**Abstract.** During the Quaternary, ice sheets experienced several ~~retreat-advanced~~ retreat-advance cycles, strongly influencing climate patterns. In order to properly simulate these phenomena, it is preferable to use physics-based models instead of parameterizations to estimate surface mass balance (SMB) ~~which has a strong influence on the ice sheet evolution, which strongly influences the evolution of the ice sheet~~. To further investigate the potential of these SMB models, this work evaluates

5 BESSI (BERgen Snow Simulator), a multi-layer snow model with high computational efficiency, as an alternative to providing SMB for the Earth system model *i*LOVECLIM for paleo studies. We compared the behaviors of BESSI and ITM - Insolation Temperature Melt, an existing SMB scheme of *i*LOVECLIM during the Last Interglacial (LIG). First, we validate the ~~snow model~~ two SMB models using the regional climate model MAR (Modèle Atmosphérique Régional) as forcing and reference

10 for the present-day climate over Greenland and Antarctic Ice Sheets. The evolution of SMB over the Last Interglacial period (LIG) (130-116 kaBP) is computed by forcing BESSI and ITM with transient climate forcing obtained from ~~an Earth system model~~ *i*LOVECLIM for both ice sheets. For present-day climate conditions, ~~BESSI exhibits both BESSI and ITM exhibit~~ good performance compared to MAR despite a much simpler model ~~set-up. The model also captures well the variation of SMB and its components during the LIG. Compared to the current simple melt estimation scheme of *i*LOVECLIM (ITM), BESSI is able to capture different SMB patterns for two particular ice sheet climate conditions thanks to its higher physical constraints while~~

15 setup. While BESSI performs well for both Antarctica and Greenland for the same set of parameters, the ITM parameters need to be adapted specifically for each ice sheet. This suggests that the physics embedded in BESSI allows better capture of SMB changes across varying climate conditions, while the ITM displays a ~~strong~~ much stronger sensitivity to its ~~parameters and input fields (temperature)~~ tunable parameters. The findings suggest that BESSI can provide more reliable SMB estimations for the *i*LOVECLIM framework to improve the model simulations of the ice sheet evolution and interactions with climate during

20 paleo periods.

## 1 Introduction

The Quaternary (since 2.6 ~~Ma~~BPMa) has experienced several glacial-interglacial cycles. These episodic ~~events~~periods influenced the whole Earth system, with climate shifting periodically from cold to warm phases and repeated retreat-advance cycles of the ice sheets and glaciers. Ice sheets and their interactions with climate strongly influence phenomena such as sea level evolution (Dutton et al., 2015; Spratt and Lisiecki, 2016; Turney et al., 2020) or changes in the atmospheric circulation (Ullman et al., 2014; Liakka et al., 2016). Ice sheets gain mass through surface accumulation (snow and rain) and internal accumulation (refreezing). In contrast, they lose mass due to melting and sublimation/evaporation processes on the surface or through iceberg calving and sub-shelf melting. The difference between mass gains and losses at the surface is called surface mass balance (SMB), which plays a significant role in the build-up or disappearance of the ice sheets. Studies of ice sheet evolution through past events unravel the dynamics of glaciation and deglaciation, improving trajectories of ice sheets in the past as well as confidence in future projections.

Investigating ice sheets and climate ~~feedback~~feedbacks in such long-time scales requires a tool that can simulate the interactions between the main components of the Earth system ~~with~~at a reasonable computational cost. In this context, Earth system models of intermediate complexity (EMICs) are of interest as they have much lower computational costs compared to state-of-the-art general circulation models (GCMs) ~~whilst~~while still being able to simulate most of the important processes thanks to their low resolution and simplifications (Claussen et al., 2002; Eby et al., 2013). However, these simplifications result in some drawbacks, particularly in reproducing the evolution of ice sheets. Because of their coarse resolution, EMICs fail to capture the narrow ablation zones in the ice sheets' margin, leading to improper runoff estimation (Ettema et al., 2009; Noël et al., 2019). To mitigate this problem, the output of the atmospheric part can be bi-linearly interpolated (Gregory et al., 2012) or downscaled (Quiquet et al., 2021) to provide finer resolution input to the ice sheet model in the EMICs framework.

Another problem is the missing physical snow models within the EMICs framework to simulate the energy and mass transfer between the surface and the atmosphere (Lenaerts et al., 2019). In general, EMICs mostly utilize simple parameterizations such as positive degree day (PDD) (Reeh, 1991) or insolation temperature melt equation (ITM) (Van Den Berg et al., 2008) due to their simplicity and low computational cost (Born and Nisancioglu, 2012; Stone et al., 2013; Robinson and Goelzer, 2014; Goelzer et al., 2016b; Quiquet et al., 2021). However, as these schemes depend on locally calibrated parameters, their reliability is questioned when climate conditions change or when available data for calibration is limited, particularly in paleo studies. Bauer and Ganopolski (2017) report a failure of PDD in providing proper SMB values for the last glacial cycle study, which resulted from the ~~absence of albedo feedback~~albedo feedback being absent in the simulation. This poses a need to include a more physical snow model in such long-term climate simulations. The first option is ~~sophisticated surface energy balance models (SEBs) included in to use dedicated snowpack models coupled to~~ regional climate models (RCMs), which have abilities to simulate not only the ~~physically key~~key physical processes of SMB (melt, sublimation, and snow drifting) but also snow properties such as densities and metamorphism (Fettweis et al., 2017; Noël et al., 2018; Agosta et al., 2019; van Dalum et al., 2022). However, due to their complexity and computational cost, they are not suitable for long-term transient simulations and large study areas. As a compromise between parameterizations and SEB models, intermediate complexity energy balance mod-

55 els are promising SMB schemes for EMICs to run long simulations of ice sheet studies ([Calov et al., 2005](#); [Willeit et al., 2024](#))  
. These models have the appropriate level of simplicity in their structure and high computational efficiency, such as Born et al.  
(2019).

To answer the question of whether a physics-based scheme ~~can improve is a better choice for~~ the representation of SMB for  
paleo timescale, this work ~~aims to assess the possibility of replacing~~ evaluates the differences in the behaviors of the simple  
60 SMB scheme in *i*LOVECLIM ~~with and~~ a physical-based surface energy balance model BESSI (Bergen Snow Simulator) (Born  
et al., 2019) in a paleo study. Thanks to its high computational efficiency, *i*LOVECLIM has been used to carry out many pa-  
leoclimate studies ranging from ice sheet-climate interactions during the last deglaciation (Roche et al., 2014a; Quiquet et al.,  
2021; Bouttes et al., 2023), Heinrich Events (Roche et al., 2014b), to ocean circulation (Lhardy et al., 2021a) and carbon cycle  
changes between glacial-interglacial states (Bouttes et al., 2018; Lhardy et al., 2021b). BESSI is a surface energy and mass  
65 balance model designed for Earth system models of intermediate complexity. The snow model has been used to study ~~a the~~  
surface mass balance of the Greenland ice sheet during different periods (Zolles and Born, 2021; Holube et al., 2022; Zolles  
and Born, 2022) and proved to have good performance compared to other more complex models (Fettweis et al., 2020). In  
this work, we evaluate the performance of the updated version of BESSI since Zolles and Born (2021) and ITM - the current  
SMB scheme of *i*LOVECLIM for present-day climate using ~~output from~~ the regional climate model MAR (Modèle Atmo-  
70 sphérique Régional) as forcing and benchmark in Greenland and Antarctic Ice Sheets (GrIS and AIS, respectively). By doing  
this, we assess the ~~model's performance~~ models' behaviors under different climate conditions ~~and its ability to be applied~~  
~~to a new study area — Antarctica~~. In the second part, we assess the ~~possibility of applying BESSI in a paleo simulation by~~  
impact of using *i*LOVECLIM as ~~a climate forcing~~ the climate forcing on the SMB simulation of BESSI and ITM. Next, we  
compare ~~BESSI to ITM — the current SMB scheme of *i*LOVECLIM to investigate the differences between the two models~~.  
75 ~~We select~~ the SMB evolution simulated by the two SMB models during the most recent interglacial period (LIG) (130-116  
kaBP), which corresponds to the marine isotope stage (MIS) 5e. During this period, ~~as the summer insolation in the Northern~~  
~~Hemisphere increases~~ due to the change in the ~~orbit~~ orbital configuration of the Earth, ~~the annual global mean temperature is~~  
~~about 2 degrees Celsius higher in the annual~~ increasing summer insolation in the high latitude of the Northern Hemisphere leads  
to warmer conditions in polar regions (Capron et al., 2014). The estimation of the global mean temperature ~~than the change~~  
80 during the LIG with respect to the pre-industrial ~~period~~ (Kukla et al., 2002; Turney and Jones, 2010; Otto-Bliesner et al., 2013)  
~~— inducing retreats of ice sheets and glaciers~~ (Dutton and Lambeck, 2012; Dyer et al., 2021) ranges from almost no change  
(Capron et al., 2014; Hoffman et al., 2017; Otto-Bliesner et al., 2021) to a 1 to 2°C warming  
(Turney and Jones, 2010; McKay et al., 2011; Fischer et al., 2018). A warming in the high-latitude regions is nonetheless  
reported by both proxy data and model outputs. In addition, the sea level is reported to be at least 1.2 meters higher during the  
85 LIG (Dutton and Lambeck, 2012; Dutton et al., 2015; Dyer et al., 2021). Hence, the LIG provides documented records and  
insights into the behaviors of different Earth system components under warm climates to benchmark models and study the  
dynamics behind the phenomena (Fischer et al., 2018). This period has been well-studied for various aims such as reconstruct-  
ing temperature (Lunt et al., 2013; Landais et al., 2016; Obrecht et al., 2022) and sea level (Kopp et al., 2013; Dutton et al.,  
2015); investigating climate and ice-sheet interactions (Bradley et al., 2013; Goelzer et al., 2016a; Sutter et al., 2016). Applying

90 BESSI for the LIG has been done before in the work of Plach et al. (2018) for the Greenland Ice Sheet only by using climate forcings from MAR with equilibrium runs of some LIG time slices: 130, 125, 120, and 115 kaBP. In our work, as *i*LOVECLIM is much more computationally inexpensive compared to MAR, we can ~~run the model transiently to investigate~~ obtain transient climate forcings for BESSI and ITM to simulate the evolution of SMB throughout the whole LIG period. ~~For this work, we for both GrIS and AIS. We~~ select the LIG to investigate the abilities of ~~ITM and BESSI in reproducing the~~ BESSI and ITM in 95 simulating the evolution of SMB under different boundary conditions (deglaciation and glacial inception). From this, we can ~~fully evaluate the advantage~~ thoroughly investigate the effects of using a more physics-based model in simulating SMB for an intermediate complexity Earth model.

Section 2 provides background information about the models ~~and~~, the climate forcings, together with the design of the experiments. The results are presented in ~~Sect-~~ section 3, followed by a discussion about the ~~model's performance in Sect-~~ 100 models' behaviors and the climate forcings in section 4. Finally, a summary of the work is in ~~Sect-~~ section 5.

## 2 Methods

### 2.1 Models description

#### 2.1.1 BESSI

~~Bergen~~ BErgen Snow Simulator - BESSI is a multi-layer snow model simulating the surface energy and mass balance with 105 high computational efficiency, designed to be coupled with low-resolution Earth system models (Born et al., 2019). The model, which in its current configuration uses 15 vertical snow layers, requires near-surface air temperature, total precipitation, humidity, surface pressure, and downward long-/short-wave radiation ~~in daily timestep~~ as input. ~~From the forcings~~ BESSI runs at a daily time step and simulates albedo, which decays in exponential relationship with the latest snowfall event. Based on the energy transfer between the surface and the air, the model simulates important processes of surface mass balance, such as 110 melt, refreezing, runoff, and sublimation/evaporation, which resulted in the changing mass of the snow column. Among the snow layers, heat diffusion and mass compaction are also simulated (Fig. 1). ~~Full details on the implementation of these two processes are given in Born et al. (2019). In the following, we only detail the methodology used for surface energy and mass balance.~~ Compared to the version in Zolles and Born (2021), in this work, BESSI acquires the incoming long-wave radiation flux from the input instead of using parameterization. A detailed description of surface energy and mass balance processes is 115 presented in Appendix A.

~~Table of constant parameters of BESSI model~~ Parameter Symbol Value Unit Albedo of firn  $\alpha_{firn}$  0.7 Albedo of fresh snow  $\alpha_{freshsnow}$  0.82 Albedo of ice  $\alpha_{ice}$  0.4 Coefficient of sensible heat flux  $D_{sh}$   $15 \text{ W m}^{-2} \text{ K}^{-1}$  Emissivity of the surface  $\epsilon_s$  0.98 Density of water  $\rho_w$   $1000 \text{ kg m}^{-3}$  Heat capacity of air  $c_a$  1003 at  $0^\circ\text{C}$   $\text{J kg}^{-1} \text{ K}^{-1}$  Heat capacity of ice  $c_i$  2110 at  $-10^\circ\text{C}$   $\text{J kg}^{-1} \text{ K}^{-1}$  Heat capacity of water  $c_w$  4181 at  $25^\circ\text{C}$   $\text{J kg}^{-1} \text{ K}^{-1}$  Latent heat of melting  $L_m$   $3.34 \times 10^5 \text{ J kg}^{-1}$  Latent heat of 120 vaporization  $L_v$   $2.5 \times 10^6 \text{ J kg}^{-1}$  Ratio of latent and sensible heat  $r_{th/sh}$  1.0 Stefan-Boltzmann constant  $\sigma$   $5.670373 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$

**Figure 1.** Sketch of BESSI model with required inputs and simulated processes

### Surface energy balance

The exchange of energy between the surface (the top layer of the model) and the atmosphere resulted in the change of temperature in this layer ( $T_s$ ), influenced by the net solar flux  $Q_{SW}$ , the net longwave radiation flux  $Q_{LW}$ , the sensible heat flux  $Q_{SH}$ , the latent heat flux  $Q_{LH}$ , the heat flux from the precipitation  $Q_{precip}$  and the melting flux  $Q_{melt}$  (when temperature reaches melting point). This can be expressed as follows-

$$\frac{c_i m_{top}}{1} \frac{\partial T_s}{\partial t} \Big|_{surface} = \frac{Q_{SW} + Q_{LW} + Q_{SH} + Q_{LH}}{1} + \frac{Q_{precip} + Q_{melt}}{1}$$

in which,  $c_i$  is the heat capacity of ice ( $2110 \text{ J kg}^{-1} \text{ K}^{-1}$  at  $-10^\circ \text{C}$ ) and  $m_{top}$  is the mass of the top layer in  $\text{kg m}^{-2}$ .

