1992; Price et al., 1997). This parameterization
279 is dependent on cloud height, which includes a stronger dependence over land versus ocean
280 (Emmons et al., 2010). The CAM-Chem and WACCM models used here derive tropical (and
281 global) lightning NO_x values of 2.34 (3.23) and 2.78 (4.11) Tg (N) yr^{-1} , respectively (Table 1),
282 with no significant trends over the course of these simulations. These global values are within the
283 generally accepted global range of 3–8 TgN yr^{-1} for lightning NO emission (Schumann and
284 Huntrieser, 2007).

285 Aircraft emissions from CMIP6 were employed in WACCM6 (see Hoesly et al., 2018). Both
286 CAM-chem simulations use the version 2.1 of CAMS-GLOB-AIR for aircraft emissions described
287 by Soulié et al. (2024). Gaubert et al. (2020, 2023) found that this version of CAM-chem tends to
288 overestimate tropospheric oxidants, such as ozone, hydrogen peroxide, nitric acid, and hydroxyl
289 radical, resulting in a shorter lifetime of tropospheric methane and CO, mainly in the northern
290 hemisphere extra-tropics. Some of the main model characteristics (with a focus on the differences)
291 are summarized in Table 1.

292 In terms of the model run analyses, we follow the same basic approach as for the MLS data.
293 The daily model profiles are first interpolated (as a function of $\log(\text{pressure})$) onto the MLS
294 pressure grid and then binned and averaged to produce the monthly zonal means (on a 4° latitude
295 grid) and gridded data on the same latitude/longitude grid as is described in Sect. 2.1 for MLS. We
296 note also that we do not find much impact on the MLS versus model comparisons if we use a
297 vertically smoothed version of the model profiles, which more properly takes into account the
298 vertical resolution of the MLS observations, as the differences between smoothed and unsmoothed
299 zonal mean values are much smaller than the model biases. For general simplicity, and for the
300 above reasons, we use unsmoothed model values in this work. A more detailed example of
301 smoothed model profile analyses is provided further below, in connection with observed seasonal
302 CO differences between the models and the MLS measurements.

303 **2.3 Trend analysis methods**

304 For both MLS and model time series trend analyses in the upper troposphere, we use the
305 multivariate linear regression (MLR) method discussed as part of similar studies performed by
306 Froidevaux et al. (2019) for the stratosphere. We refer the reader to Appendix (A3) of the above
307 reference for more details on the regression fit model, which includes commonly used functional
308 terms, namely a linear trend, and cosine and sine functions with annual and semi-annual
309 periodicities, to account for these known variabilities in atmospheric composition, with 3- and 4-
310 month periodic components to better fit shorter-term (intra-seasonal) variations, which also helps
311 to reduce the trend error bars. In addition, we include functions describing multi-year variations
312 caused by the QBO (which mostly affects the stratosphere) and by ENSO, which has been tied, for
313 example, to regional droughts and biomass burning events, with related increases in convection
314 and transport of surface pollution into the upper troposphere. The QBO-related equatorial wind
315 dataset is obtained from the publicly available datasets at the Free University of Berlin. ENSO-
316 related data are in the form of a multivariate index, following the initial work of Wolter and Timlin
317 (2011), as updated by Zhang et al. (2019). We have also included a fitted component that follows
318 variations in solar radio flux (at 10.7 cm), based on Canadian solar measurements (Tapping, 2013);
319 this component typically plays a negligible role in our results. For trend uncertainty estimates, as
320 discussed also by Froidevaux et al. (2019, 2022), we use the block bootstrap resampling method
321 (Efron and Tibshirani, 1993), as done by Bourassa et al. (2014) and others in such atmospheric
322 composition analyses. For every fitted time series, we analyze thousands of re-samplings of the fit
323 residuals, with year-long blocks of residual values replaced by residual series from randomly
324 chosen years; twice the standard deviations in these random distributions' trends provide the (2σ)
325 trend uncertainty values that we use as trend error bars throughout this work.

326 **3 Results**

327 **3.1 Tropical UT O₃**

328 **3.1.1 O₃ climatologies**

329 Although this work focuses on variability and underlying trends, we start in Fig. 1 by showing
330 annually-averaged climatological ozone comparisons between MLS, the WACCM-CEDS
331 simulation, and the CAM-chem-CEDS simulation for 2005–2020 at 147 and 215 hPa for low

332 latitudes (4-degree bin centers between 24°S and 24°N); mapped fields and zonal mean line plots
333 are compared in this Figure. At 215 hPa near 20°N and 20°S, the zonal mean O₃ values from both
334 models are ~5–15% lower than the MLS fields; differences of this order are also observed in the
335 mapped fields. The differences reach about -20% in the deep tropics, as the MLS latitudinal
336 gradients are flat in this region, in contrast to the models' more curved behavior, with a minimum
337 at the equator (see panel (k)). The differences observed here are within the MLS systematic
338 uncertainties mentioned in Sect. 2.1 (up to 24 ppbv, 2σ). These two models agree quite well in the
339 UT region as a whole (typically within about 5 ppbv); such a good level of agreement is not too
340 surprising, given that these models are based on a very similar framework, with nearly identical
341 inputs (see Sect. 2.2). At smaller pressures (147 hPa and also for 100 hPa, which is not shown
342 here), the models follow the MLS latitudinal gradients better (see panel (d) for the comparison at
343 147 hPa), as well as the longitudinal features (including the well-known wave-one ozone pattern
344 discussed by Thompson et al., 2000, 2003, Wang et al., 2006, and others). However, the models
345 exhibit a positive average bias versus MLS at these two pressure levels (see panel (e), where the
346 model bias for 147 hPa is about +20%). However, MLS UT O₃ profiles have been found to be
347 biased positively (by about 10–20%) versus averaged tropical ozonesonde profiles (Sect. 2.1).
348 Thus, positive model biases versus MLS ozone in the tropical UT are not likely caused by a
349 significant underestimate by MLS. We note that the positive model biases (at 147 and 100 hPa)
350 occur for all months of the year (not shown here), so this is not caused by a very large bias in some
351 months, that could be partially compensated for by negative model biases in other months.

352 As mentioned previously, we focus on the upper tropospheric region, somewhat removed from
353 the tropopause, with 147 to 215 hPa being the main levels of interest in the analyses below; while
354 the UT average differences between model and MLS are worth noting, this is not a primary concern
355 in terms of the trend comparisons that we focus on here.

356 **3.1.2 O₃ zonal mean trends**

357 Figure S1 gives some time series examples for ozone at 12°N and 12°S at 147 and 215 hPa,
358 with the MLS and modeled (WACCM-CEDS) series and their respective regression fits, along
359 with the fitted trend lines. The linear correlation coefficients listed above each panel provide a
360 measure of how well the chemistry climate model can fit the MLS series variability. The UT O₃
361 WACCM-CEDS trends roughly follow the trends that are obtained from the MLS regression fits.

362 Regarding the ozone trends, we now switch to results from our analyses of the monthly zonal
363 mean MLS and model time series. Figure 2 displays ozone trend results for MLS and the three
364 simulations for 147, 178, and 215 hPa, based on a multiple linear regression analysis of the
365 respective time series from 2005 through 2020. Figure 2 shows that the tropical upper tropospheric
366 MLS ozone trends are generally positive and significant (meaning that a zero trend lies outside the
367 2σ estimate of trend uncertainty). The observed average ozone trends at all three pressure levels
368 lie within about 0.3 to 0.5 % yr⁻¹; the peak average trends occur at 178 hPa. There are fairly small
369 latitudinal differences at 178 and 215 hPa. At 147 hPa, the MLS results indicate ~50% larger trends
370 in the NH tropics than in the SH tropics, although this difference is not significant. The zonal mean
371 MLS ozone trend (averaging the three pressure levels at 147, 178, and 215 hPa) for 2005–2020 in
372 the 20°S–20°N UT region is 0.39 ± 0.28 % yr⁻¹. The error bars here indicate the 2σ trend uncertainty
373 (calculated here as the root mean square of the 2σ trend uncertainties at all three pressure levels in
374 Fig. 2). This tropical UT O₃ trend is equivalent to 0.21 ± 0.15 ppbv yr⁻¹ (based on the annual
375 average tropical UT values of 56 ppbv measured by MLS). The corresponding model O₃ zonal
376 mean trend results obtained here for 2005–2020 have a positive trend, with excellent agreement
377 with MLS from CAM-chem-CEDS (0.38 ± 0.28 % yr⁻¹) and nearly identical results from CAM-
378 chem-CAMS (0.38 ± 0.29 % yr⁻¹). This agreement is also apparent in the latitudinal pattern, with
379 larger trends in the NH than in the SH, even if the error bars are large enough that there is no
380 “statistically significant difference” between the hemispheres. There is also good statistical
381 agreement between the MLS zonal mean ozone trends and the slightly smaller WACCM-CEDS
382 trends (0.21 ± 0.23 % yr⁻¹).

383 We note that statisticians have been working to guide “common practices” regarding
384 statements of “significance”, and one should be sensitive to some of the broad differences that
385 occur even within “formal criteria” (such as 2σ or a p-level of 0.05), which could sometimes be
386 interpreted too strictly (Wasserstein et al., 2019), as pointed out also by Y. Cohen (private
387 communication, 2024). We keep this in mind here, but we also wish to comment on the use of
388 broader latitude bins. Indeed, if broader latitude regions were analyzed for trends, the
389 corresponding trend uncertainties would be reduced, which could make some of the compared
390 trends differ by more than their 2σ error bar variability. However, the trend error reduction in our
391 testing with a 20°-wide latitude bin instead of 4° bins is only 5–10%, so the uncertainties get
392 divided by much less than the square root of the number of bins used. Thus, we do not readily

393 obtain more significant differences in our comparisons by just averaging over broader regions.