The net incoming solar radiation  $Q_{SW}$  is calculated from the albedo of the surface ( $\alpha_{snow}$  or  $\alpha_{ice}$ ) and the incoming shortwave radiation  $F_{SW}$  ( $\text{Wm}^{-2}$ ) available from the forcing:-

$$Q_{SW} = (1 - \alpha) F_{SW}$$

The albedo of ice  $\alpha_{ice}$  is fixed at 0.4 while the albedo of snow  $\alpha_{snow}$  is calculated considering the exponential decay with time since the last snowfall event (Oerlemans and Knap, 1998; Zolles and Born, 2021):-

$$\alpha_{snow} = \alpha_{firn} + (\alpha_{freshsnow} - \alpha_{firn}) \exp\left(\frac{-N_{snowfall}}{t^*}\right).$$

in which the albedo of firn  $\alpha_{firn}$  is 0.7, the albedo of the fresh snow  $\alpha_{freshsnow}$  is 0.82,  $N_{snowfall}$  is the number of days since the last snowfall event and  $t^*$  is the number of days for the fresh snow to reach firn condition. Depending on the temperature  $T_{air}$ ,  $t^*$  is set to 20 days for  $T_{air} < 273.15 \text{ K}$  or 5 days for  $T_{air} = 273.15 \text{ K}$ .

The difference between the upcoming longwave radiation  $F_{LW}$  from the atmosphere (read from the input) and the emitted longwave radiation flux is the net longwave radiation  $Q_{LW}$ :-

$$Q_{LW} = F_{LW} - \sigma \epsilon_s T_s^4$$

in which,  $\sigma$  is the Stefan-Boltzmann constant ( $5.670373 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ ),  $\epsilon_s$  is the emissivity of the surface (0.98)-

The turbulent sensible heat flux  $Q_{SH}$  equals to the difference between the temperature of the air  $T_{air}$  and that of the surface  $T_s$  multiplied by a coefficient  $D_{sh}$  ( $15 \text{ W m}^{-2} \text{ K}^{-1}$ ):-

$$145 \quad Q_{SH} = D_{sh}(T_{air} - T_s)$$

The turbulent latent heat flux  $Q_{LH}$  depends on the difference between the water vapor pressure of the air  $e_{air}$  and of the surface  $e_s$  (calculated from the humidity), the surface pressure  $p_{air}$  from input and a coefficient  $D_{lh}$ :-

$$Q_{LH} = \frac{D_{lh}}{p_{air}}(e_{air} - e_s)$$

$$\text{with } D_{lh} = 0.622 r_{lh/sh} \frac{D_{sh}}{c_a} (L_v + L_m)$$

150 where  $r_{lh/sh}$  is the ratio of the exchange rates between the latent heat and sensible heat (equal to 1.0 in this work),  $c_a$  is the heat capacity of the air ( $1003 \text{ J kg}^{-1} \text{ K}^{-1}$  at  $0^\circ\text{C}$ ) whilst  $L_v$  and  $L_m$  are latent heat of vaporization and melting, respectively ( $2.5 \times 10^6 \text{ J kg}^{-1}$  and  $3.34 \times 10^5 \text{ J kg}^{-1}$ ). Details of the turbulent sensible and latent heat fluxes calculation methods are available in Zolles and Born (2021)-

Based on the air temperature ( $T_{air}$ ), BESSI classifies total precipitation as snow ( $T_{air} \leq 273.15 \text{ K}$ ) or rain ( $T_{air} > 273.15 \text{ K}$ )-

155 When snow/rain falls, the air temperature is transported to the surface . Hence, the heat flux from the precipitation is different for snow and rain:-

$$Q_{precip,s} = Precip \times \rho_w c_i (T_{air} - T_s)$$

$$Q_{precip,r} = Precip \times \rho_w c_w (T_{air} - 273.15)$$

where  $\rho_w$  is the density of water ( $1000 \text{ kg m}^{-3}$ ) and  $c_w$  is heat capacity of water ( $4181 \text{ J kg}^{-1} \text{ K}^{-1}$  at  $25^\circ\text{C}$ )-

160 The model uses an implicit scheme, for which the energy fluxes are calculated first, then the energy required to heat the top layer to the melting point. As the temperature of the surface cannot exceed the melting point, the remaining energy is considered as energy available to melt snow/ice  $Q_{melt}$  (Eq. (1)). The main parameters of the model are presented in Table 1.-

### Surface mass balance

165 Surface mass balance SMB is an important element of the ice sheet mass balance, apart from the ice discharge and basal melting. In BESSI, SMB is calculated as the remaining mass of total precipitation from runoff and sublimation/evaporation processes :-

$$SMB = Precip - (m_{runoff} + m_{sub})$$

In BESSI, the incoming precipitation (rain/snow) accumulates first on the surface (Fig. 1). Generally, the precipitation adds snow mass to the top snow layer ( $T_{air} \leq 273.15 \text{ K}$ ) or liquid mass to the water content of the surface ( $T_{air} > 273.15 \text{ K}$ )-

170 As more snow accumulates in the top layer, BESSI generates new snow layers below to prevent the mass of the layer from exceeding the maximum threshold ( $500 \text{ kg m}^{-2}$ ). The mass of the new layer is set at  $300 \text{ kg m}^{-2}$ , and the old layer keeps the remaining mass, continuing to accumulate snow. Depending on the precipitation and the temperature, up to 15 layers can be formed. When more than one layer exists, the masses of these layers are shifted down to leave space for the new forming layer. In contrast, when  $Q_{melt}$  is available, the snow column melts from the top. To prevent the mass of the surface layer from sinking below the minimum threshold ( $100 \text{ kg m}^{-2}$ ), BESSI merges this layer with the next one. After the merging, the masses of the layers below are shifted up.

The water resulting from melt and rain is retained by the snow column up to 10% of its pore volume. The excess water percolates through the snow column, either refreezing due to low temperatures or leaving the lowest layer as runoff. The energy for refreezing, according to the assumption that the snow and the liquid water inside the snowpack are in thermodynamic equilibrium (Born et al., 2019), is calculated as:

$$Q_{refreezing} = c_i m_s (273.15 - T_{snow})$$

in which  $T_{snow}$  is the temperature of the snow layer where the process takes place. Refreezing can occur anywhere among the snow layers, unlike melt, which happens only at the top.

185 In case  $Q_{melt}$  is enough to melt all the snow layers, ice starts to melt, adding water to the runoff. Hence, the mass of runoff, which is the resulting amount of water from processes of rain, melt, and refreezing, is calculated as below:

$$\frac{\partial m_{runoff}}{\partial t} = Precip \times \rho_w + \frac{Q_{melt} - Q_{refreezing}}{L_m}$$

Sublimation/Evaporation, depending on the humidity of the air, is converted from the turbulent latent heat flux  $Q_{LH}$  to mass as:

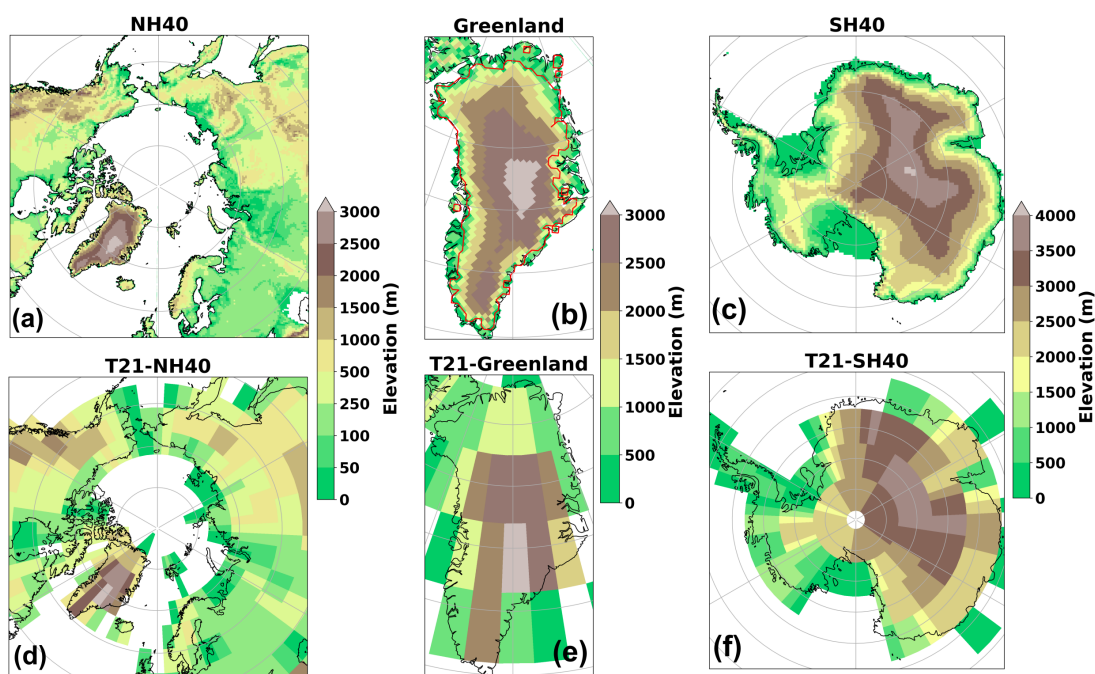

$$\frac{\partial m_{sub}}{\partial t} = - \frac{Q_{LH}}{L_v + L_m}$$

190 Positive values indicate sublimation/evaporation happens, subtracting mass from SMB. On the contrary, deposition/condensation occurs, adding mass to SMB. Additional details on these calculations are available in Born et al. (2019) and Zolles and Born (2021).

### 2.1.2 iLOVECLIM

The Earth system model of intermediate complexity iLOVECLIM (version 1.1) is a code fork of the LOVECLIM 1.2 model originated from Goosse et al. (2010). The key components of the model include the modules ECBILT for the atmosphere, CLIO for the ocean, and VECODE for the vegetation. ECBILT is a quasi-geostrophic atmospheric model that runs on a T21 spectral grid (Opsteegh et al., 1998). Meanwhile, CLIO is a 3D free-surface ocean general circulation model coupled to a thermodynamic sea-ice model and discretized on  $3^\circ \times 3^\circ$  spherical grid (Goosse and Fichefet, 1999). VECODE is a dynamical vegetation

model that allocates carbon and simulates land cover and tree fraction on the same grid as the atmospheric model (Brovkin et al., 1997). *i*LOVECLIM runs with a 360-day calendar.

**Figure 2.** Topography of *i*LOVECLIM for different resolution (a) NH40, (b) NH40-Greenland with the red contour indicates present-day ice sheet extent, (c) SH40, (d) T21-NH40, (e) T21-Greenland and (f) T21-SH40.

Climate forcings for BESSI are obtained from the online downscaling module within *i*LOVECLIM framework, which recomputes the surface energy budget and total precipitation on a subgrid resolution for the ice sheet areas (Quiquet et al., 2018). In this work, we run the downscaling for two polar regions to obtain near-surface air temperature, total precipitation, and humidity on a  $40\text{km} \times 40\text{km}$  Cartesian grid (referred to as NH40 and SH40 for the North and South Poles, respectively) (Fig. 2a-c). To obtain other input variables for BESSI, long-/short-wave radiation, and surface pressure are bi-linearly interpolated from the native T21 grid (Fig. 2d-f) to the NH40/SH40 grid.

In fact, due to its coarse resolution and simplification in physics, *i*LOVECLIM displays some incorrect climate patterns. Particularly, Heinemann et al. (2014) reported surface air temperature biases of *i*LOVECLIM compared to observation in North America and Northern Europe, which are preserved in the downscaling version NH40 (Quiquet et al., 2018). To evaluate the impacts of these biases on the SMB simulation, we carry out a simple bias correction process by using ERA5 (Muñoz-Sabater et al., 2021), a reanalysis climate data as reference (see Appendix C). In general, the variables with strong biases are total precipitation, short-wave radiation and air temperature. In addition, for the Antarctic Ice Sheet, the humidity is strongly underestimated in *i*LOVECLIM.

### 2.1.3 ITM stand-alone

215 In terms of the SMB scheme, ~~iLOVECLIM uses~~ the insolation temperature melt method (ITM) (Van Den Berg et al., 2008). This ~~module is developed~~ parameterization is implemented to provide SMB to the ice sheet model embedded in iLOVECLIM named GRISLI (~~Roche et al., 2014a~~) for coupling purposes (Quiquet et al., 2021).

This parameterization calculates the ~~melt water~~ Melt as runoff water as

$$\frac{\partial Melt}{\partial t} - \frac{\partial m_{runoff}}{\partial t} = \frac{1}{\rho_w L_m} ((1 - \alpha_s)SW + \underline{c}rad + \underline{T}_s \lambda (T_{air} - 273.15)) \geq 0 \quad (1)$$

220 in which,  $\rho_w$  is liquid water density ( $1000 \text{ kg m}^{-3}$ ),  $L_m$  is the specific latent heat of melting ( $3.34 \times 10^5 \text{ J kg}^{-1}$ ),  $\alpha_s$  is the surface albedo,  $SW$  is the surface shortwave radiation ~~and  $T_s$  is the surface temperature. Here, we used  $\lambda = 10 \text{ W m}^{-2} \text{ K}^{-1}$ , similar to Quiquet et al. (2021). For the empirical parameter  $c$ , we use  $c = -25 \text{ W m}^{-2}$ . Considering the temperature bias of~~ and  $T_{air}$  is the near-surface air temperature (K). Meanwhile,  $\lambda$  and  $c$  are two empirical parameters.

225 ~~For the coupling between iLOVECLIM and GRISLI, Quiquet et al. (2021) carried out local modification to the parameter  $c$  according to the annual mean temperature bias compared to ERA-Interim (Dee et al., 2011). Quiquet et al. (2021) also implemented an albedo interpolation to take into account the altitude of the grid points (vertical) and to create a smooth transition of albedo value from ocean to land area (horizontal). Here, to provide a comparable ITM to BESSI, these albedo modifications are not included.~~

The equation of SMB (Eq.10) in this case is calculated as:-

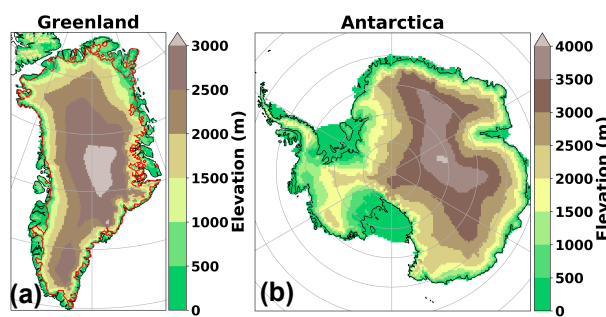

230  $SMB = Precip - Melt$

~~Climate forcings for BESSI are obtained from the online downscaling module within In addition, to take into account the temperature bias of iLOVECLIM framework, which recomputes the surface energy budget and total precipitation on a subgrid resolution for the ice sheet areas (Quiquet et al., 2018). This downscaling module is only carried out for land grid boxes. In this work, we run the downscaling for two polar regions to obtain near-surface air temperature, total precipitation, and humidity on a  $40\text{km} \times 40\text{km}$  Cartesian grid (referred to as NH40 and SH40 for the North and South Poles, respectively). To obtain other input variables for BESSI, long-/short-wave radiation, and surface pressure are bi-linearly interpolated from, a local modification of the parameter  $c$  based on the native T21 grid to the NH40/SH40 grid. annual mean temperature difference compared to ERA-Interim (Dee et al., 2011) is also included in ITM as explained in Quiquet and Roche (2024).~~

240 ~~Here, to provide a clean comparison to BESSI, a stand-alone version of ITM is used with the same albedo value as the ice grid points in iLOVECLIM ( $\alpha_s = 0.85$ ) and  $\lambda = 10 \text{ W m}^{-2} \text{ K}^{-1}$  as in Quiquet et al. (2021). The input data  $SW$  and  $T_s$  are read from BESSI input, hence, ITM also runs at a daily time step. The empirical parameter  $c$  is tuned during the present-day climate with MAR as forcing. The SMB is the remaining of the total precipitation after subtracting the calculated runoff.~~

## 2.2 Present-day climate reference data

For calibration/validation purposes, we use the present-day climate data from one of the state-of-the-art regional climate models - MAR (Modèle Atmosphérique Régional). MAR has been widely applied to study the SMB changes and surface melt for polar regions (Fettweis et al., 2017; Agosta et al., 2019; Mankoff et al., 2021). The model, with a typical sub-daily time step of 120 s (Fettweis (2007)), includes a 3D atmospheric model coupled with a 1D surface-atmosphere energy mass exchange scheme named SISVAT (Soil Ice Snow Vegetation Atmosphere Transfer) (Fettweis et al., 2017) that is more complex and physical than BESSI. It can simulate up to 30 layers of snow/ice and consider snow properties and metamorphism (Kittel et al., 2021). Also, the simulated surface albedo takes into account more variables, including snow's optical properties, clouds, snow depth, the presence of bare ice, and liquid water (Tedesco et al., 2016). Detailed about the MAR model and its setup can be found in Fettweis (2007) and Fettweis et al. (2013).

**Figure 3.** [Topography of MAR for \(a\) Greenland \(15km×15km\) with the present-day ice sheet extent in red contour and \(b\) Antarctica \(35km×35km\).](#)

In this study, MAR acts as present-day forcing and reference benchmarks to compare with BESSI [and ITM](#) for both Greenland and Antarctic Ice Sheets (denoted as GrIS and AIS, respectively). The resolution of the climate forcings is 15km×15km for GrIS (version 3.13) [\(Fig. 3a\)](#) and 35km×35km grid for AIS (version 3.12) [\(Fig. 3b\)](#), covering the period 1979 - 2021.

## 2.3 Study design

In this work, we carry out ~~two~~ [three](#) sets of experiments corresponding to the two climate forcings: MAR [for present-day conditions](#) and [iLOVECLIM -for both present-day and the LIG conditions. The climate characteristics of these experiments are presented in Table 1.](#)

260 In the first experiment, we investigate the ~~performance of BESSI behaviors of BESSI and ITM~~ [for present-day climate by using MAR as forcing \(BESSI-MAR \). The SMB calculated by MAR itself is used as a reference. The and ITM-MAR\).](#) The calibration and validation are carried out for GrIS and AIS during the study period from 1979 to ~~2021. Initially, the snow model~~ [2021 with the calibration carried out for GrIS only. To evaluate the results, we use two goodness-of-fit metrics, which](#)

are the coefficient of determination  $R^2$  and the Root Mean Squared Errors (RMSE) to assess the differences of BESSI-MAR and ITM-MAR refer to MAR (see Appendix B). Initially, BESSI is spun up by looping the forcing several times until it reaches an equilibrium state ~~with an ice sheet mask of~~. The ice mask corresponds to present-day ice sheet extent, classified in MAR as grid cells with more than 50% of permanent ice. Some of BESSI's parameters ~~, including related to albedo simulation ( $\alpha_{freshsnow}$ ,  $\alpha_{firn}$ , and  $\alpha_{ice}$ ), and turbulent latent heat flux calculation ( $r_{lh/sh}$  and  $D_{sh}$ )~~ are tuned to obtain lowest RMSE value between BESSI and MAR output and the narrowest gap in term of total SMB (SMB integrated over the ice sheet mask). The final values of these parameters are presented in Table 1. ~~The 43-year mean SMB value from GrIS and AIS run is then analyzed. For validation, we use several goodness-of-fit metrics, such as coefficient of determination  $R^2$ , Root Mean Squared Errors (RMSE), and Normalized Root Mean Squared Errors (NRMSE) to assess BESSI-MAR performance refer to MAR (see Appendix A).~~

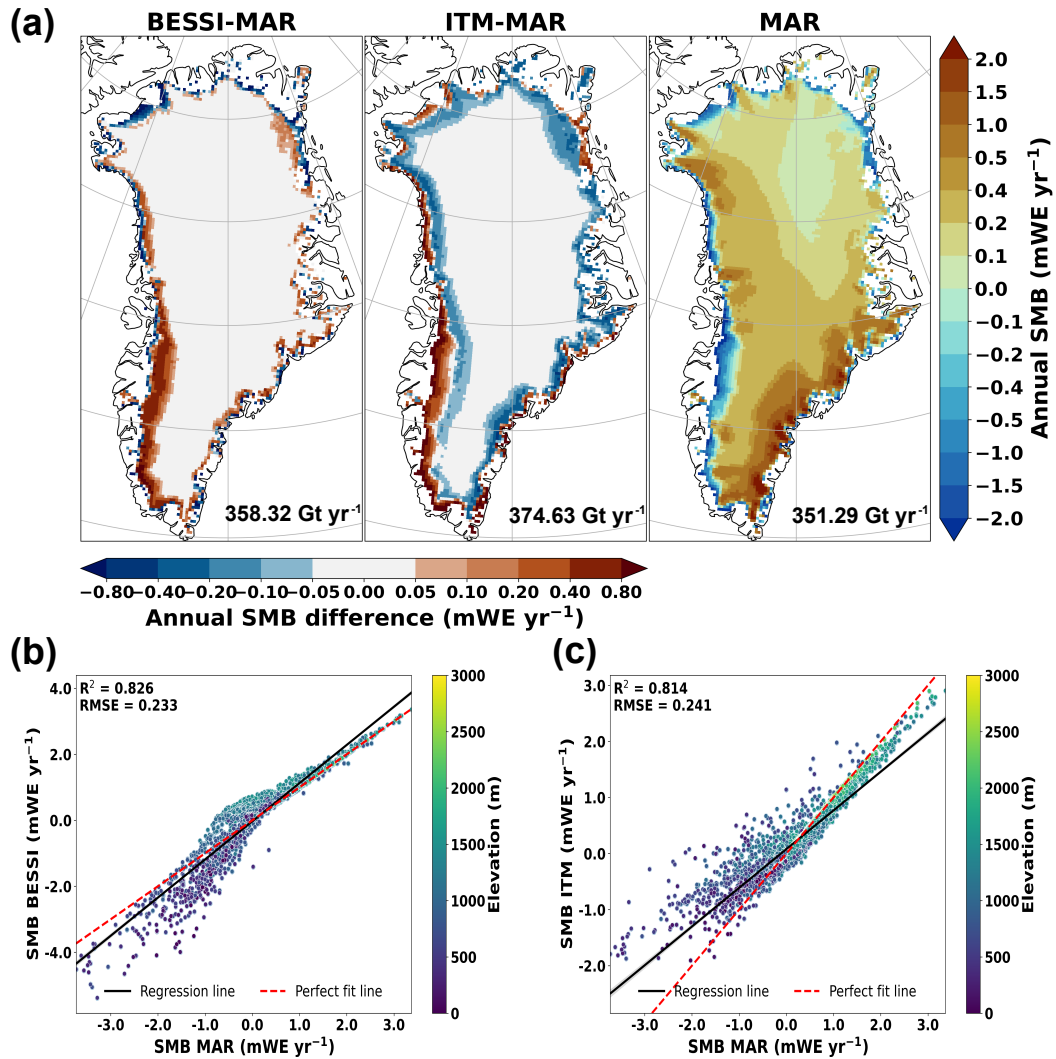

In the second set of experiments, we force the snow model by downscaled iLOVECLIM (BESSI-iLOVECLIM) to evaluate the possibility of replacing the current SMB scheme ~~ITM~~ with BESSI. We run BESSI-iLOVECLIM for three different periods: the pre-industrial, A1. The same tuning procedure is applied for the empirical parameter *crad* of ITM, and the present-day, and the Last Interglacial. For each period, BESSI is always first spun up by looping the forcings several times for the snowpack to reach equilibrium before results are obtained for analysis. ~~optimized value is -10.~~

280 First, BESSI-*i*LOVECLIM is run for the pre-industrial to provide a reference for the calibration of ITM. As the ITM version used here is different from Quiquet et al. (2021), we obtain the value for the melt parameter  $c$  in Eq.15 by tuning it aiming at the minimum RMSE between the climatological annual mean SMB of ITM and BESSI and the lowest difference in annual mean total SMB of the two models for the pre-industrial period (PI). By doing this, the comparison between ITM and BESSI Before applying BESSI and ITM for the LIG is more robust as the performance of the two models is similar for the PI. To obtain climate forcing for BESSI, we run downscaled with *i*LOVECLIM for 50 years from a 1000-year spin-up under pre-industrial boundary conditions.

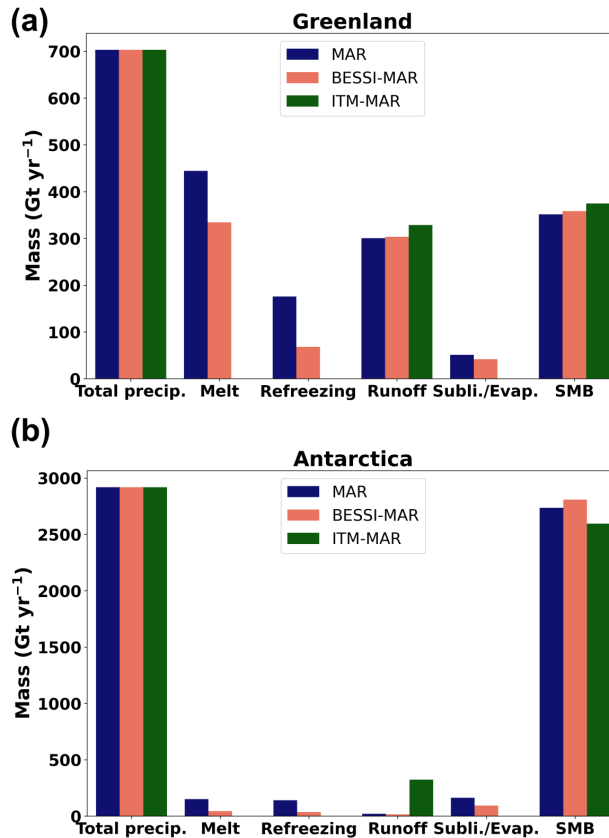

285 Due to its coarse resolution and simplification in physics, *i*LOVECLIM displays some incorrect climate patterns. Particularly, Heinemann et al. (2014) reported bias in surface air temperature of *i*LOVECLIM compared to observation in North America and Northern Europe, which are preserved in the downscaling version NH40 (Quiquet et al., 2018). To understand the impacts of climate in *i*LOVECLIM on the performance of the snow model, the comparison between LOVECLIM as forcing, we investigate the influences of the input on the behavior of the two SMB models by comparing the results of BESSI-*i*LOVECLIM and BESSI-MAR is carried out-ITM-*i*LOVECLIM to MAR for the present-day period condition. *i*LOVECLIM forcings for present-day is obtained by running the model with the prescribed greenhouse gases (GHG) concentrations during the same period as MAR, 1979-2021.

290 Finally, from 1979 to evaluate the feasibility of applying BESSI for paleoclimate studies, SMB evolution during the LIG is simulated by BESSI-2021. As mentioned above (Sec 2.1.2), we implement a simple bias correction process to correct the climate field of *i*LOVECLIM. At first To quantify the impact of these biases on the SMB simulation, we run BESSI and ITM with the bias-corrected *i*LOVECLIM transiently during.

300 For the LIG, 135-115 to obtain the climate forcing, we run *i*LOVECLIM transiently from 135 to 115 kaBP, with present-day ice sheet topography and varying orbital configuration and concentrations of GHG to obtain restart files. Then, for For every 500 years, we sample 50 years of climatological daily output to provide forcings for BESSI and ITM. In total, we have there are 41 time slices sets of inputs corresponding to 41 timeslices covering the entire LIG period. Next BESSI is spun up with the input data from the first time slice - 135 kaBP to reach the equilibrium state. Then, for each time slice, we run BESSI for 100 years with the snowpack from the spin-up of 135 kaBP and take the annual mean of the last 50 years for further analysis. The evolution of SMB simulated by BESSI and ITM during the LIG is then compared to investigate the models' behaviors.  
305 In order to assess the trend of SMB evolution, we compute the differences in the annual mean SMB during the LIG with respect to the PI-pre-industrial (PI) value for both BESSI-*i*LOVECLIM and ITM. The evolution of SMB simulated by BESSI and ITM during the LIG is then compared to investigate-ITM-*i*LOVECLIM. The climate forcing of PI is obtained by running downscaled *i*LOVECLIM for 50 years from a 1000-year spin-up under pre-industrial boundary conditions. To quantify the biases of climate forcings on the models' performance behaviors, assuming the biases in *i*LOVECLIM are constant with time,  
310 we use the present-day bias correction factors to correct the climate forcings for LIG and PI. The results of before and after the bias correction are then compared.

**Figure 4.** (a) Annual mean SMB values anomalies (in mWE yr<sup>-1</sup>) of MAR-BESSI-MAR and BESSI in (row a) ITM-MAR compared to MAR for Greenland and (row b) Antarctica Ice Sheet. The reference, MAR, is shown in absolute annual SMB values. The total SMB (in Gt yr<sup>-1</sup>) integrated for the ice sheet area is also included. The grid points from scatter plots of (b) BESSI-MAR vs. MAR and (c) ITM-MAR vs. MAR indicate the maps are plotted SMB of each grid point (in mWE yr<sup>-1</sup>) with elevation classification in the scatter plots, including the linear regression line in red-black and the perfect fit line (1,1) in dashed-blackred.