394 In Figure 3, the MLS and CAM-chem-CEDS UT O₃ trend sensitivity analysis is repeated for
395 2005–2018, 2005–2019, 2006–2020, and 2007–2020, showing the relative insensitivity of the
396 MLS results to the choice of time period. This is also true for the CAM-chem-CEDS trends in the
397 NH tropics, although there is more ozone trend sensitivity to the time period choice in this model’s
398 results over the SH tropics. The WACCM-CEDS tropical UT ozone trend results versus time
399 period (not shown here) lead to a spread in the SH tropical trends that is about halfway between
400 the small MLS trend spread and the larger CAM-chem-CEDS trend sensitivity shown in Fig. 3.

401 **3.1.3 O₃ mapped trends and variability**

402 We now turn to the mapped tropical UT trends by analyzing subsets of the O₃ fields from MLS
403 and the models, based on monthly mean time series for 2005–2020 in latitude/longitude bins,
404 rather than on zonal means. As mentioned previously, these bins are also 4° wide in latitude, and
405 the longitude bins are 30° wide. The same regression methodology as described previously here is
406 used for each of the binned time series; we focus on the WACCM-CEDS and CAM-chem-CEDS
407 ozone trends, as we have found that the CAM-chem-CAMS and CAM-chem-CEDS results are
408 quite similar, in the case of ozone at least. Figure 4 shows the resulting mapped O₃ trends from
409 MLS and the two models for 147 and 215 hPa (top and bottom rows, respectively), with the maps
410 spanning 26°S to 26°N. Hatched bins indicate trends for which the 2σ uncertainty range
411 encompasses the zero trend value which is often interpreted as a low level of “statistical
412 significance”, although one should be cautious (see the previous Section) regarding the strict
413 application of such a criterion or wording. The largest MLS trends are observed over the
414 Indonesian region and (mostly) to the East of that region, as well as over the northern Atlantic.
415 The mapped trends confirm the overall zonal mean result of slightly larger O₃ trends in MLS than
416 in WACCM-CEDS. Broad regions with positive tendencies are observed in both model trend
417 results; these regions include SouthEast Asia, Indonesia, northern Australia, the Atlantic, and
418 northern Africa, with some, but not exact agreement with the regions mentioned above for the
419 larger MLS trends. At 215 hPa, the slightly larger positive trends in CAM-chem-CEDS than in
420 WACCM-CEDS over the Australian region (bottom right quadrant, south of the equator)
421 contribute to the better correspondence between the zonal mean O₃ trend results (Fig. 2c) between
422 CAM-chem-CEDS and MLS over the southern tropics. The mapped trend discrepancies between

423 the simulations and MLS are rarely outside the 2σ error bar ranges. Nevertheless, some of the
424 discrepancies are worth noting, especially when they cover multiple adjacent bins; in particular,
425 the easternmost longitude band shows MLS trends with (significant) positive values, in contrast to
426 the simulation results, with binned trends that are often small and/or negative.

427 We have compared these mapped ozone trend results to those for tropospheric column ozone
428 (TCO) obtained by Ziemke et al. (2019), using a combination of total O₃ columns from the Aura
429 Ozone Monitoring Instrument (OMI) and MLS-based stratospheric O₃ columns. In Fig. 5, we show
430 in the top two rows the trends from MLS ozone at 178 hPa (top map) versus the bottom map which
431 provides the mapped TCO trends for the same time period, arrived at from appropriate horizontal
432 smoothing of the results obtained following the above reference, to make the MLS and TCO
433 horizontal resolutions comparable; this smoothing comes from an interpolation versus latitude and
434 a weighted averaging in longitude, since the TCO results have finer longitudinal resolution (5°-
435 wide bins) than the MLS longitudinal grid used here (30°-wide bins). Similarities are observed in
436 the longitudinal pattern of UT MLS O₃ and TCO trends, as shown also for 3 different latitude bins
437 in panel (c) of Fig. 5; variations of a factor of two to three are observed, mostly in the northern
438 half, between the western and eastern hemispheres for both sets of trends, which tend to lie between
439 roughly 0.3 and 1.2 % yr⁻¹. However, the agreement between MLS UT O₃ and TCO trends is often
440 worse for other MLS pressure level choices; this can be deduced from panel (d), where R
441 (correlation coefficient) values relating to the longitudinal variations obtained from MLS at
442 different pressures versus the longitudinal variations in TCO are displayed as a function of latitude
443 (y-axis). In fact, one might not expect the MLS ozone UT trends to track the TCO trends very well,
444 given that TCO measures the entire column whereas MLS measures trends in a vertical region
445 about 5 km wide in the upper troposphere, but this was worth looking into. Regional variability
446 and horizontal sampling differences between MLS and OMI will also play a role (see Thompson
447 et al., 2021, for variability aspects of sonde-derived tropospheric trends). Our comparisons imply
448 that the correlation between lower and upper tropospheric ozone trends is not a strict “one-to-one
449 mapping”, but there are nevertheless some similarities between these regions.

450 We have also analyzed the level of explained variance in the regression fits for these binned
451 trend results. Figure 6 shows the square of the correlation coefficient values (R^2) as a function of
452 latitude and longitude for different explanatory variables used in the binned O₃ fits at 147 hPa,
453 based on fit comparisons to the MLS series (top 6 panels), and for the regression fit versus the

454 WACCM-CEDS series (bottom 6 panels). We have ignored the solar component in these plots as
455 it was found to be of negligible importance; we display the remaining contributions, namely the
456 annual, semi-annual, short-term (sum of the 3-month and 4-month terms), QBO, and ENSO terms,
457 as well as the contribution from the full regression fit, which shows that most (but certainly not
458 all) of the time series variance can be explained by such a regression model. The annual term and
459 semi-annual terms can generally explain a large part of the variance, usually followed in
460 importance by the ENSO term, over most of the Pacific. The QBO component is very small in the
461 upper troposphere, even though it is a well-known and large contributor to stratospheric trace gas
462 variability in the lowermost stratosphere. There is also a significant annual cycle in the tropical
463 lowermost stratosphere related to variations in vertical velocities and in the Brewer-Dobson
464 circulation (Randel et al., 2007; Witte et al., 2008). The R^2 patterns observed in the MLS panels
465 are reproduced in a broad sense by the fits to the CCM, as shown in the bottom 6 panels; this is
466 also a result of the close match between the CCM and the MLS O_3 time series, shown earlier in
467 this work. The ENSO model pattern for O_3 does not match the MLS-derived pattern that well over
468 Indonesia, but this comparison is generally better in the Pacific region between -90° and -180° . A
469 somewhat weaker R^2 value in the model simulation also exists in parts of the Eastern hemisphere
470 for the semi-annual term. The combination of these differences helps to explain the somewhat
471 poorer overall fits (and variance contributions) for the model than for MLS. For the most part, it
472 does not matter much which model run is used for these analyses, or even which pressure level is
473 used; indeed, the results at 215 hPa (see Fig. S5) are generally similar to those in Fig. 6.

474 To pursue the ENSO-related patterns further, one can obtain a (mapped) sensitivity coefficient
475 to ENSO from the regression fits regarding this component's importance in ppbv/K (where "K"
476 relates to tropical sea surface temperatures changes). The O_3 ENSO sensitivity is shown in Fig. 7
477 for the 2005–2020 MLS and WACCM-CEDS results at 147 and 215 hPa. This provides more
478 information about the sign of the sensitivity over different regions, and we observe generally
479 positive (negative) sensitivity in the Eastern (Western) hemisphere, for both MLS and WACCM-
480 CEDS cases; moreover, at 147 hPa, there are two strong negative minima on each side of the
481 Equator in the central Pacific region. A positive change (or a negative change) in tropical Pacific
482 sea surface temperatures during El Niño (La Niña) conditions will correlate with ozone increases
483 (decreases) in the regions with positive (negative) sensitivity coefficients. The model results are
484 quite consistent with those from MLS in terms of the ENSO-related sensitivity coefficient patterns

485 and magnitudes, although the model response is often slightly smaller than seen in the MLS result.
486 As we discuss further below, such ozone sensitivity patterns have been described and interpreted
487 before. Figure 16 provides the same analysis, but for the CO sensitivity to ENSO. These maps
488 show a positive CO ENSO sensitivity coefficient throughout the tropics, with local maxima in both
489 the Eastern and Western hemispheres, rather than the O₃ dipole (positive/negative) structure shown
490 in Fig. 7. The model CO ENSO sensitivity broadly matches the MLS results, although it is not as
491 strong; the different patterns in the western hemisphere, compared to the O₃ sensitivity to ENSO,
492 might be caused by differences in O₃ and CO vertical profile gradients in these regions, but this
493 would require further detailed investigations. We also note that, especially in the MLS case, the
494 peak magnitudes of the CO ENSO sensitivity coefficients in Fig. 16 match the peak magnitudes
495 of the positive O₃ ENSO sensitivity in Fig. 7.