### 3 Results

#### 2.1 BESSI-validated-by-present-day-forcings-from-MAR

### 3 Results

#### 315 3.1 MAR as present-day climate forcings

##### 3.1.1 Greenland

The map of the annual mean SMB ~~simulated by the BESSI and MAR for Greenland~~ differences simulated by BESSI-MAR and ITM-MAR compared to MAR (shown in absolute value) for the Greenland ice sheet during the period 1979 - 2021 is presented in Fig. 2a. ~~Generally,~~ 4a. ~~For BESSI-MAR, in the 43-year mean SMB simulated by BESSI is in good agreement~~

320 with MAR despite a simpler model structure. Particularly, in the center of the ice sheet, where sublimation/evaporation is dominant due to dry climate, the SMB is simulated correctly by BESSI as referred to MAR southwest of Greenland, there is a widespread of positive SMB anomalies, indicating an underestimation of this ablation zone which is also reported by Plach et al. (2018); Fettweis et al. (2020) (Supplementary Fig. S1a). However, in the southwest of Greenland, the ablation zone extent is noticeably underestimated in BESSI, which is also reported by Plach et al. (2018); Fettweis et al. (2020). S1).  
325 Such high SMB values in BESSI-MAR for this area is related to the albedo simulation. Compared to MAR, the annual albedo simulated for the southwest of GrIS is higher in BESSI-MAR, leading to a lower runoff rate (Supplementary Fig. S2). Even though the extent is underestimated, the magnitude of ablation in BESSI-BESSI-MAR is higher than MAR around the margins, particularly in the North and West of Greenland. For Antarctica, the SMB simulated by the two models also shows high agreement (Fig. 2b). The problem related to melting in Greenland is limited in this ice sheet as it has a much colder climate  
330 (these grid points, BESSI-MAR simulates high melt rates while the amount of water refreeze remains low (Supplementary Fig. S3a-b), resulting in negative SMB anomalies compared to MAR. In the center of the ice sheet, where sublimation/evaporation is dominant due to dry climate, the SMB is simulated correctly by BESSI-MAR as referred to MAR. However, this process is slightly underestimated in some areas, noticeably the west of the ice sheet (Supplementary Fig. S3c). In general, the 43-year mean SMB simulated by BESSI-MAR is in good agreement with MAR despite a simpler model structure with a 2% difference  
335 in the total SMB.

For ITM-MAR, the differences in SMB compared to MAR come from the runoff simulation, as the model does not simulate other processes. Hence, the differences are located mostly in low elevation areas where the temperature is not low enough to compensate for the short-wave radiation influence (Eq. (1)) during the summer months (Supplementary Fig. S4a-b). Around the ice sheet margin, ITM-MAR simulates less runoff around the margins due to a constant albedo value (0.85) (Supplementary  
340 Fig. S1b)S2), resulting in SMB overestimation for these grid points. The total SMB difference between ITM-MAR and MAR is around 6.64%, three times more than that of BESSI-MAR. In terms of total SMB, the difference between the two models is in an acceptable range: 1.24% for GrIS and 2.54% for AIS.

Contribution of different key processes to the 43-year mean total SMB in (a) Greenland and (b) Antarctica (in  $Gt\ yr^{-1}$ ), with corresponding  $R^2$  and NRMSE.

345 Temporal variation of the yearly mean total SMB integrated on present-day ice sheet extent (in  $Gt\ yr^{-1}$ ) during 1979-2021 for (a) Greenland and (b) Antarctica.

The scatter plots of the grid points with different elevations in the SMB maps are also presented in Fig. 24, with the evaluation metrics to illustrate the goodness-of-fit between the two models for both ice sheets. For GrIS, BESSI of BESSI-MAR and ITM-MAR to MAR. Compared to MAR, BESSI-MAR tends to underestimate SMB of the low-elevation grid points located  
350 in the ice sheet margin in the North and West (Fig. 2a). On the other hand, for 4b). For points located near the equilibrium line (with  $SMB \approx 0$ ), SMB is slightly overestimated. Unlike GrIS, the scatter plot of AIS shows no under-/over-estimation in the mean SMB, consistent with the SMB map in BESSI-MAR. Meanwhile, ITM-MAR shows a trend of SMB overestimation for grid points located in the ablation area (Fig. 2b4c). In general, the evaluation metrics illustrate a good fit between BESSI and MAR for both ice sheets, with AIS slightly better. In particular, the coefficient of determination  $R^2$  in AIS is 0.993 while that

355 in-GrIS is 0.806; RMSE is 0.022 for AIS and 0.246 for GrIS (unit here is  $mWE\ yr^{-1}$ ). an acceptable SMB simulation of both BESSI-MAR and ITM-MAR with respect to MAR.

BESSI's performance in simulating key processes of SMB in Greenland is presented in Fig.3a . This bar chart Fig.5a illustrates the mean value of total SMB elements with the corresponding evaluation metrics:  $R^2$  and NRMSE. We simulated by the three models for GrIS. For BESSI-MAR, we can see strong underestimations in melt and refreezing in-BESSI compared to MAR, especially refreezing with less than half of MAR's value. This might result from the model's daily timestep/daily time step, which causes the model to neglect the diurnal temperature cycle (Krebs-Kanzow et al., 2018). These However, these underestimations are compensated in the runoff, leading to an acceptable value in BESSI-BESSI-MAR compared to MAR. Among these major processes of SMB, refreezing, with the lowest  $R^2$  (0.461) and highest NRSME (0.734), is not simulated as well as other processes. Sublimation Meanwhile, the sublimation/Evaporation, on the other hand, is shown to be well simulated with  $R^2$  (0.832) and NRSME (0.41). The results of BESSI in Antarctica are not much different (Fig. 3b). As discussed above, evaporation rate in BESSI-MAR is slightly lower than MAR due to the underestimation of this process. For ITM-MAR, the contribution of runoff to total SMB in this ice sheet is very small due to cold climate conditions. On the other hand, model compensates for the absence of the sublimation/evaporation process by simulating more runoff to obtain a similar SMB rate compared to MAR. Both BESSI-MAR and ITM-MAR overestimate the SMB with MAR as a reference. This trend is consistent during the study period (Supplementary Fig. S5a).

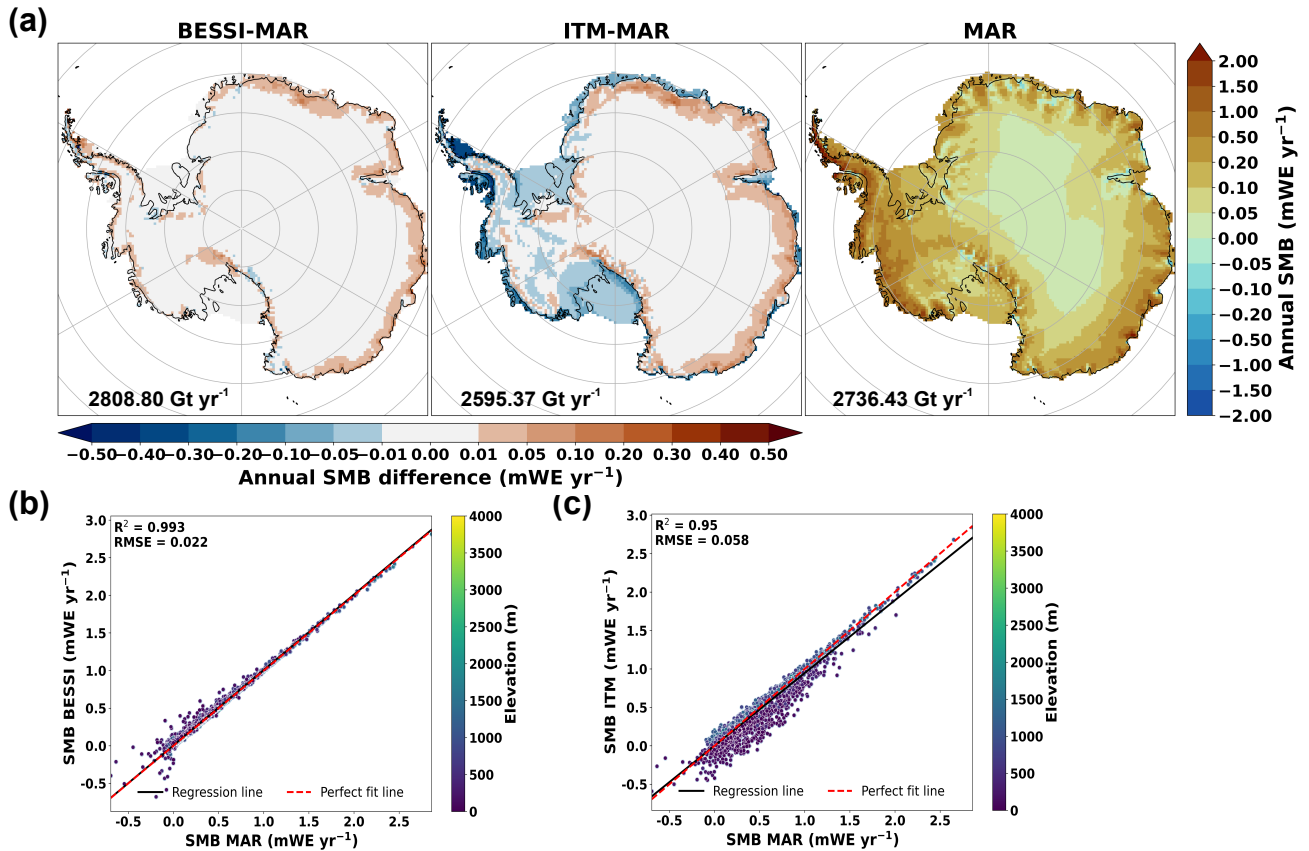

### 3.1.2 Antarctica

The annual mean SMB differences of BESSI-MAR and ITM-MAR with respect to MAR for the Antarctic Ice Sheet are shown in Fig. 6a. For Antarctica, BESSI-MAR shows a high agreement with MAR on the SMB simulation with very limited differences. The problem related to melting in Greenland is limited here as it has a much colder climate (Supplementary Fig. S6a), and sublimation/evaporation differences between BESSI and MAR are larger than in Greenland as they are more dominant in Antarctica. This leads to slightly higher differences between the total SMB becomes dominant. The differences between the two models come from the underestimation of sublimation/evaporation around the ice sheet margin in BESSI-MAR (Supplementary Fig. S6b), leading to the larger gap between BESSI-MAR and MAR for this process compared to GrIS (Fig. 5).

380 Meanwhile, ITM-MAR exhibits large differences from MAR for the annual mean SMB. The anomalies located in the interior of the ice sheet come from the absence of sublimation/evaporation in this parameterization. The underestimation of SMB around the edge of the ice sheet and the ice shelves comes from the high simulated runoff by ITM-MAR (Supplementary Fig. S6a). ITM-MAR simulates runoff for these grid points due to high short-wave radiation that overweighs the mild temperature during the melting season (Supplementary Fig. S7a-b). In terms of the two models.

385 The variation of total SMB of the two ice sheets throughout the studied period is shown in Fig. 4. The figure shows that the temporal variation of total SMB is well captured in BESSI. For both cases, there is an overestimation of the total SMB in BESSI in comparison to MAR. In Greenland, BESSI reproduces the total SMB in very good accordance with that of, the

**Figure 6.** (a) Annual mean SMB anomalies (in  $\text{mWE yr}^{-1}$ ) of BESSI-MAR and ITM-MAR compared to MAR for Antarctic Ice Sheet. The reference, MAR, is shown in absolute annual SMB values. The total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the ice sheet area is also included. The scatter plots of (b) BESSI-MAR vs. MAR and (c) ITM-MAR vs. MAR indicate the SMB of each grid point (in  $\text{mWE yr}^{-1}$ ) with elevation classification, including the linear regression line in black and the perfect fit line (1,1) in red.

differences between the two SMB models compared to MAR are in an acceptable range: 2.64% for BESSI-MAR and -5.15% for ITM-MAR (Fig.5b).

390 Similar to GrIS, scatter plots of the grid points with different elevations in the maps of Fig. 6a are also presented in Fig. 6b-c. For AIS, there is no significant trend of under-/over-estimation of annual mean SMB in BESSI-MAR compared to MAR (Fig. 4a). Meanwhile, for Antarctica, the gap is slightly larger (6b). On the other hand, ITM-MAR shows a strong SMB underestimation trend for low elevation grid points (Fig. 4b), which is consistent with the gap in the annual mean total SMB shown in Fig. 2b and Fig. 3b. However, considering the magnitude of total SMB in AIS, this small difference is deemed  
 395 acceptable (6c) due to high runoff rates. These points correspond to the ablation zone over ice shelves that is not present in MAR. This trend is observed throughout the study period (Supplement Fig. S5b). The evaluation metrics suggest a good fit of the two SMB models to MAR, with BESSI-MAR having a slightly better value.

## 3.2 **BESSI-with** *i*LOVECLIM as climate forcing: present-day

### 3.2.1 **Climate in** *i*LOVECLIM Greenland

#### 400 **Greenland**

Annual-mean-value-of-climate-variables-including (a) precipitation (in  $\text{mWE yr}^{-1}$ ), (b) near-surface temperature (in degree Celsius) and (c) relative humidity of MAR and *i*LOVECLIM for Greenland Ice Sheet.

Comparison-of-annual-mean-SMB (in  $\text{mWE yr}^{-1}$ ) between BESSI with different forcings: MAR and *i*LOVECLIM, and ITM for Greenland Ice Sheet. The total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent (red line) is also included.