496 **3.1.4 O₃ discussion** 497 498

499 We have found some climatological differences between the MLS observations of O₃ in the
500 tropical upper troposphere and the WACCM-CEDS simulation, as well as both CAM-chem
501 simulations. The models underestimate the mean MLS O₃ values at 215 hPa; at 147 hPa, the
502 models are biased high by about 15–25%, and we have no reason to believe that such positive
503 biases result from an average negative bias in the corresponding MLS values.

504 The averaged zonal mean tropical UT O₃ trend from MLS for 2005–2020 is $0.39 \pm 0.28 \text{ \%yr}^{-1}$
505 (or about $0.22 \pm 0.16 \text{ ppbv yr}^{-1}$), where the error bars indicate 2σ uncertainties. We note that the
506 MLS ozone profile trend detection capability lies within the most stable among ozone sounders,
507 based on the satellite and ground-based ozone intercomparison work by Hubert et al. (2016). In
508 addition, differences between stratospheric ozone columns from MLS and the Aura Ozone
509 Monitoring Instrument (OMI) exhibit no significant drift (Ziemke et al., 2019), thus providing
510 added confidence in the temporal stability of both measurement systems; also, we expect a similar
511 level of confidence in the stability of MLS CO, since CO is retrieved using the same radiometer
512 as the MLS standard ozone product. We get excellent agreement with MLS tropical UT zonal
513 mean trends from the CAM-chem-CEDS O₃ zonal mean trends ($0.38 \pm 0.28 \text{ \%yr}^{-1}$) and somewhat
514 poorer agreement from the smaller WACCM-CEDS trends ($0.21 \pm 0.23 \text{ \%yr}^{-1}$). We also show that
515 the zonal mean MLS O₃ tropical UT trend results for different time periods, with start and end

516 years adjusted by 1–2 years, do not significantly depart from the 2005–2020 results; there is more
517 sensitivity to the choice of period in the CAM-chem-CEDS trend results over the southern tropics.

518 In terms of mapped ozone trends, the largest MLS-derived tropical trends (up to $+1.4\% \text{ yr}^{-1}$) are
519 observed over Indonesia and East of that region, as well as over the northern Atlantic region. The
520 mapped model O_3 UT trends broadly match the MLS trends, albeit with somewhat smaller
521 variations. The significant model maxima over Southeast Asia and the North Atlantic are similar
522 to the significant MLS patterns in those regions. More qualitatively, the Indonesian region displays
523 smaller model O_3 trends than those derived from MLS data; parts of the western Pacific region
524 exhibit some negative trends in the MLS and model trends, but not with good spatial correlation.
525 The mapped MLS-based UT O_3 trends and TCO trends for the same period (see Fig. 5), based on
526 the analyses of Ziemke et al. (2019), provide good correlations in parts of the tropics, with similar
527 values and longitudinal patterns; however, the MLS UT O_3 trend maxima over the western Pacific
528 are symmetric about the equator, whereas the TCO maxima in that region are found in the northern
529 part only. Since the TCO measurement weighting does not favor the UT region, we would not
530 necessarily expect a really high correlation versus the MLS UT trends.

531 There have been large differences between past satellite-based tropospheric O_3 trends (Gaudel
532 et al., 2018). Leventidou et al. (2018) pointed out that tropical tropospheric ozone column trends
533 derived from a combination of European satellite measurements from 1996 to 2015 showed
534 regional increases as large as $1\text{--}2\% \text{ yr}^{-1}$, with some negative trends over the oceans, but with
535 significant uncertainties (see also Heue et al., 2016, and Ebojie et al., 2016). The TCO analyses by
536 Ziemke et al. (2019) using combined OMI and MLS ozone columns showed that TCO trends are
537 larger for 2005–2016 than in the two decades before 2005; for 2005–2016, the derived TCO
538 tropical trends are $\sim 0.4\text{--}0.7\% \text{ yr}^{-1}$ (see also Gaudel et al., 2020). These two investigations found
539 regional differences in TCO trends, with maxima over India, Southeast Asia, the eastern Pacific
540 region and tropical Atlantic, with near zero or slightly negative TCO trends over the Western
541 Pacific. Similar TCO trends (based on combined OMI and MLS data) were also given by Liu et
542 al. (2022) for the 2005–2018 period.

543 A recent study (Gaudel et al., 2024) of tropical tropospheric ozone trends from several satellite-
544 based and in situ datasets between 1994 and 2019 yields “maximum mid- and upper tropospheric
545 increases above India, Southeast Asia and Malaysia, with values from 3.4 ± 0.8 to 6.8 ± 1.8 ppbv
546 decade $^{-1}$.” The tropical UT O_3 trend results obtained here from MLS data, converted to the same

547 units, are 2.2 ± 1.6 ppbv decade⁻¹, which is consistent with the above results, considering also that
548 the maximum mapped UT trends obtained here (about 1.4 %yr⁻¹) translate to ~8 ppbv decade⁻¹.
549 The MLS-derived results for zonal mean tropical UT trends versus latitude are tabulated in Table
550 S1 in both sets of units. The OMI/MLS tropical trends (2004–2021) from the above reference are
551 listed as 2 ± 5 % decade⁻¹ for 0 to 20°S and 3 ± 2 % decade⁻¹ for 0 to 20°N; these numbers are
552 consistent with the slightly larger UT averages from MLS, which show an increase from ~3 %
553 decade⁻¹ near 20°S to ~4 % decade⁻¹ near 20°N (see Table S1 for more details).

554 Regarding other past O₃ trend results for the upper troposphere, IAGOS-derived trends were
555 previously discussed by Cohen et al. (2018) for the 1994–2013 period, but with an emphasis on
556 the extra-tropics. The IAGOS trend analysis by Gaudel et al. (2020) for 5 tropical regions over
557 1994–2016 gave positive UT trends averaging ~0.6 % yr⁻¹, with largest values over Southeast Asia.
558 As mentioned above, the MLS results also show peak ozone trends over this general region. Wang
559 et al. (2022) showed that ozone trends from ozonesonde profiles for a very similar time period
560 agree broadly with IAGOS results, although the sonde spatio-temporal coverage is limited, and
561 there can be significant scatter in trends from various sonde sites. Their non-satellite UT data sets
562 and derived trends are similar to those from Gaudel et al. (2020). Thompson et al. (2021) observed
563 significant seasonal variations in tropical ozonesonde trends (based on data for 1994–2019 from
564 the Southern Hemisphere Additional Ozonesondes, or SHADOZ network); these authors noted
565 that dynamical influences (besides emissions changes) likely play a role in these tropical
566 tropospheric trends, which average ~0.1–0.4 %yr⁻¹ (for annual trends), but with trends in certain
567 regions/seasons (February to May in particular) as large as 1–2.5 %yr⁻¹. While model studies in a
568 recent paper by Ma et al. (2024) also confirm that lower stratospheric O₃ and related dynamical
569 transport effects can significantly impact long-term UT O₃ trends, their results suggest that, for the
570 tropics, the largest influence (of order 60–70% or more) comes from the tropospheric O₃ source.
571 Table 2 provides trend averages and trend ranges from MLS, along with those from two of the
572 above references regarding UT O₃ trends, not including column results or references with
573 redundancy or poorer matches to the MLS period. For tropical tropospheric O₃ column trends, a
574 comprehensive review is given by Gaudel et al. (2024). The trends in Table 2 are consistent with
575 MLS tropical UT trends, which are based on more dense and daily coverage. Given the different
576 periods and tropical sampling patterns between IAGOS and sondes versus MLS, these UT trend

577 comparisons give as reasonable an agreement as one might expect; see also the significant impacts
578 on O₃ trends from in situ sampling limitations mentioned by Gaudel et al. (2024).

579 Zhang et al. (2016) and Wang et al. (2022) have ascribed the positive sign of post-2000 tropical
580 ozone trends to an equatorward redistribution of surface emissions over the years. Moreover, Wang
581 et al. (2022) discussed how increases in aircraft emissions of nitrogen oxides should also have
582 contributed to enhancements in UT ozone. The UT zonal mean model O₃ trends shown in our work
583 are typically larger (by ~30–50%) in the NH tropics than in the SH tropics. This is also true for the
584 model simulation (also from CESM2) provided by Wang et al. (2022); these authors also point out
585 that uncertainties in estimates of ozone precursor emission inventories (including those for volatile
586 organic carbons species, or VOCs) may well contribute to differences between modeled and
587 observational ozone trends. While VOC source strengths might be difficult to invoke as a major
588 source of uncertainty for the tropical regions, other potential model issues (e.g., larger than
589 currently expected uncertainties in lightning-generated ozone in the tropical upper troposphere)
590 may be worth further consideration. We note that there are large differences (a range of a factor of
591 two or more) between the tropospheric ozone burden changes predicted by various global models
592 in the work by Wang et al. (2022). Also, Liu et al. (2022) show that significant regional differences
593 in ozone column trends exist in their model results (using the NASA Goddard Earth Observing
594 System Chemistry Climate Model, GEOSCCM), with near zero trends over the tropical western
595 Pacific; their modeled TCO trend results underestimate the observed positive TCO trends.