405 *i*LOVECLIM has a coarser resolution and simpler model setup than MAR - a state-of-the-art regional climate model used to calibrate/validate BESSI and ITM. This difference in the simulated climate strongly influences the performance-of-the snow model. The comparison-of-the-climate-of-MAR-and-behaviors-of-the-two-SMB-models. Annual mean SMB during the period 1979-2021 simulated by BESSI-*i*LOVECLIM in terms of precipitation, temperature, and relative humidity is shown and ITM-*i*LOVECLIM for GrIS is presented in Fig. 5. In general, the native T21 grid pattern is clearly visible in 7a. Switching the climate forcings, the resolution of *i*LOVECLIM climate as the downscaling mostly redistributes climatic variables of the coarse resolution according to the subgrid topography (Quiquet et al., 2018). Also influences BESSI-*i*LOVECLIM significantly with the SMB patterns following the input fields grid (Supplement Fig. S4). Particularly, compared to BESSI-MAR for the same study period (Supplement Fig. S1), the narrow ablation zones in the southwest of GrIS is missing while there are larger ablation zones in the South. Also, the magnitude of negative SMB in BESSI-*i*LOVECLIM is very high. This results from

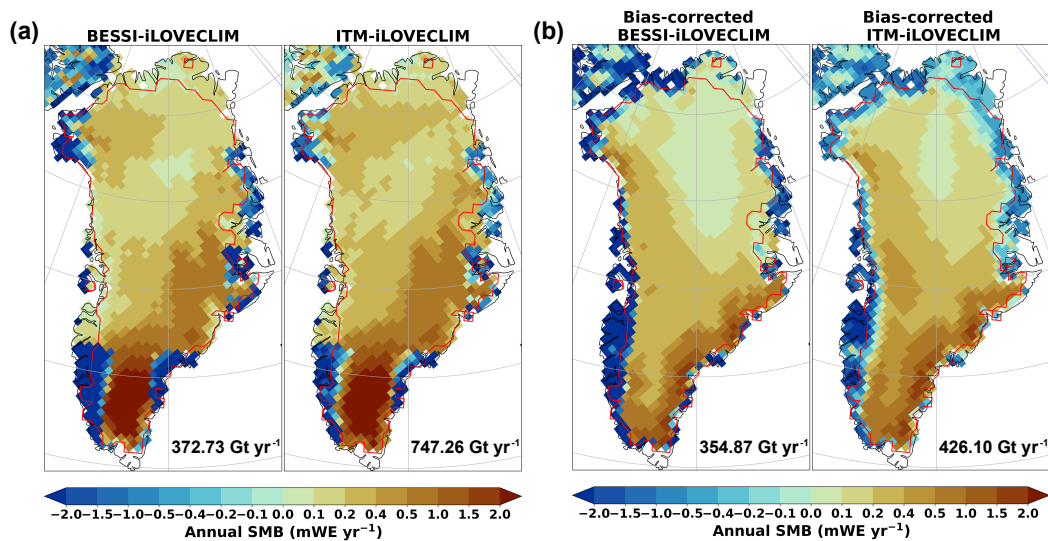

410 a warm climate that induces high melt rates, while the model does not simulate the refreezing process well due to a large time step (as mentioned in Sect. 3.1.1). Consequently, the contribution of runoff to the total SMB in BESSI-*i*LOVECLIM are very high compared to MAR as illustrated in Fig. 8a, leading to similar SMB value even for higher total precipitation rate ( $372.73 \text{ Gt yr}^{-1}$  vs  $351.29 \text{ Gt yr}^{-1}$ , respectively). On the other hand, due to the drier atmosphere (Supplement Fig. S4d), it is noticeable that some ice sheet areas are not covered due to the coarse land grid boxes of the native T21 grid. Compared to

420 MAR, sublimation/evaporation in BESSI-*i*LOVECLIM has a higher annual mean precipitation rate in the South and in the center-North of GrIS (Fig. 5a). Hence, the total precipitation is larger in *i*LOVECLIM is around 30% higher than in MAR.

The climate forcing also strongly influences ITM-*i*LOVECLIM with a gap of more than  $200 \text{ Gt yr}^{-1}$  (Table 2). In addition, the climate simulated by similar large ablation zones in the South of GrIS as in BESSI-*i*LOVECLIM. However, the magnitude of negative SMB in ITM-*i*LOVECLIM is as large as in BESSI, which is a result of the low short-wave radiation rates in this

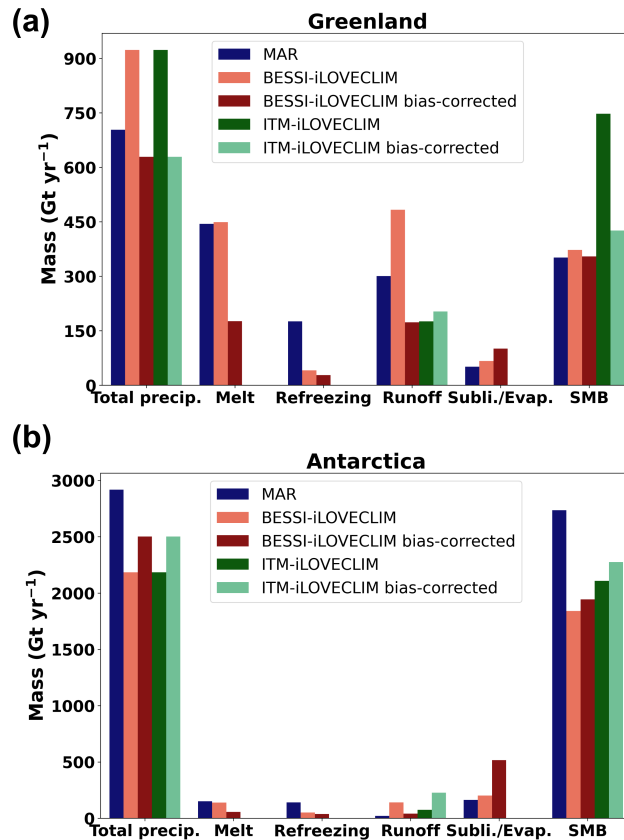

425 climate forcing (Table 1 and Supplement Fig. S4b). Therefore, the runoff contribution to the total SMB for ITM-*i*LOVECLIM is generally warmer and less humid than MAR as *i*LOVECLIM has a higher range of annual mean near-surface temperature and a significantly lower humidity value lower than MAR (Fig. 5b and 5c). However, considering a much coarser original resolution of *i*LOVECLIM, it can still properly produce the climate major pattern in the right order of magnitude, except for humidity in Greenland after downscaled to a  $40\text{km} \times 40\text{km}$  grid. 8a). For a higher total precipitation rate, this results in a much

430 higher SMB value as indicated in Fig. 7a.

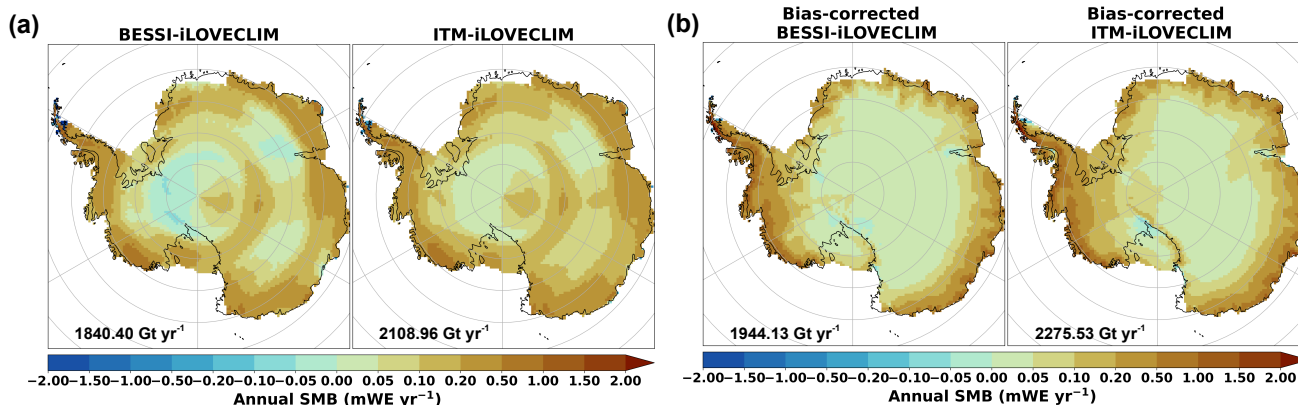

**Figure 7.** Comparison of annual mean SMB (in  $\text{mWE yr}^{-1}$ ) between BESSI-*iLOVECLIM* and ITM-*iLOVECLIM* (a) before and (b) after bias correction for Greenland Ice Sheet. The total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent (red line) is also included.

To investigate the influences of the forcings on the BESSI model, we compare As the biases in *iLOVECLIM* exhibits a strong influence on BESSI and ITM, the annual mean SMB during 1979-2021 between BESSI-MAR and simulated with a corrected climate forcing is presented in Fig. 7b. With the adjusted input, BESSI-*iLOVECLIM* (Fig. 6). The patterns of the simulated SMB follow the patterns of precipitation of the climate forcings (Fig. 5a). BESSI-MAR has smoother SMB simulation as the resolution of MAR is finer than *iLOVECLIM*, particularly 15km vs 40km. This helps the model to capture narrow ablation around the margin in the West and North of the ice sheet, which is absent from the result of BESSI-*iLOVECLIM*. BESSI-*iLOVECLIM* overestimates both ablation and accumulation in the South simulates more appropriate SMB patterns with the narrow ablation zone in the southwest presence and a bigger extent of the low accumulation zone in the center North of the ice sheet due to the bias in the climate of the forcing. Particularly, the magnitude of the negative SMB is very high in BESSI-. For ITM-*iLOVECLIM*, which is a result of the model setup itself, as this is also observed in BESSI-MAR and MAR comparison (Fig. 2a). Due to such warmer and drier climate conditions, similar patterns are observed with additional ablation zones in the North as in ITM-MAR (Supplement Fig. 1), resulting from high short-wave radiation rates in these grid points (Fig. C1). The contribution of difference processes to the total SMB of bias-corrected BESSI-*iLOVECLIM* has higher rates of melt and sublimation/evaporation than MAR (Table 2). Despite these discrepancies in the magnitude of SMB, the patterns of SMB for both cases, overall, are quite similar. Also, the value of the total SMB from the two forcings is in the same range with around 20 *iLOVECLIM* and ITM-*iLOVECLIM* are shown in Fig. 8a together with results from MAR and original *iLOVECLIM*. Noticeably, the total precipitation after the bias correction in *iLOVECLIM* decreases from  $923 \text{ Gt yr}^{-1}$  to  $629 \text{ Gt yr}^{-1}$ , around 10.5% lower than MAR's value ( $703 \text{ Gt yr}^{-1}$  difference.

**Figure 8.** Comparison of the contribution of different key processes to the 43-year mean total SMB of BESSI-iLOVECLIM and ITM-iLOVECLIM before and after bias correction in (a) Greenland and (b) Antarctica with MAR as reference (in Gt yr<sup>-1</sup>).

In the same figure, we also compare BESSI with the current SMB scheme iLOVECLIM climate  $\hat{O}\hat{C}\hat{\delta}$  ITM to gain insight into the behavior of the two models. A noticeable difference with reference to  $\hat{O}\hat{C}\hat{\delta}$  ITM is that the negative SMB zone around the West margin of the ice sheet is present and expands deep into the center (Fig. 6), which can possibly be a result of the temperature patterns (Fig. 5b). This indicates that ITM in this work overestimates the ablation zone, leading to excessive melt simulation with nearly 100% higher than BESSI-iLOVECLIM (Table 2). On the other hand, the low accumulation zone in the center North of the ice sheet related to  $\hat{O}\hat{C}\hat{\delta}$  ITM is nearly three times less than before the bias correction (487 Gt yr<sup>-1</sup>). Because of the colder climate, the sublimation/evaporation is not as clear as shown in BESSI-rate increases from 67 Gt yr<sup>-1</sup> to 101 Gt yr<sup>-1</sup>, nearly double the MAR's value (51 Gt yr<sup>-1</sup>). For ITM-iLOVECLIM as ITM simulates only melt. Both models, unlike BESSI-MAR, have accumulation outside the ice sheet mask, possibly, the simulated runoff increases slightly from 176 Gt yr<sup>-1</sup> to 203 Gt yr<sup>-1</sup> after the bias correction, which is due

**Figure 9.** Annual-mean-value Comparison of climate variables including annual mean SMB (a) precipitation (in  $\text{mWE yr}^{-1}$ ), between BESSI-*i*LOVECLIM and ITM-*i*LOVECLIM (ba) near-surface temperature (in degree Celsius) before and (eb) relative humidity of MAR and *i*LOVECLIM after bias correction for Antarctica Antarctic Ice Sheet. The total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent is also included.

460 to the native T21 grid of higher short-wave radiation rates. Since there is a reduction in the total precipitation, the total SMB in ITM-*i*LOVECLIM. Neglecting other processes besides melt, ITM obtains a higher total SMB value than BESSI even with a much larger ablation zone estimation (about 413 LOVECLIM also declines to 426.10  $\text{Gt yr}^{-1}$  compared to 379 from 747.26  $\text{Gt yr}^{-1}$ ) (around 43 %), as shown in Fig. 7. The results indicate the importance of the climate forcings quality on the results of the two SMB models.

### 3.2.2 Antarctica

Comparison of annual mean SMB (in  $\text{mWE yr}^{-1}$ ) between BESSI with different forcings: MAR and *i*LOVECLIM, and ITM for Antarctica Ice Sheet. The total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent is also included.

475 For AIS, the climate simulated by annual mean SMB from 1979-2021 simulated by BESSI-*i*LOVECLIM is not as wet as that of MAR, with a lower annual mean total precipitation value (Table 2). The bias in and ITM-*i*LOVECLIM is consistent for both ice sheets in terms of temperature and humidity as similar patterns are observed for Antarctica (Fig. 7). Particularly,

relative humidity in *i*LOVECLIM is much lower than in MAR, with a value of around 25%, resulting in an unrealistically dry climate (presented in Fig. 7e).

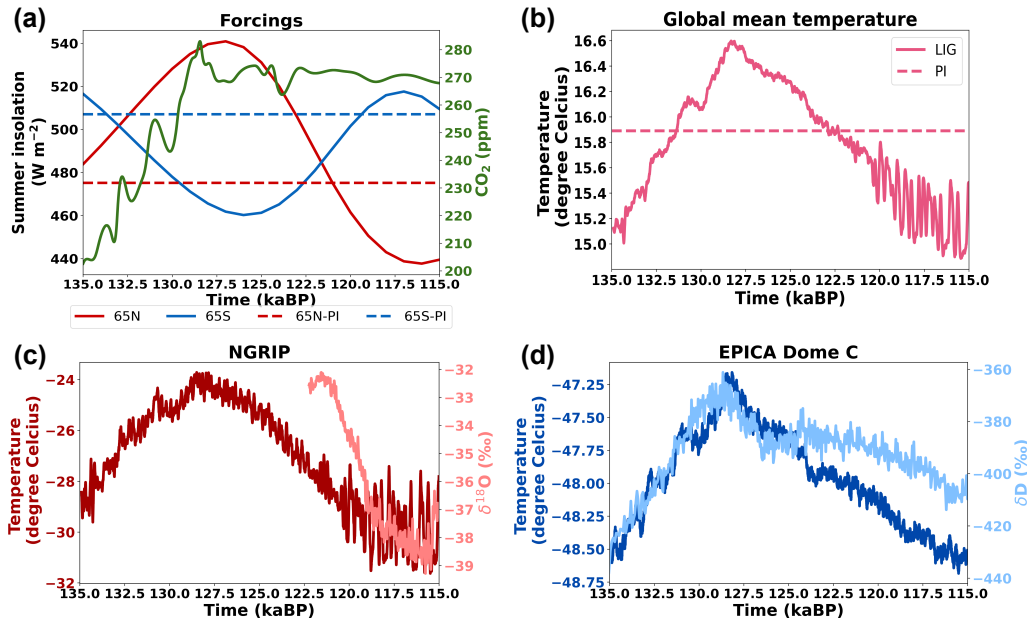

480 A comparison of the annual mean SMB value of three different simulations, namely BESSI-MAR, BESSI-*i*LOVECLIM, and ITM for Antarctica, is illustrated in Fig. 8. A noticeably large ablation zone located 9a. Similar to GrIS, the patterns of climate fields, mostly total precipitation (Supplement Fig. S7), strongly influence the simulated SMB by the two SMB models. Noticeably, there are large ablation zones observed in the center West and some parts of the East of the ice sheet in BESSI-*i*LOVECLIM that are not present in BESSI-MAR or even ITM is a result of, caused by the very low humidity (Fig. 7e). This C2 and Supplement Fig. S7d). As shown in Fig. 8b, this bias leads to unrealistic sublimation/evaporation simulation by BESSI-*i*LOVECLIM which is two times more than BESSI-MAR, around 25% higher than in MAR (around 202 Gt yr<sup>-1</sup> compared to 95-162 Gt yr<sup>-1</sup>). As the downscaling is only carried out for land grid boxes and due to T21 grid size, some parts of the ice sheet margins in Fig. 8b also indicates a low total precipitation rate of only 2184 Gt yr<sup>-1</sup> in *i*LOVECLIM, nearly 25% lower than in MAR (2919 Gt yr<sup>-1</sup>). The total SMB simulated by BESSI-*i*LOVECLIM for this ice sheet is around 1840.4 Gt yr<sup>-1</sup>, around 33% lower than in MAR (2736.43 Gt yr<sup>-1</sup>). Meanwhile, the total SMB simulated by ITM-*i*LOVECLIM is 2108.96 Gt yr<sup>-1</sup>. 490 This rate is slightly higher than in BESSI-*i*LOVECLIM and around 23% lower than MAR's value. Because of the low values of short-wave radiation and summer temperature, the contribution of runoff to the total SMB in ITM-*i*LOVECLIM for this ice sheet is relatively low, which is only 75 Gt yr<sup>-1</sup> compared to 141 Gt yr<sup>-1</sup> of BESSI-*i*LOVECLIM simulation are missing, for example, the North of AIS.

The annual mean SMB simulated by BESSI and ITM with bias-corrected *i*LOVECLIM for AIS is shown in Fig. 9b. For 495 both the two models, the SMB patterns improve significantly with the corrected climate forcings. In BESSI-*i*LOVECLIM, the widespread ablation zones are removed. However, the bar chart indicates that the sublimation/evaporation in BESSI-*i*LOVECLIM is nearly two times higher after the bias correction (Fig. 8b). This is because of the colder climate as the temperature decreases while the humidity around the margin remains low after the bias correction (Fig. C2). For ITM-*i*LOVECLIM, the larger values of short-wave radiation around the ice sheet edge induce a three times higher runoff rate (Fig. 8). The gap between BESSI 500 forced by two different forcings is more than 1000 (8b). Such a high runoff contribution is also observed before in ITM-MAR (Fig. 5). Despite the bias correction, the total precipitation in *i*LOVECLIM remains below MAR's value due to the restriction range of the bias correction factor (see Appendix C). The gap is about 417 Gt yr<sup>-1</sup>, around 34%, much higher than in Greenland (about 6.8%) due to lower precipitation but higher melts and excessive sublimation/evaporation. The melt estimated by ITM for AIS is slightly lower than which is around 14% of the total precipitation in MAR. This leads to lower total SMB rates in 505 both BESSI-*i*LOVECLIM and ITM-*i*LOVECLIM in comparison with MAR, with the difference is nearly -29% in BESSI and around -17% in ITM.

### 3.3 *i*LOVECLIM as climate forcing: Last Interglacial

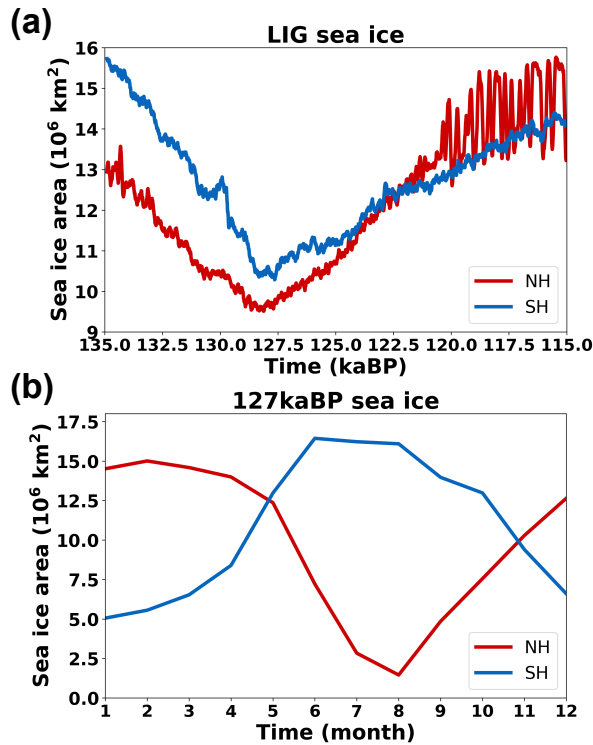

#### 3.3.1 Climate of the Last Interglacial

**Figure 10.** (a) Temporal variation of external forcings during the LIG: summer insolation of 65°N and 65°S (in W m<sup>-2</sup>) (Berger, 1978) as well as the carbon dioxide concentration (in ppm) (Lüthi et al., 2008). The dashed lines indicate summer insolation of pre-industrial (PI). (b) Temporal variation of the 100-year mean of the global mean temperature (in degree Celsius) during the LIG with the value of PI in dashed line. (c) The 100-year mean of the simulated temperature (in degree Celsius) and δ<sup>18</sup>O (in ‰) (Andersen et al., 2004; Lemieux-Dudon et al., 2010) at North GRIP (NGRIP). (d) The 100-year mean of the simulated temperature (in degree Celsius) and δD (in ‰) (Jouzel et al., 2007; Lemieux-Dudon et al., 2010) at EPICA Dome C (EDC).

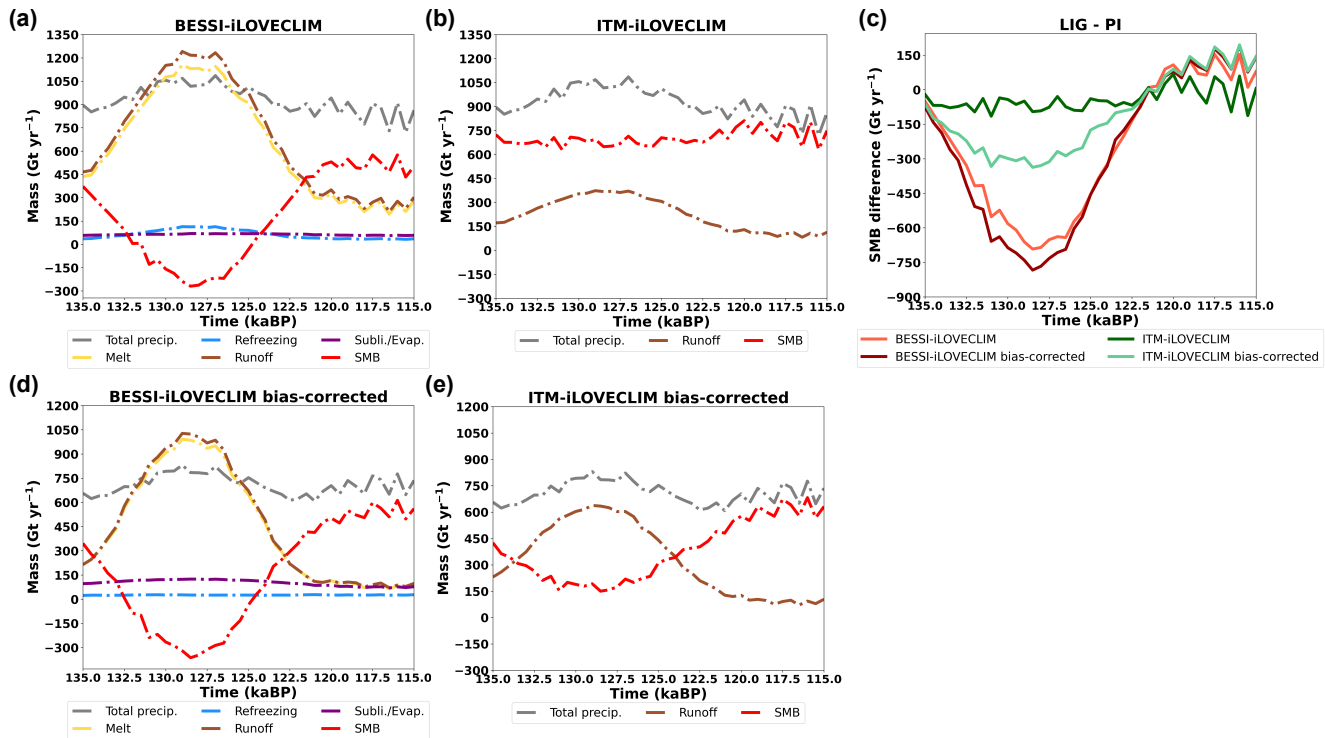

The external forcings of *i*LOVECLIM, including the summer insolation of 65°N and 65°S together with the carbon dioxide concentration, are presented in Fig. 10a. The range of these forcings for the LIG and PI is also shown in Table 1. Fig. 10b illustrates the evolution of simulated global mean temperature by *i*LOVECLIM (around 132 and 137 Gt yr<sup>-1</sup>, respectively), which is different from GrIS simulation due to a colder climate. Compared to IEM, BESSI during LIG compared to PI. The global mean temperature reaches a maximum value of 16.6 °C at around 128 kaBP, similar to the peak of carbon dioxide and 1000 years before the summer insolation of 65°N. The temperature difference between 127 kaBP and PI in this work is 0.49 °C, which is at the upper end of the range -0.48 to 0.56 °C suggested by the CMIP6/PMIP4 models (Otto-Bliesner et al., 2021). The comparison of the simulated temperature of *i*LOVECLIM and temperature change proxy which reaches back to 123 kaBP at North GRIP (NGRIP) is shown in Fig. 10c. The simulated temperature at NGRIP peaks at nearly the same time as the global mean temperature (around 128 kaBP). Meanwhile, the proxy-based data shows a similar value around 6500 years later. This could result from the absence of ice sheet and climate interaction in our simulations, as the ice sheet component is not activated. The melting of the ice sheet could possibly delay the increase in temperature. The temperature difference between the LIG and PI at NGRIP in our simulations is 4.2 °C, consistent with the range 5.2 ± 2.3 °C suggested by Landais et al. (2016).

**Figure 11.** Simulated sea ice extent (in  $10^6 \text{ km}^2$ ) for the Northern (NH) and Southern Hemisphere (SH) (a) during the LIG and (b) during 127 kaBP.

. For Antarctica, the comparison of the simulated temperature of iLOVECLIM again has a lower annual mean total SMB value with a difference of around  $200 \text{ Gt yr}^{-1}$  due to unrealistic sublimation and temperature change proxy at EPICA Dome C (EDC) is presented in Fig. 10d. The change in the simulated temperature shows a good agreement with the proxy-based data.

525 The simulated sea ice extent of the Northern and Southern Hemisphere (NH and SH, respectively) during the LIG are shown in Fig. 11a. For both hemispheres, the sea ice extent decreases during the LIG following the temperature changes, reaching the minimum value also around 128 - 127.5 kaBP. The evolution of sea ice extent of the two hemisphere during 127 kaBP in our simulation fall within the range suggested by CMIP6/evaporation estimation-PMIP4 models (Fig. 4 in Otto-Bliesner et al. (2021)).

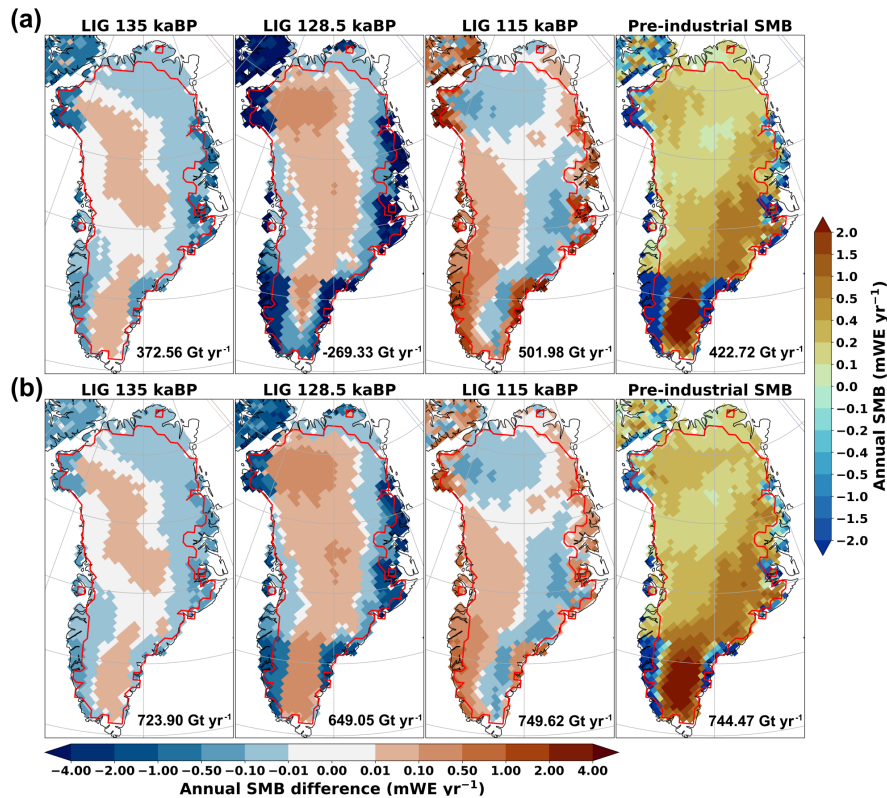

**Figure 12.** (a) Temporal variation of external forcings during the LIG: summer insolation of  $65^{\circ}$  N and  $65^{\circ}$  S (Berger, 1978) as well as the carbon dioxide concentration (in ppm) (Lüthi et al., 2008). (b) Temporal variation of the annual mean total SMB and its elements integrated on the present-day ice sheet extent during the LIG of (a) BESSI-iLOVECLIM and (b) ITM-iLOVECLIM (in  $\text{Gt yr}^{-1}$ ) during LIG for Greenland. (c) Same as Annual mean total SMB anomalies between LIG and pre-industrial of different cases. (d) and (e) Similar like (a) and (b) but for Antarctica with bias-corrected iLOVECLIM

### 530 3.3.2 LIG transient simulations with BESSI forced by iLOVECLIM Surface mass balance evolution during the Last Interglacial

#### Greenland

To study the evolution of SMB during LIG, we present the temporal variation of the external forcings, the annual mean total SMB and its sub-processes simulated by BESSI-iLOVECLIM for both ice sheets GrIS in Fig. 9-12a. The rise of summer insolation in the North and the carbon dioxide concentration during the beginning of the LIG (Fig. 9a10a) induce an increase in the melt rate of Greenland (Fig. 9b, 12a). During the same period, runoff has a higher accelerated rate than melt the values of runoff are higher than melt's, indicating both rain and melt are not well refreeze-refreezed due to warm climate (Eq. (12A12)). As the insolation starts to drop drops after 127 kaBP, runoff and melt also decrease. In the same figure, total precipitation is shown to be slightly increase during the peak of insolation increase slightly during the insolation peak, which is expected

**Figure 13.** Comparison of BESSI-iLOVECLIM and ITM in terms of the annual Annual mean total SMB differences anomalies (in  $\text{Gt-mWE yr}^{-1}$ ) between several LIG time slices (135, 128.5 and 115 kaBP) and the pre-industrial for simulation of (a) Greenland-BESSI-iLOVECLIM and (b) Antarctica-ITM-iLOVECLIM for Greenland Ice Sheet. The absolute annual SMB value of PI and the total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent (red line) of each simulation are also included.