596 Regarding ozone UT variability, we found that the annual, semi-annual, and ENSO terms
597 dominate the variability in the tropical upper troposphere. The TCO interannual variability has
598 been known to be heavily influenced by ENSO (Ziemke and Chandra, 2003; Ziemke et al., 2010).
599 Oman et al. (2013) found that the ENSO relationship for ozone could be simulated by a chemical
600 climate model driven by observed SSTs. The observed and matching simulated sensitivity
601 coefficients imply increased downwelling from the stratosphere and suppressed convection during
602 El Niño periods for regions of positive sensitivity (Chandra et al., 1998; Sudo and Takahashi,
603 2001; Oman et al., 2013). The MLS UT ozone variations and their relation to ENSO were
604 discussed by Oman et al. (2013), who showed patterns of ozone sensitivity to ENSO at 147 hPa
605 (their Figure 6) that resemble the ones we produced here (in Fig. 7) from analyses of MLS data
606 over almost twice as long a period.

607 **3.2 Tropical UT CO**

608 **3.2.1 CO climatologies**

609 For CO, a similar set of annual mean climatological plots as those from Fig. 1 is provided in
610 Fig. 8. We observe that the model CO values follow the patterns of the MLS UT CO fields fairly
611 well, and the zonal mean model biases are usually around -10% to -20%; the model biases are
612 most often negative, and more so in the northern tropics at 215 hPa. The model mean CO biases
613 shown in Fig. 8 are well within the MLS CO systematic uncertainties mentioned in Sect. 2.1; the
614 CAM-chem-CEDS climatological UT CO is slightly closer to the MLS UT CO climatology than
615 is the WACCM-CEDS CO climatology. As in the case of ozone, the aforementioned model versus
616 data CO biases are found to exist not only for annual averages, but also on a month-to-month basis.
617 The SPARC Data Initiative report (SPARC, 2017) and the more recent update by Hegglin et al.
618 (2021) showed that MLS CO values in the tropical UT are within about 10–15% of the mean values
619 that include other data from ACE-FTS and the Michelson Interferometer for Passive Atmospheric
620 Sounding (MIPAS). However, the MLS mean values are larger than the multi-instrument mean at
621 100 hPa by about 10–20%, which can account for more than half of the MLS/model bias at this
622 level (not shown here). Also, just considering the theoretical systematic uncertainty estimates
623 provided in Sect. 2.1, it is possible that most (or even all) of the bias between models and MLS at
624 100 hPa is caused by a positive bias in the MLS CO data. However, an earlier WACCM-CEDS
625 version (WACCM4) underestimated CO and other hydrocarbon data in the southern tropical UT,
626 as described by Park et al. (2013); those authors noted that model deficiencies in emission source
627 strengths or in the upward rate of transport could potentially explain these model underestimates.
628 In summary, while we cannot pin down the exact causes for the mean biases between the UT CO
629 climatologies from MLS and the models shown here, a combination of MLS and model systematic
630 errors likely provides a reasonable explanation.

631 **3.2.2 CO zonal mean trends**

632 For CO, the zonal mean time series provided in Fig. S2 show that there are some slight
633 differences in the trends between observed and modeled (WACCM-CEDS) CO, with more
634 negative trends in the MLS series than in the model series. The large variability seen in the MLS
635 CO series shows correlation with WACCM-CEDS (see the large correlation coefficient values, R ,
636 in the 12°S series for 147 and 215 hPa). We know that the largest CO peaks in these time series
637 are tied to surface emissions, convection, and subsequent transport into the upper troposphere and

638 lower stratosphere (UTLS), with a strong connection to El Niño-related droughts and intense fire
639 (biomass burning) events (see, e.g., Schoeberl et al., 2006, Jiang et al., 2007, Liu et al., 2013, Park
640 et al., 2021, Duncan et al., 2003, 2007). The largest CO peaks in the MLS upper tropospheric
641 tropical record have been correlated with El Niño events in late 2006, in 2009–2010, and especially
642 from late 2015 into 2016 (see Park et al., 2021, and references therein, for further information). At
643 12°N, the observed CO variability is somewhat smaller than at 12°S, and the model variability is
644 much more muted, while the model versus MLS phasing agreement is quite poor, especially at
645 215 hPa (where R is very small and the MLS time series annual phase is very poorly matched by
646 the model). We have checked that this poor correlation is not tied to an issue involving the
647 smoothing of model profiles to account for the MLS averaging kernels; indeed, Fig. S3 shows the
648 small relative impact resulting from a smoothed (versus vertically interpolated) model series on
649 the average CO profile at 215 hPa and 12°N, as well as regarding the smoothed time series and its
650 phasing.

651 For the UT CO zonal mean trends, Figure 9 provides results in a similar way to Fig. 2 for ozone,
652 but for just the two MLS CO retrieval levels at 147 and 215 hPa. In contrast to ozone, we can see
653 that the MLS-derived tropical UT CO values have typically decreased from 2005 to 2020; these
654 CO trends display negligible latitude dependence. Using the same approach as for ozone, but based
655 on the Fig. 9 results, we obtain an average MLS-based UT CO trend of $-0.25 \pm 0.30 \text{ \% yr}^{-1}$
656 (equivalent to $-0.20 \pm 0.23 \text{ ppbv yr}^{-1}$). The trends at 215 hPa (-0.16 \% yr^{-1}) are a factor of two
657 smaller than those at 147 hPa (-0.34 \% yr^{-1}), although both of these numbers agree within the (2σ)
658 trend uncertainties of 0.3 \% yr^{-1} ; based on the error bars, the CO trend from MLS at 147 hPa is
659 different from zero, while the corresponding MLS trend at 215 hPa is not. In contrast, the average
660 CAM-chem-CAMS UT CO trend at these levels is $0.22 \pm 0.19 \text{ \% yr}^{-1}$, with little difference
661 between 147 and 215 hPa. The two simulations that use CEDS emissions (WACCM-CEDS and
662 CAM-chem-CEDS) yield smaller trends for CO, namely $0.0 \pm 0.14 \text{ \% yr}^{-1}$, with slightly negative
663 average trends at 147 hPa and slightly positive average trends at 215 hPa. This difference in trends
664 can be explained by significant decreases in Chinese anthropogenic emissions in CEDSv2, despite
665 the increasing anthropogenic tropical CO emissions in both CAMS-GLOB-ANTv5.1 and CEDSv2
666 (see Fig. S4).

667 Furthermore, larger MLS CO abundances in 2020 explain why the MLS CO UT trends are
668 more negative if one stops the analyses in 2018 or 2019, as can be seen from Fig. 10, which is

669 analogous to the ozone trend sensitivity study provided in Fig. 3. Regarding another aspect of CO
670 trend sensitivities, we considered the issue of large peaks in the observed MLS CO time series (see
671 examples in Fig. S2) typically resulting from El Niño related biomass burning events, followed by
672 convective uplift and CO advective transport into the UTLS. If the model has smaller peaks than
673 the MLS data show, it may be that this could explain some differences, or even a change of sign
674 in the trends. This would stand out more if the large peaks occurred close to the beginning or end
675 of the time series. As a sensitivity test, we artificially suppressed the peaks in these series by setting
676 any CO value larger than 2.5 times the (1σ) variability to a value of 1.5 times this variability, and
677 we found the impact on the linear trends to be negligible (well within the error bars shown here).
678 Such a sensitivity study gives added confidence in the robustness of these trends.

679 In Fig. 11, we show the MLS, WACCM-CEDS, and CAM-chem-CEDS climatological mean
680 CO changes over the annual cycle at 215 hPa for 12°N and 12°S, along with the range of variability
681 (twice the standard deviations about the means). The fits from the models to the MLS CO behavior
682 at 12°S are quite good. The MLS CO curves show the two maxima previously observed in seasonal
683 analyses of biomass burning events, with related upward injections of CO and their subsequent
684 transport to the UT being implicated. Based on fire counts from satellite data (see e.g., Duncan et
685 al., 2003, 2007), a March biomass burning maximum has been associated with the northern
686 hemisphere (mainly from Southeast Asia, but also from northern Africa); outflow from the Asian
687 monsoon contributes to the August NH maximum. The September/October maximum arises from
688 the southern hemisphere (Indonesia, Malaysia, Southern Africa, Brazil). We should also note
689 (more broadly) that the climatological double maximum CO structure measured by MLS near
690 215 hPa over the broader (20°S–20°N) tropics is well matched by MIPAS CO zonal means (see
691 SPARC DI, 2017, chapter 4). At 12°N, however, the lack of correlation between the model
692 variations and those deduced from MLS in Fig. 11 appears to stem from the poorly modeled double
693 maximum structure; we also find that these poorer fits occur more generally throughout the
694 northern tropics. The model underestimates the boreal winter buildup of CO (Gaubert et al., 2020;
695 2023), which may explain a poor representation of the northern hemisphere March/April
696 maximum. Also, biomass burning emission biases can vary regionally and this might explain some
697 of the model/data differences, with some regions providing somewhat better comparisons than
698 others. We do not ascribe the larger model/MLS discrepancies at 215 hPa in the northern tropics
699 to an undue influence of the MLS a priori on the retrievals in this region, as the (averaged) a priori

700 MLS values (although not shown in Fig. 11) follow the WACCM-CEDS fields quite well, and the
701 MLS CO retrievals are producing significantly different variations. To explore this hemispherical
702 asymmetry further, we show CO column comparisons between zonal mean time series from
703 MOPITT, CAM-chem-CEDS and WACCM-CEDS in Fig. 12; all CO columns are averaged over
704 the same latitudes (10°N–14°N and 10°S–14°S). We obtain much better agreement in the phasing
705 of these CO column comparisons for 12°N than we do in the model versus MLS CO comparisons
706 at 215 hPa in Fig. 11. This is clearly seen in the time series evolution, as well as in the correlation
707 coefficients shown in both of these Figures, although R is smaller at 12°N than at 12°S in Fig. 12
708 (but still about 0.75 to 0.8). We also look at this issue for the gridded fields and provide R values
709 for the 12°N and 12°S bins in Fig. 13, where we superpose the column CO model results versus
710 MOPITT and the 215 hPa model results versus MLS as a function of longitude. Again, we observe
711 that R is much higher for the CO total columns than for the 215 hPa level, especially so in the
712 northern tropics. The patterns versus longitude indicate that poorer correlations exist over the
713 Atlantic Ocean (just West of the Greenwich meridian) than over land masses. We do not have clear
714 explanations for the exact patterns in Fig. 13, except for the suggestion that regions with strong
715 land convection might show better UT correlations between models and data, while outflow
716 regions (downwind of convection) in the upper troposphere could be more poorly modeled. The
717 models do not follow the observed UT CO seasonal behavior in a narrow UT region of the northern
718 tropics, even if the modeled seasonal total columns compare well to MOPITT columns in that
719 region. More in-depth analysis would be needed to probe whether this might be caused by a poor
720 representation of emissions and/or transport to this region. Alternatively, it might be that currently
721 unaccounted for variations of the MLS vertical averaging kernels could affect the (properly
722 smoothed) model values in the northern hemisphere tropics at 215 hPa, in ways that are somehow
723 significantly different than what we show in Fig. S3; this is highly unlikely, given that the
724 smoothed model plots in this Figure hardly change if we replace the tropical MLS averaging kernel
725 values used in that plot by kernels appropriate for 70°N. Another potential issue might be poorly
726 understood cloud impacts on the 215 hPa MLS retrievals, specifically in the northern hemisphere
727 tropics; although this is speculative, it might be worth exploring in the future.

728 3.2.3 CO mapped trends and variability

729 In Fig. 14, we show the mapped CO trend results for MLS and all three simulations (WACCM-
730 CEDS, CAM-chem-CAMS, and CAM-chem-CEDS) at 147 and 215 hPa. As seen above, MLS
731 CO trends in the UT are generally negative, with the more statistically significant result occurring
732 at 147 hPa (where the trends are more negative than at 215 hPa). There is an indication of slightly
733 positive trends over or near western Africa, mainly at 215 hPa, although this is not statistically
734 significant. The binned model results from CAM-chem-CAMS confirm the zonal mean view from
735 this model, with mostly positive trends, in contrast to the generally negative tendencies in the MLS
736 trend results. The average trends (from both pressure levels) based on all grid cells for MLS is
737 -0.25 \%yr^{-1} , as opposed to $+0.24 \text{ \%yr}^{-1}$ obtained from CAM-chem-CAMS. Of note, these values
738 lie well outside twice the standard errors in the means (of 0.1 \%yr^{-1}), although one should
739 understand that there are limitations in the use of such a small error bar, given the existence of
740 correlations in atmospheric variability between the various bins. When the CEDS emissions are
741 used, as done for WACCM-CEDS and CAM-chem-CEDS, there is a general decrease in the UT
742 CO trends, with some small negative values, although the vast majority of the model CO trends
743 obtained here are not statistically different from zero within any given bin. The averaged UT
744 mapped trend for CAM-chem-CEDS is 0.0 \% yr^{-1} , with twice the standard error in the mean also
745 about 0.1 \%yr^{-1} . While the use of the model CEDS emissions does lead to a better model agreement
746 with the gridded MLS UT CO trends, the MLS-derived trends are still, on the whole, more negative
747 than these simulated CO trends.

748 For CO, we repeat in Fig. 15 the explained variance analysis provided in Fig. 6 for O₃. Overall,
749 the full fits explain less of the variability in the CO case, in part because of the large ENSO-related
750 peaks that occur throughout the MLS and WACCM-CEDS records, which the regression model,
751 as designed, can only imperfectly match. Also, there are regions in the southern tropics where the
752 annual cycle in the model is better fit by the regression than in the MLS case, and this translates
753 to a somewhat better overall full fit. For both MLS and model, the semi-annual cycle component
754 shows peaks over the South Atlantic region, which is likely linked to biomass burning in Africa
755 and related CO transport to the UT following convective activity (e.g., Duncan et al., 2007; Park
756 et al., 2013, 2021). As for the ozone case, the QBO-related UT variability in the tropics is very
757 small (as seen from the QBO R² contributions). For both MLS and model representations, the
758 ENSO-related correlation patterns are broadly similar to the ozone case, in that there is larger

759 variance in the more extreme longitudes of both western and eastern sides. As for O₃, there are
760 somewhat smaller variance contributions in the Eastern hemisphere from ENSO and the semi-
761 annual term than in the MLS case. At 215 hPa (see Fig. S6), the ENSO variance contribution is
762 slightly larger than at 147 hPa only in a small number of bins, but the overall ENSO-related
763 patterns are not stronger, as seen also in the CO sensitivity coefficients to ENSO in Figure 16
764 below, which shows only slight differences between the two pressure levels.

765 **3.2.4 CO discussion**

766 Regarding the CO climatology, the models underestimate the MLS UT values by up to 20%,
767 and these differences could be readily caused by systematic biases in either MLS or the models,
768 or both. Park et al. (2013) also found that model CO values from a (WACCM4) simulation at
769 147 hPa were smaller than the ACE-FTS (and MLS) CO abundances, especially in the SH sub-
770 tropics; they attributed this to a possible underestimation of surface emissions or transport via deep
771 convection. We note that low biases in simulated tropospheric CO have also been found before at
772 northern latitudes and may arise from various factors, such as underestimated CO emissions, high
773 biases in modeled tropospheric OH (Strode et al., 2016; Gaubert et al., 2023), or issues with
774 simulated CO dry deposition rates (Stein et al., 2014). Based on our model/MLS comparisons of
775 UT CO seasonal changes, we find significantly poorer matches at 215 hPa in the northern tropics
776 than in the southern tropics. The detailed causes of this discrepancy are currently not clear to us,
777 given the better matches (correlation coefficients) we obtain between MOPITT total CO columns
778 and modeled CO columns. Potential causes could include model inaccuracies (possibly related to
779 convection and/or CO emissions and subsequent transport in this fairly narrow latitude region),
780 stratosphere-troposphere exchange, or an alternate explanation having to do with poorly
781 understood limitations of the MLS data in this same region.

782 For the CO trends, the average tropical MLS UT trend is $-0.25 \pm 0.30 \text{ \%yr}^{-1}$, whereas the
783 corresponding trends from CAM-chem-CEDS and WACCM-CEDS are close to zero (0.0 ± 0.14
784 \%yr^{-1}) for this region; these average trend results are statistically in agreement, even if the MLS
785 CO trends tend to generally be more negative than the simulation results. Note, however, that the
786 MLS-derived CO UT trends for 2005–2023 are closer to zero (about $-0.1\% \text{ yr}^{-1}$), as we mention in
787 the Conclusion section, but we have no model simulations (or model trends) for that extended
788 period. The (2005–2020) CAM-chem-CAMS simulations (which use CAMS anthropogenic CO
789 emissions, see sect. 2.2), yield statistically significant positive average tropical UT CO trends

790 (+0.22 ± 0.19 %yr⁻¹). More specifically, these simulated latitude-dependent trends are significantly
791 different from the MLS CO trends in the 12°N-24°N latitude bins. Larger MLS CO abundances in
792 2020 explain why the MLS CO UT trends are more negative if one stops the analyses in 2018 or
793 2019. The mapped MLS CO trends in the UT are also negative, with the more statistically
794 significant result (stronger negative trends) occurring at 147 hPa.

795 While there have not been any past decades-long trend estimates for CO in the broad tropical
796 UT region, our results yield somewhat smaller rates of decrease than other trends mentioned in the
797 Introduction, for example -0.5 to -2 %yr⁻¹, based on IAGOS UT data at northern midlatitudes
798 (Cohen et al., 2018). Column CO in the free troposphere has generally shown decreasing trends
799 since the turn of the century, typically between -0.5 and -1.5 %yr⁻¹, as observed in particular by
800 MOPITT and AIRS (Worden et al., 2013a, Strode et al., 2016; Buchholz et al., 2021; Hedelius et
801 al., 2021); however, these trends are not necessarily expected to agree with UT CO trends, since
802 they represent two different altitude regimes. Liu et al. (2022) presented a recent analysis of
803 MOPITT CO data from 2005–2018, along with tropospheric model comparisons to observed CO
804 and O₃ time series. These authors found (as shown here and described for MLS and ACE-FTS data
805 by Park et al., 2021) that their modeled and observational time series both exhibit large interannual
806 variability, with some of the largest interannual changes driven by El Niño events in 2006 and
807 2015 and related biomass burning and CO enhancements tied to droughts over the Indonesian
808 region (see also Logan et al., 2008; Zhang et al., 2011; Livesey et al., 2013; Worden et al., 2013b;
809 Park et al., 2013; Field et al., 2016). Liu et al. (2022) found that modeled CO column trends over
810 various regions of the globe were generally negative, although a lower latitude region (India)
811 exhibited a positive model trend. Jiang et al. (2017) provide some arguments (and other references)
812 pointing to flat biomass burning emission trends over Africa for the first 10–15 years since the
813 turn of the century. Not including the strong tropical anomaly caused by El Niño in 2015, they
814 infer a negative trend in global biomass burning emissions. Uncertainties in the temporal evolution
815 of OH (a major sink for CO) could also explain model CO trend issues. However, Jiang et al.
816 (2017) implied that changes in global OH abundances could not readily explain global CO
817 decreases, given constraints from methyl chloroform surface data (this species also having OH as
818 a major sink, as discussed by Montzka et al., 2011) and despite large uncertainties in OH,
819 especially during the last decade. Rather, these authors conclude that decreasing CO emissions
820 from anthropogenic and biomass burning sources are the main cause of tropospheric CO decreases,

821 although some regional increasing emission trends do exist. While a systematic model bias cannot
822 readily lead to a significant discrepancy in model trend estimates (in percent per year) versus
823 observations, time-dependent emission biases could (e.g., Gaubert et al., 2023). To first order, the
824 decreasing UT CO tropical trends derived from MLS for 2005–2020 agree with (but tend to be
825 smaller in magnitude than) total column CO trends discussed previously in the literature. As
826 discussed by others, some temporal non-linearity in CO trends may be responsible for some of the
827 differences between past tropospheric CO trend results over different periods.