540 as the climate is getting gets warmer. Meanwhile, sublimation/evaporation remains stable throughout the period with a low magnitude as this process is not dominant for GrIS. Refreezing also remains in low value. Similarly, refreezing also remains low for this ice sheet, however, a slight increase during the peak of the LIG is observed in Fig. 9b12a. The total SMB, in this case, is mostly mainly driven by runoff (melt), strongly decreases during the rise of summer insolation, and then recovers after 127 kaBP. The maximum change of total SMB during the LIG is more than 600. At 128.5 kaBP, the total SMB shrinks to its minimum value ( $-269.33 \text{ Gt yr}^{-1}$ ), which is around 170% less than the beginning of LIG (135 kaBP) value.

545 Compared to Greenland, during the same period, the annual mean values of total SMB and its elements fluctuate less in Antarctica (Fig. 9c). Particularly, the biggest gap of the total SMB is about 250 SMB at the beginning of the LIG ( $372.56 \text{ Gt yr}^{-1}$ ), which is nearly 15% of the value of the first time slice (135 kaBP), which is much lower than GrIS. Also, the magnitude of the simulated).

550 Similarly, the annual mean total SMB during the LIG is quite low for Antarctica if we consider the value of BESSI-MAR in the present-day climate. From the results of Sect. 3.2.1, the total SMB for Antarctica simulated by BESSI-runoff also increases following the increase of the external forcings in ITM-iLOVECLIM might be around 1000 Gt yr<sup>-1</sup> lower than BESSI-MAR if we consider the difference between two forcings is constant with time. During the LIG, even though the insolation at the South Pole decreases (Fig. 9a), AIS still experiences an increase in the melt (Fig. 9c). This is a result of a warmer climate which results in higher global mean temperature. The sublimation is more dominant in AIS than in GrIS because of a much drier climate. Even though the sublimation is impacted by iLOVECLIM biases, no temporal change of this flux is simulated by the model. This suggests that the influences of the bias in the humidity of iLOVECLIM is constant. Due to this and the low value of runoff, for this ice sheet, the variation of the total SMB follows the pattern of the total precipitation. It slightly increases during the peak of summer insolation in the North as a warmer climate induces more precipitation. (12b). However, the magnitude of the runoff is low, leading to the positive total SMB throughout the LIG. This results from low short-wave radiation in the climate forcing (as discussed in Sect. 3.2.1).

By plotting the total SMB differences between the Last Interglacial and the pre-industrial periods simulated by the same model, we investigate the magnitude of SMB variation for both BESSI-iLOVECLIM and ITM-iLOVECLIM (Fig. 10). Figure 10a shows that, for Greenland, (12c). During the peak of the LIG, the gap between the two models widens during the peak of the LIG. This indicates the overestimation of melt in ITM compared to BESSI forced by the same climate conditions (Supplementary Fig. S2a), consistent with Fig. 6. When the temperature drops at the end of the LIG, ITM has slightly higher SMB differences than with BESSI-iLOVECLIM. In other words, when the climate is colder during the end of the LIG, ITM has a higher SMB rate compared to its pre-industrial simulation. This suggests that ITM displays a large sensitivity to temperature change. For Antarctica, the discrepancies between ITM and BESSI as we compared the value of LIG and pre-industrial are less significant than in Greenland (Fig. 10b), as the change of total SMB in this region is insignificant. As Fig. 9c indicates that sublimation/evaporation is almost constant during the LIG, the gap between ITM and BESSI in Fig. 10b can only be explained by the difference in melt simulation. In contrast to BESSI-much lower than ITM-iLOVECLIM results, the melt rate in ITM simulation is quite stable (Supplementary Fig. S2b). This can be explained that, since the climate of AIS is not as warm as GrIS, the sensitivity of ITM to the change of temperature is limited for this ice sheet. Also, albedo feedback is not taken into account in parameterizations such as ITM, which could also be the reason behind the difference in the simulation of melt between the two models. LOVECLIM. The difference between the two models reaches a maximum value of nearly 600 Gt yr<sup>-1</sup> at 128.5 ka, the same time as the highest global mean temperature. As discussed above, the difference between the two models comes from the runoff simulation, which is also observed in the present-day climate condition (Sect. 3.2.1)

Annual mean SMB anomalies (in Gt yr<sup>-1</sup>) between several LIG time slices (135, 128.5 and 115 kaBP) and the pre-industrial simulation of (a) ITM and (b) BESSI-iLOVECLIM for Greenland Ice Sheet. The absolute annual SMB value of PI and the total SMB (in Gt yr<sup>-1</sup>) integrated for the present-day ice sheet extent (red line) of each simulation are also included.

Annual mean SMB anomalies (in Gt yr<sup>-1</sup>) between several LIG time slices (135, 128.5 and 115 kaBP) and the pre-industrial simulation of (a) ITM and (b) BESSI-iLOVECLIM for Antarctica Ice Sheet. The absolute annual SMB value of PI and the total SMB (in Gt yr<sup>-1</sup>) integrated for the present-day ice sheet extent of each simulation are also included.

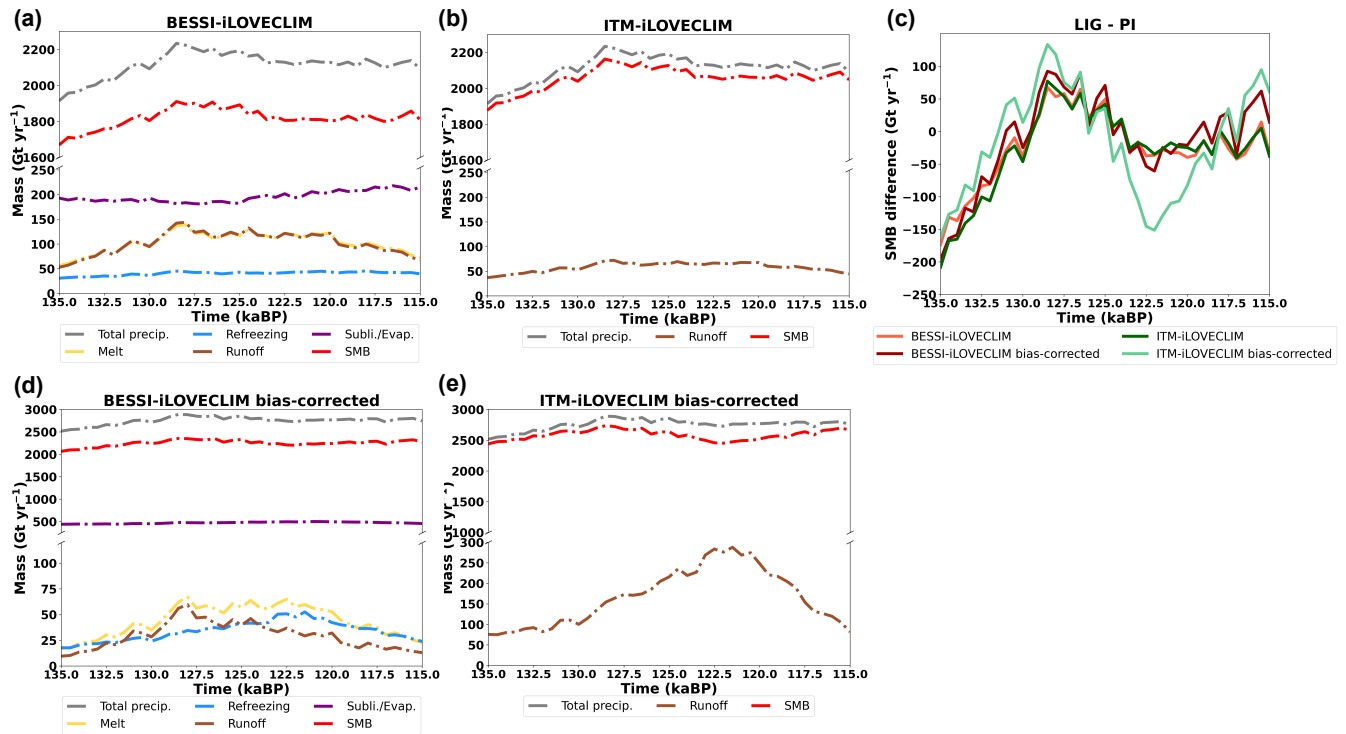

585 ~~The patterns of the annual mean SMB differences between LIG and PI of ITM and BESSI-iLOVECLIM for GrIS are To~~  
~~further investigate the differences between the two SMB schemes, the map of SMB anomalies of BESSI and ITM is shown~~  
~~in Fig. 41-13. In this figure, we select three different time slices from the LIG simulation: the first (135 kaBP), the peak of~~  
~~the deglaciation runoff (128.5 kaBP) and the last (115 kaBP) to further investigate the differences between the two different~~  
~~SMB schemes compare with the pre-industrial results.~~ The pre-industrial annual mean SMB of the two models is quite similar  
590 to the present-day value (Fig. 6). ~~For the LIG, the 7a). The~~ two models display similar patterns for the first and the last  
time slices. ~~Particularly, in of the LIG. Notably, at~~ the beginning of the LIG, for the two models, positive SMB differences  
can be seen in the inner part of the ice sheet as there is more precipitation. Meanwhile, SMB rates around the margin are  
lower than the pre-industrial value since the melting process ~~is accelerated accelerates~~ due to warmer climate conditions.  
This SMB trend is enhanced during the peak of deglaciation (128.5 kaBP). In ~~the simulation of BESSI-iLOVECLIM, the~~  
595 ~~magnitude of the negative differences around the margin is very high compared to ITM, which is due to the model itself, as~~  
~~mentioned before (Fig. 2 and Fig. 6). On the other hand, for the same time slice, the number of grid boxes with a higher~~  
~~SMB rate than the pre-industrial value ITM-iLOVECLIM, similar to the present-day climate condition (Fig. 7a). Additionally,~~  
~~BESSI-iLOVECLIM has larger ablation zones with very low SMB than ITM-iLOVECLIM, leading to a much lower total SMB~~  
~~rate in BESSI than in ITM (Supplement Fig. S8). Then, at the end of the LIG, both models simulate higher SMB rates around~~  
600 ~~the margins as colder climate accelerates accumulation.~~

~~As the climate forcing impacts strongly the simulated SMB, similar runs of BESSI and ITM are carried out with input from~~  
~~the bias-corrected iLOVECLIM (Fig. 12 d-e). With this forcing, the simulated total SMB declines for both the SMB models.~~  
~~Particularly, the minimum total SMB simulated by BESSI-iLOVECLIM decreases from -269.33 Gt yr<sup>-1</sup> to -362.83 Gt yr<sup>-1</sup> due~~  
~~to a lower total precipitation rate. Similarly, for ITM-iLOVECLIM, the minimum total SMB also declines by nearly 500 Gt yr<sup>-1</sup>,~~  
605 ~~from 649.05 Gt yr<sup>-1</sup> to 150.3 Gt yr<sup>-1</sup>. This reduction results from the lower total precipitation and higher short-wave radiation~~  
~~in bias-corrected iLOVECLIM. As the mean total SMB decreases, the SMB anomalies between the LIG and PI of BESSI and~~  
~~ITM also decline (Fig. 12c). At the minimum peak (128 kaBP), LIG-PI anomalies in BESSI-iLOVECLIM simulation is much~~  
~~higher than that of ITM. This results from overestimating decreases by over 90 Gt yr<sup>-1</sup> (from -692 Gt yr<sup>-1</sup> to -783 Gt yr<sup>-1</sup>).~~  
~~Meanwhile, for ITM, the magnitude of LIG-PI anomalies changes is about 240 Gt yr<sup>-1</sup>, nearly 250% more than before the bias~~  
610 ~~correction (-95 Gt yr<sup>-1</sup>). The results suggest that ITM is more sensitive to the biases in iLOVECLIM than BESSI, which is also~~  
~~true for present-day experiments (Fig. 8a). After the bias correction, the simulated SMB patterns are improved for both SMB~~  
~~models with a better shape of ablation zones in ITM (Supplementary Fig. S3a). GrIS (Supplement Fig. S9).~~

## Antarctica

~~Fig. 14a-b illustrates the temporal variation of the annual mean total SMB and its sub-processes simulated by BESSI-iLOVECLIM~~  
615 ~~displays a very extreme value for the negative SMB rate; however, the spreading of ablation zones in its simulation is~~  
~~more restricted (Supplementary Fig. S3b) and ITM-iLOVECLIM for AIS. Compared to Greenland, during the same period,~~  
~~the annual mean values of total SMB and its elements fluctuate less in Antarctica for both SMB models. Particularly, in~~  
~~BESSI-iLOVECLIM, the total SMB peaks at 128.5 kaBP of 1910.27 Gt yr<sup>-1</sup>, nearly 15% higher than the value of 135 kaBP~~