828 For CO in particular, the temporal variability that MLS has observed in the upper troposphere
829 is difficult to fit completely using standard linear regression, given the existence of short-term
830 variability in the troposphere (e.g., Dunkerton and Crum, 1995; Ziemke et al., 2015), as well as
831 large episodic and somewhat random enhancements in the UT CO abundances. Regarding this CO
832 variability, we note that ACE-FTS UT CO monthly zonal mean time series track those from MLS,
833 as shown by Park et al. (2021); this helps to validate the UT time series and variability from MLS.
834 We find that the CO sensitivity to ENSO is much more spatially uniform in sign than the O₃
835 sensitivity; UT O₃ generally increases toward the tropopause while CO decreases, leading to
836 opposite sensitivities to increased upwelling phase over the Pacific (Figs. 7 and 16). In some
837 regions, the CO sensitivity has the same sign as for ozone, and in other regions, it differs;
838 moreover, the model’s UT CO sensitivity coefficient to ENSO seems to broadly match the
839 observational sensitivity from MLS, as it shows positive values throughout the tropics. These
840 different behaviors between tropical UT O₃ and CO seem to mainly reflect a stronger (and positive)
841 sensitivity to biomass burning events in the case of CO.

842 **5 Conclusions**

843 We have analyzed tropical ozone (O₃) and carbon monoxide (CO) distributions in the upper
844 troposphere (UT) and their temporal changes for 2005–2020 using Aura Microwave Limb Sounder
845 (MLS) observations and chemistry climate model simulations. Upper tropospheric trends and
846 variability diagnostics were obtained from multiple linear regression analyses.

847 ***Tropical UT O₃:***

848 We have compared the model and MLS annual ozone climatologies, focusing on the 147 hPa
849 and 215 hPa pressure levels; the model abundances are typically ~5–15% smaller than MLS O₃ at
850 215 hPa, but larger than the MLS values at 147 hPa by ~20%. MLS O₃ has an averaged UT zonal

851 mean trend at 20°S–20°N of $+0.39 \pm 0.28 \text{ \%yr}^{-1}$. We obtain excellent agreement with the above
852 result from the (averaged) CAM-chem-CEDS O₃ zonal mean trends ($0.38 \pm 0.28 \text{ \%yr}^{-1}$) and
853 somewhat poorer agreement from the smaller WACCM-CEDS trends ($0.21 \pm 0.23 \text{ \%yr}^{-1}$). We
854 note that the MLS tropical UT zonal mean O₃ trends for 2005–2023 are $0.34 \pm 0.22 \text{ \%yr}^{-1}$, so these
855 trends have only changed by a small amount versus the 2005–2020 results; it is useful that the
856 trend error bars are reduced by about 23% for the analysis using 3 more years (the same holds for
857 the CO 2005–2023 trends mentioned below). However, we cannot readily update any of the model
858 simulations (and related trend comparisons) with more analysis years at the time of this writing.

859 Our analyses for various latitude/longitude bins produce positive mapped O₃ trends of up to
860 1.4 \%yr^{-1} over Indonesia and East of that region, as well as over tropical Africa and the tropical
861 Atlantic. Positive tropical UT mapped O₃ trends are generally captured by the model simulations,
862 although in a more muted way. We find broad similarities (and some differences) between the
863 mapped MLS UT O₃ trends and corresponding mapped trends of tropospheric column ozone for
864 the same time period.

865 ***Tropical UT CO:***

866 The model climatologies generally show an underestimate versus the MLS CO climatology,
867 with model average biases usually about -10% to -20%. Also, in the northern hemisphere tropics,
868 we find significantly poorer model fits to the observed phasing of CO seasonal changes at 215 hPa
869 than at 147 hPa. This discrepancy is much smaller for the comparison of modeled and
870 Measurements of Pollution in the Troposphere (MOPITT) V9J CO columns. The MLS zonal mean
871 CO UT trend is $-0.25 \pm 0.30 \text{ \%yr}^{-1}$, while the corresponding model CO trends are close to zero
872 ($0.0 \pm 0.14 \text{ \%yr}^{-1}$) when the anthropogenic emissions used in CAM-chem and WACCM are taken
873 from Community Emissions Data System (CEDS) version 2. The non-CEDS version of CAM-
874 chem (the CAM-chem-CAMS simulation) yields averaged CO UT trends of $0.22 \pm 0.19 \text{ \%yr}^{-1}$, in
875 contrast to the negative tendencies prevalent in the MLS CO trends throughout the tropics. These
876 three average CO trend results agree within the limits of the (2σ) error bars provided above,
877 although the model versus MLS agreement is more marginal when non-CEDS CO emissions are
878 used. We note that the MLS tropical UT CO trends for 2005–2023 are $-0.09 \pm 0.23 \text{ \%yr}^{-1}$, so these
879 trends have changed by somewhat more than the ozone trend results and are closer to zero than
880 the 2005–2020 MLS CO UT trends. Unfortunately, the coming end of the MLS data record will

881 soon make such MLS updates impossible. As we noted for O₃, we cannot readily update any of
882 the model simulations (and related trend comparisons) with more analysis years.

883 The negative MLS tropical UT CO trends for 2005–2020 agree with (but tend to be smaller in
884 magnitude than) previously published total column CO trends, although one does not expect
885 complete agreement between UT and column trends. We also find that the sensitivity of UT CO
886 to El Niño / Southern Oscillation (ENSO) is positive at all tropical longitudes, in contrast to the
887 (well-known) dipolar longitudinal structure that exists for the UT O₃ ENSO sensitivity.

888 The MLS-derived upper tropospheric tropical trends in O₃ and CO arise from a well-sampled
889 multi-year data set, with the results showing a first-order correlation to large-scale changes in
890 lower tropospheric composition (O₃ increases and CO decreases). We find that there are broad
891 similarities (and a few differences) between the measured UT trends and corresponding results
892 from model simulations, which incorporate state-of-the-art representations of the complex
893 interplay between emissions, photochemistry, convection, and transport in the upper troposphere
894 and lower stratosphere. These results will contribute to the continuing assessments of tropospheric
895 evolution, in particular the large community efforts regarding TOAR-II and CMIP-7.

896 Changes in O₃ precursor emissions have been implicated previously as a driver for global
897 tropospheric O₃ changes (e.g., long-term increases), while decreasing CO emissions from
898 anthropogenic and biomass burning sources have been suggested as the main causes of recent
899 decreases in tropospheric CO. We believe that further investigations into how well different
900 models of O₃ and CO in the tropical UT match the corresponding MLS UT trends are warranted,
901 to provide better understanding of differences between models. There may still be adjustments to
902 make to the models regarding the assumed CO surface emissions, convection, and/or transport-
903 related issues, even though such studies are beyond the scope of this paper. Indeed, biomass
904 burning from Africa or South America and emissions from Asia, followed by transport, can (and
905 will continue to) influence the tropical upper tropospheric abundances of CO and O₃ (e.g.,
906 Tsvilidou et al., 2023). On a longer timescale, the troposphere is a region where the relative
907 importance of multiple factors might change over the multi-decadal timescale of climate change;
908 also, longer-term projections from (free running) models may not be representative of changes
909 from a particular decade or two (see Fiore et al., 2022, regarding model ensemble projections). For
910 example, long-term positive trends in the influx of ozone from the stratosphere to the troposphere
911 may be expected as a result of climate change (Meul et al., 2018), probably with more of an

912 influence on the extra-tropical upper troposphere. Regarding the tropics, Stevenson et al. (2013)
913 showed that a number of chemistry climate model simulations of climate change scenarios yielded
914 long-term ozone decreases in the lower troposphere as a result of enhancements in water vapor
915 (implying more ozone destruction), but low latitude upper tropospheric ozone could be expected
916 to rise, following increased production from lightning. Obtaining accurate enough observations of
917 large-scale tropospheric composition change over the long-term is expected to represent a
918 continuing, but worthy challenge.

919

920 **Data availability.**

921 The MLS data files analyzed here come from the MLS Level 3 data sets (zonal mean and gridded
922 quantities), which are publicly available from the Goddard Earth Sciences Data and Information Services
923 Center (GES DISC) at <https://earthdata.nasa.gov/eosdis/daacs/gesdisc>.
924 The MOPITT Version 9 products are available from NASA through the Earthdata portal
925 (<https://earthdata.nasa.gov/>; https://asdc.larc.nasa.gov/project/MOPITT/MOP03JM_9; or directly from the
926 ASDC archive (<https://asdc.larc.nasa.gov/data/MOPITT/>). We used the following site,
927 ftp://ftp.seismo.nrcan.gc.ca/spaceweather/solar_flux/monthly_averages/solflux_monthly_average.txt to
928 obtain monthly means of the Canadian F10.7 solar flux measurements (Tapping, 2013); these series (see
929 <http://www.spaceweather.gc.ca>) were included in our regression fits. The QBO-related equatorial wind
930 monthly time series were obtained from the public website at [https://www.geo.fu-](https://www.geo.fu-berlin.de/en/met/ag/strat/produkte/qbo)
931 [berlin.de/en/met/ag/strat/produkte/qbo](https://www.geo.fu-berlin.de/en/met/ag/strat/produkte/qbo). The multivariate ENSO index dataset was obtained from the NOAA
932 Physical Sciences Laboratory website at <https://www.psl.noaa.gov/enso/mei/> (Wolter and Timlin, 2011;
933 Zhang et al., 2019). OMI/MLS tropospheric ozone data were obtained from the NASA satellite tropospheric
934 ozone webpage https://acd-ext.gsfc.nasa.gov/Data_services/cloud_slice/. The CESM2.2 model is a publicly
935 released version of the Community Earth System Model that is available at (<https://www.cesm.ucar.edu>,
936 last accessed on 15 November 2024). Also, the model simulation results for this work are available at the
937 following website link: [Zenodo website link to be added here when available, before publication].

938

939 **Supplement.** Supplementary material is included as a separate file.

940

941 **Author contributions.** LF analyzed the MLS and model data for trends and variability, and prepared the
942 manuscript, along with contributions from all co-authors. DEK, CGB, and BG provided inputs for running
943 the model runs, as well as properly averaged and formatted outputs from the model, as well as pertinent
944 model-related comments and interpretation of results. JRZ provided TCO datasets and comments on the

945 manuscript. NJL, MJS, WGR, and others on the MLS team provided analyses and expertise to enable the
946 production of the Aura MLS data sets; NJL, MJS, and WGR also provided comments on the manuscript;
947 RAF provided programming assistance for the creation of the MLS data sets and for storage and analyses
948 of the MLS and model files.

949

950 **Competing interests.** The authors declare that they have no conflict of interest.

951

952 **Acknowledgments.** We are thankful to the whole MLS team (past and present) for their contributions over
953 the years to the MLS instrument, data, processing, and database management. We very much acknowledge
954 the referees, who helped improve the initial manuscript with quite a list of useful and detailed comments.
955 We acknowledge the encouragement from Owen Cooper and Helen Worden to link our paper to the
956 TOAR-II Copernicus special issue; thanks also to Kai-Lan Chang for briefly reviewing aspects of our
957 statistical approach regarding the guidelines adopted for reporting TOAR-linked results. WACCM-CEDS
958 is a component of the CESM, supported by the National Science Foundation (NSF). We acknowledge high-
959 performance computing support from Cheyenne (doi:10.5065/D6RX99HX) provided by NCAR's
960 Computational and Information Systems Laboratory, sponsored by the NSF. F10.7 data collection and
961 dissemination are supported by the National Research Council of Canada, with the participation of Natural
962 Resources Canada and support by the Canadian Space Agency. Work at the Jet Propulsion Laboratory,
963 California Institute of Technology, was performed under contract with the National Aeronautics and Space
964 Administration (80NM0018D0004). Copyright 2024. All rights reserved.

965

966 **Financial support.** LF and RAF were funded by the NASA Atmospheric Composition Modeling and
967 Analysis Program (ACMAP). NJL, MJS, and WGR (as well as LF) were supported by the Aura Microwave
968 Limb Sounder project. DEK, BG, and CGB were funded separately by NASA and NSF grants. Part of this
969 material is based upon work supported by the NSF National Center for Atmospheric Research, which is a
970 major facility sponsored by the U.S. National Science Foundation under Cooperative Agreement No.
971 1852977. The NSF NCAR MOPITT project is supported by the National Aeronautics and Space
972 Administration (NASA) Earth Observing System (EOS) program.

1458

1459 **Table 1.** Some characteristics of the three chemistry climate model simulations used in this work.
 1460

Model Designation	Simulation Name	CO Anthropogenic Emissions Dataset	CO Biomass Burning dataset	Nudging timescale (hours)	Tropical Lightning NO_x (Tg N yr⁻¹)	Aircraft NO_x Dataset¹
CAM-chem	CAM-chem-CAMS	CAMS-GLOB-ANT_v5.1	QFED	6	2.34	Soulié et al. (2024)
CAM-chem	CAM-chem-CEDS	CEDSv2	QFED	6	2.34	Soulié et al. (2024)
WACCM	WACCM-CEDS	CEDSv2	QFED	12	2.78	CMIP6

1461
 1462 ¹For 2005–2014, the aircraft NO_x emissions for WACCM-CEDS and both CAM-chem model simulations
 1463 are identical. From 2015 onward, the WACCM-CEDS emissions are kept constant.

1464 **Table 2.** Trend results from recent tropical upper tropospheric O₃ data analyses. See Sec. 3.1.4
 1465 for other references and comments.
 1466

Reference	Data	Time Period	Trends		Comments
			ppbv decade ⁻¹	% decade ⁻¹	
This work	Aura MLS UT data at 147, 178, and 215 hPa for 20°S–20°N ~8–14 km range	2005–2020	2.0 (1.4) -2 to 7	3.9 (2.8) -4 to 14	trend average (2σ error) trend range* (the negative values are not significantly different from 0)
Based on Thompson et al. (2021)	ozonesonde data from the free troposphere at 5 SHADOZ stations ~5–15 km range	1998–2019	~1 (~2) 0.5 to 2	~2 (~4) 1 to 4	(annual) trend average (annual) trend range
Based on (Fig. S24 of) Gaudel et al. (2024)	IAGOS and sonde UT data from 5 tropical regions ~200–300 hPa range	2004–2019	~3 (~3) -1 to 7	~6 (~6) -2 to 14	trend average trend range

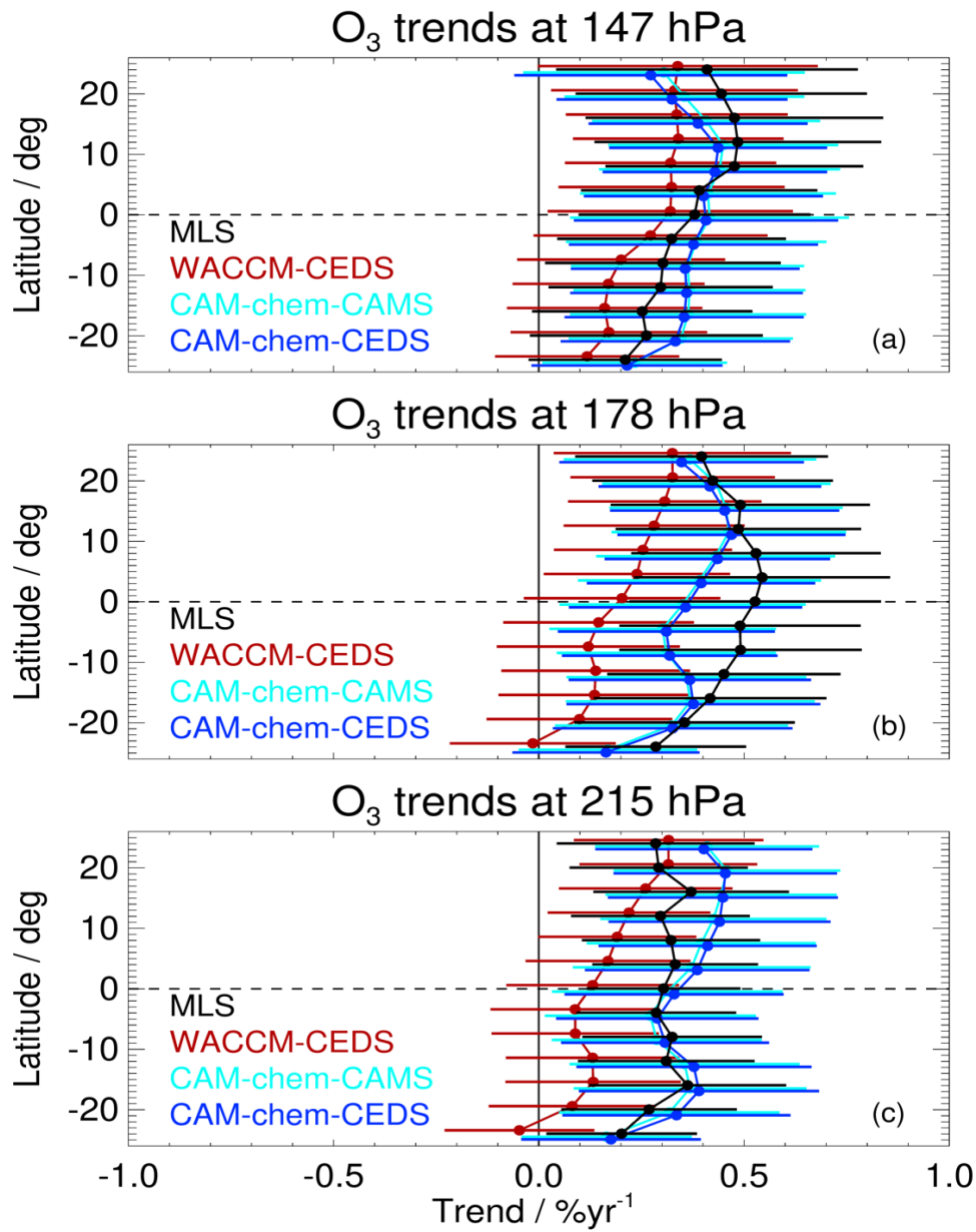

1467 * Trend range for MLS is taken from the minimum and maximum values in mapped tropical UT trends.

1470
 1471
 1472 **Figure 1.** Annually-averaged climatological comparisons between MLS and model ozone fields for 2005-
 1473 2020 at low latitudes (full range shown from 26°S to 26°N) at 147 hPa ((a) through (g)) and at 215 hPa ((h)
 1474 through (n)). For 147 hPa: (a) climatological O₃ maps from MLS, (b) from WACCM-CEDS, (c) from
 1475 CAM-chem-CEDS; (d) shows the zonal mean climatology from the MLS data and both model simulations,
 1476 with (e) giving the differences in zonal means for both model simulations minus MLS (color-coded as
 1477 shown in the (d) legend), while (f) provides a difference map of the climatologies from WACCM-CEDS
 1478 minus MLS, and (g) gives the difference map for CAM-chem-CEDS minus MLS. Panels (h) through (n)
 1479 provide the same information as (a) through (g), but for 215 hPa. We note that in panels (d) and (k), CAM
 1480 is an abbreviation for the CAM-chem-CEDS simulation, and WACCM is an abbreviation for the WACCM-
 1481 CEDS simulation.

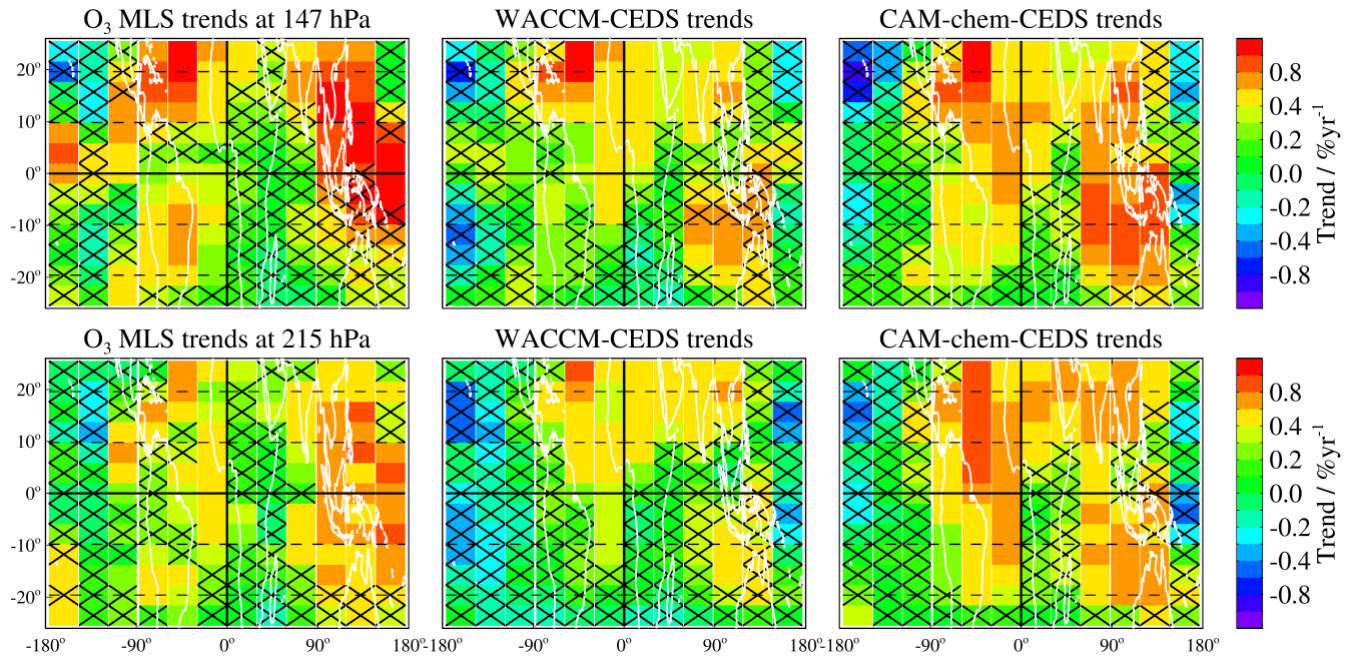

Figure 2. Ozone zonal mean trends versus latitude in the tropical upper troposphere, for 2005–2020, based on MLR analyses of time series from MLS (black), WACCM-CEDS (red), CAM-chem-CAMS (cyan) and CAM-chem-CEDS (blue). Each row corresponds to a different pressure level: (a) for 147 hPa, (b) for 178 hPa, and (c) for 215 hPa, as labeled above each panel. Error bars give the uncertainties (2σ) in the estimated linear trends (see text for more details).

Figure 3. Ozone zonal mean trends versus latitude in the tropical upper troposphere, with results from MLS data analyses shown in the left panels, and model results from CAM-chem-CEDS in the right panels. Each row corresponds to a different pressure level, as labeled. All panels show the trend sensitivity to the time period used in the regression fits. For example, black is used to show the period from 2005 through 2020; results from four other time periods are also shown, with the start or end year shifted by one or two years (see legend for the meaning of the various colors). The error bars given here represent the (2σ) uncertainties in the estimated linear trends.

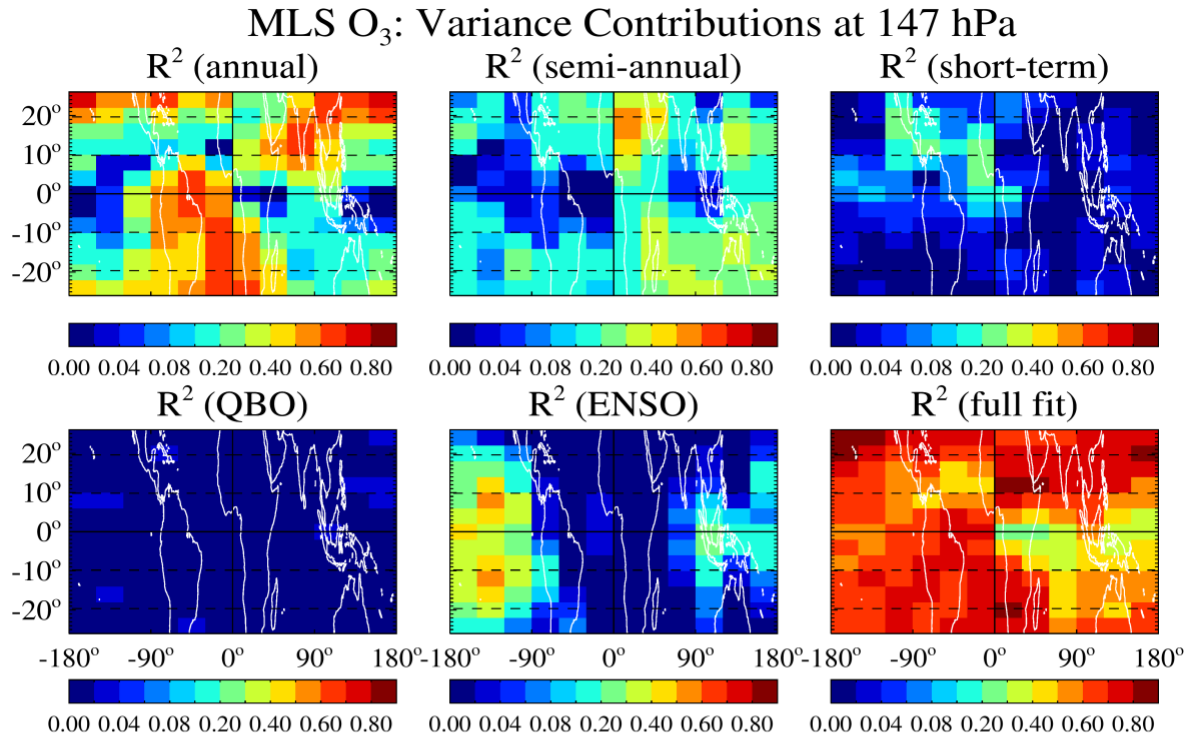

Figure 4. Maps of upper tropospheric O₃ trends (% yr⁻¹) in the tropics for 147 hPa (top row) and 215 hPa (bottom row); the latitude range is from 26°S to 26°N, with maps all centered on the Greenwich meridian. MLS trends (left column) are compared to trends from WACCM-CEDS (middle column) and CAM-chem-CEDS (right column). Black crosses show grid boxes for which the trend estimate is not significantly different from zero (based on our 2 σ error estimates).

Figure 5. (a) The top map shows MLS ozone trends (2005–2020) at 178 hPa, (b) the bottom map displays horizontally-smoothed tropospheric column ozone trends for the same time period, following the analyses of Ziemke et al. (2019), (c) cross sections of the above mapped trends in 4°-wide latitude bins centered at 12°N, 0°, and 12°S (see legend) for MLS (black) and TCO (red), and (d) correlation coefficient values R (on the x axis) between the MLS ozone trends at different pressures (see legend) and the TCO trends as a function of longitude, at different tropical latitudes (y axis). This panel provides a broader picture of the trend correlations, which exhibit a minimum near the Equator and maxima near 12°S and 12°N.