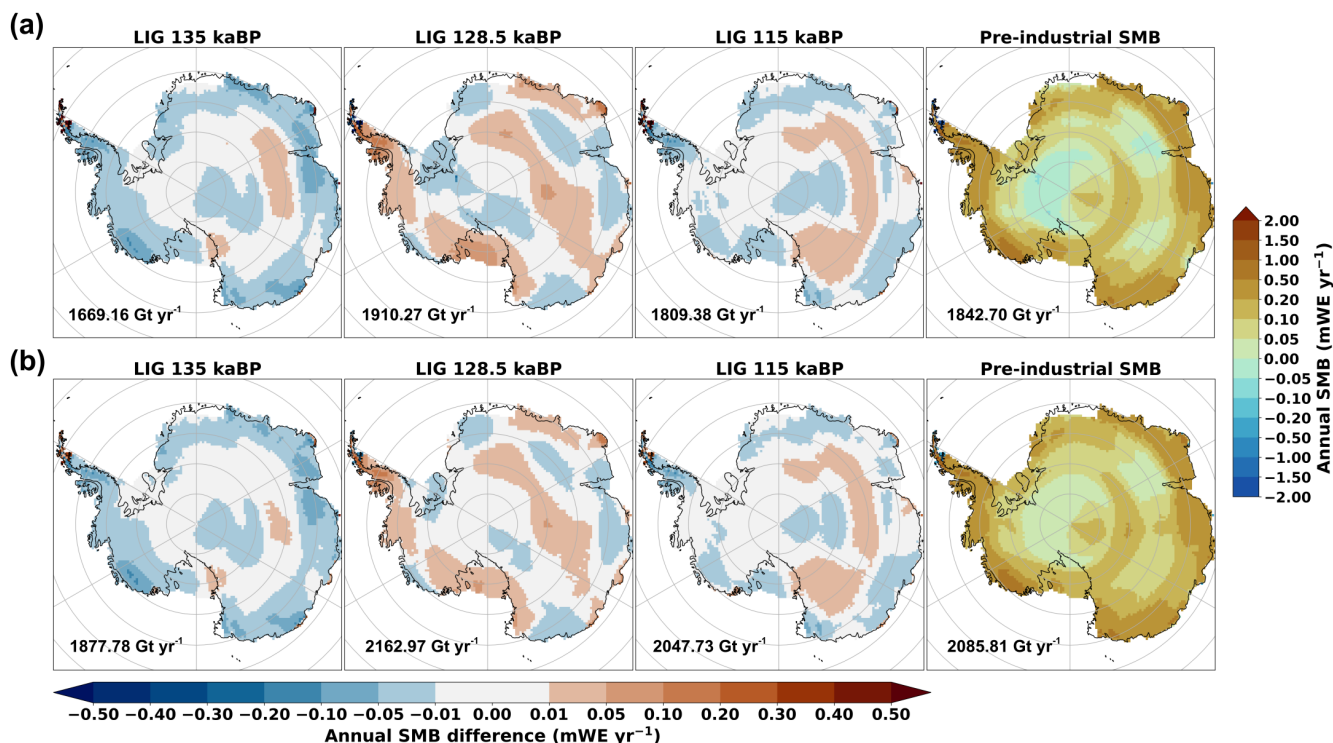

**Figure 14.** Temporal variation of the annual mean total SMB and its elements integrated on the present-day ice sheet extent during LIG of (a) BESSI-*i*LOVECLIM and (b) ITM-*i*LOVECLIM (in  $\text{Gt yr}^{-1}$ ) for Antarctica. (c) Annual mean total SMB anomalies between LIG and pre-industrial of different cases. (d) and (e) Similar like (a) and (b) but with bias-corrected *i*LOVECLIM

(1669.16  $\text{Gt yr}^{-1}$ ). This number is very low compared to the -170% differences in GrIS. Also, the magnitude of the simulated annual mean total SMB by BESSI-*i*LOVECLIM during the LIG is quite low for AIS (less than 2000  $\text{Gt yr}^{-1}$ ), which is due to the biases in humidity as discussed in Sect. 3.2.2. During the LIG, even though the insolation at the South Pole decreases (Fig. 10a), AIS still experiences an increase in the melt in BESSI-*i*LOVECLIM (Fig. 12a-b), which is caused by a higher global mean temperature (Fig. 10b). The sublimation is more dominant in AIS than in GrIS because of a much drier climate. Even though the sublimation is impacted by *i*LOVECLIM biases, no temporal change of this flux is simulated by the model. This suggests that the influences of the bias in the humidity of *i*LOVECLIM is constant. Due to this and the low value of runoff, for this ice sheet, the variation of the total SMB simulated by BESSI-*i*LOVECLIM follows the pattern of the total precipitation. It slightly increases as the global mean temperature increases since a warmer climate induces more precipitation. Then at the end of the LIG, both models simulate higher SMB rates around the margins as colder climate accelerates accumulation.

Similarly, the total SMB in ITM-*i*LOVECLIM for AIS is also driven by the total precipitation due to a low rate of runoff and the absence of sublimation/evaporation processes. The reason for low runoff rates for AIS is the

**Figure 15.** Annual mean SMB anomalies (in  $\text{mWE yr}^{-1}$ ) between several LIG time slices (135, 128.5 and 115 kaBP) and the pre-industrial simulation of (a) BESSI-*i*LOVECLIM and (b) ITM-*i*LOVECLIM for Antarctic Ice Sheet. The absolute annual SMB value of PI and the total SMB (in  $\text{Gt yr}^{-1}$ ) integrated for the present-day ice sheet extent of each simulation are also included.

low short-wave radiation simulated by the climate forcing, as discussed in Sect. 3.2.2. Such low runoff rates lead to high total SMB value in ITM-*i*LOVECLIM, which is  $2168.97 \text{ Gt yr}^{-1}$  at 128.5 ka, 15.5% higher than the value of 135 kaBP.

635 Fig. 14c indicates that the discrepancies between BESSI and ITM in terms of the SMB anomalies between the LIG and PI are less significant for Antarctica than Greenland (Fig. 12c). As Fig. 14a indicates that sublimation/evaporation is almost constant during the LIG in BESSI-*i*LOVECLIM, the gap between the two models in Fig. 14c can only be explained by the difference in runoff simulation.

640 We also investigate the patterns of the annual mean SMB differences between several time slices of LIG and PI in the simulations of *FPM* and BESSI-*i*LOVECLIM and ITM-*i*LOVECLIM (Fig. 12). Again (15). Similar to GrIS, the pre-industrial annual mean SMB of the two models is also consistent to the present-day results of AIS (Fig. 89a). However, contrary to the GrIS, fig. 12 Fig. 15 suggests not much difference in the SMB value between the LIG and PI as well as between the two models for AIS this ice sheet. This is consistent with Fig. 10b 14c, as the magnitude of the differences is very low compared to that of the absolute SMB value (Supplementary Fig. S4 S10).

645 For Antarctica, we also investigate the total SMB and its elements with the forcings from the bias-corrected *i*LOVECLIM (Fig. 14d-e). Noticeably, the simulated melt in BESSI-*i*LOVECLIM after bias-corrected reaches its peak at 128.5 kaBP, remains stable for 6000 years before gradually decreasing after 122.5 kaBP. The prolongation of high melt rates is related to the high global mean temperature (Fig. 10b) and the increase of summer insolation of 65°S during this period. The peak of refreezing at 122.5 kaBP indicates that the temperature gets colder, leading to the drop of the melt rate after this time slice (Fig. 14d). Compared to before bias correction, the sublimation/evaporation increases by a factor of two, possibly due to the colder climate, as discussed in Sect. 3.2.2. For ITM-*i*LOVECLIM, the simulated runoff also increases following the increase of the global mean temperature and the summer insolation (Fig. 14e). Around 122.5 - 121.5 kaBP, the runoff rate reaches its peak of nearly 288 Gt yr<sup>-1</sup>, four times the value before bias correction (65 Gt yr<sup>-1</sup>). This results from higher short-wave radiation and higher temperatures in some areas, such as the Wilkes Land (Fig. C2 and Supplement Fig. S11b). Such a big change in the runoff rates leads to the significant difference in LIG-PI anomalies of bias-corrected ITM-*i*LOVECLIM compared to other runs during the period of 122.5 - 121.5 kaBP in Fig. 14c. However, considering the magnitude of the total SMB in AIS, Fig. 655 14c suggests the LIG-PI anomalies of the runs are not significant both before and after the bias correction.

#### 4 Discussion

In this work, we assess the feasibility of replacing a parameterization scheme (ITM) with a ~~physical-based~~ physics-based surface energy balance model (BESSI) to provide a more physical SMB approach for the *i*LOVECLIM model framework ~~with a view to simulating to simulate~~ the change of ice sheet in the past.

660 The snow model - BESSI ~~shows good performance~~ performs well in the calibration/validation with MAR under the present-day climate. Highlighting the model's ability to simulate different climates faithfully, the first-ever simulation for Antarctica (without re-tuning) is in good agreement with MAR, which is more complex and has been intensively used to study this ice sheet. ~~The version used here has been improved with the inclusion of turbulent latent heat flux, albedo aging scheme, and more input fields instead of parameterizations. These improvements enhance the model's capacity to simulate different SMB main components as more processes are taken into account.~~ However, the issue related to the strong underestimation of re-freezing (Plach et al., 2018; Born et al., 2019) ~~still~~ remains (Fig. 35a). Lowering the time step of the model from daily to hourly might solve this problem, as the current model's large time step (daily) ~~possibly~~ neglects the diurnal cycle of temperature (Krebs-Kanzow et al., 2018). On the other hand, the ablation simulated by BESSI is underestimated in extent but mostly overestimated in magnitude. Particularly, the narrow ablation zone in the south-western part of GrIS is underestimated in BESSI-MAR, compared to MAR (Fig. 2 Supplement Fig. S1), which is also reported in Fettweis et al. (2020). However, due to the compensation of melt and refreezing, the results of the snow model are in good range with respect to MAR. On the other hand, the parameterization - ITM needs individual tuning for the GrIS and the AIS. Hence, ITM-MAR, with the parameter *crad* calibrated for the GrIS, generates an unrealistic runoff rate for the AIS due to the change in the climate condition (e.g., higher shortwave radiation) (Fig. 6a and Supplement Fig. S6a). With a lower *crad* value, the runoff rates could be reduced to obtain a more suitable total SMB value for Antarctica (Supplement Fig. S12a).

675

For long-term simulations in paleo studies, BESSI has proved to be able to provide reliable data in a short time as it has a physical model setup and is computationally inexpensive. Particularly, in this work, For the paleo study, both BESSI-*i*LOVECLIM simulates well and ITM-*i*LOVECLIM simulate the SMB evolution during the LIG, following the change of the orbital configuration and carbon dioxide concentration. ~~The snow model gives details not only about the SMB but also its major processes at a much cheaper cost than the energy surface schemes embedded in regional climate models.~~

Compared to the existing SMB scheme of ~~Despite the influences of the biases in the climate forcing, the simulated SMB during the 130 - 115 kaBP by BESSI-*i*LOVECLIM of GrIS is in a similar range with the results of MAR and BESSI-MAR from the work of Plach et al. (2018) (Fig. 12). This indicates that BESSI can provide reliable results even when forced by *i*LOVECLIM-ITM, BESSI simulates less melt with more complexity in model setup. Here we used the ITM version without any modification to adapt to the climate of~~, a climate forcing with lower resolution than MAR. On the other hand, compared to Sommers et al. (2021), the SMB simulated by BESSI-*i*LOVECLIM ~~to provide a robust comparison between BESSI and ITM. ITM is a simple parameterization that strongly depends on both before and after the bias correction is much lower during 127 - 123 kaBP for GrIS. The reason for this is the missing interactive elevation and ice sheet mask. As in this work, we use the present-day ice sheet topography and extent for all the experiments, leading to the runoff overestimation over parts that had previously melted. Meanwhile, the total SMB simulated by ITM for GrIS remains positive throughout the LIG for both original and bias-corrected *i*LOVECLIM forcings. This suggests that the parameterization is unable to give suitable results without retuning its empirical parameters and temperature.~~ As the runoff in ITM is calculated solely by one equation (Eq. (15)). ~~A small change in one of its parameters (such as  $c$ ) can influence the melt rate significantly for the region where this process is dominant. For example, we use  $c = -25 \text{ W m}^{-2}$  to obtain the results in Sect. 1), it is easy to have a desired runoff range by tuning its empirical parameters such as  $c_{rad}$  (Supplement Fig. S12a). Also, the albedo in ITM is fixed at 0.85, which is the value of ice grid points in *i*LOVECLIM, to give a clean comparison to BESSI. This can also be the reason behind the low runoff simulation in ITM-*i*LOVECLIM during the LIG. A lower albedo value, which means more solar radiation is considered, can increase the simulated runoff rate of ITM (Supplement Fig. S12b). However, using only one albedo value for the whole ice sheet is not realistic. ITM with a range of albedo for different altitudes and locations can provide satisfied results as in Quiquet et al. (2021).~~

Results of Sect. 3.2 indicates that the quality of the forcings influences both BESSI and ITM. However, the changes in the simulated SMB by BESSI-*i*LOVECLIM before and after bias correction are not as significant as in ITM-*i*LOVECLIM for both ice sheets. The same behaviors of the two models are observed in the results of Sect. 3.3.2. ~~For a lower value of  $c$ , such as  $-40 \text{ W m}^{-2}$ , ITM produces less melt in GrIS, while in AIS, there is no difference in the SMB results (Fig. Such sensitivity suggests that ITM needs to be retuned whenever there is a change in the climate forcing in order to obtain desired values. However, this can be problematic for paleo studies that are not well-documented. Also, a critical limitation of ITM is the missing sublimation/evaporation processes, which resulted in runoff overestimation. For BESSI, the runoff calculation is more realistic, and more processes are included than just solar radiation and heat. B1). It is hard to draw a conclusion about the comparison of the two models' performance. However, it is clear that results from BESSI are more physically constrained and, therefore, are more reliable.~~ Hence, ~~replacing tuning BESSI is more complicated as it is more physically constrained.~~

Replacing ITM with BESSI to provide SMB to the ice sheet model GRISLI in iLOVECLIM framework is possible and can help to produce more physical results. However, ~~this might also add more sources of uncertainties to the model as BESSI needs more input fields than ITM. Particularly, as ITM only simulates melt, the bias from BESSI is a more physical model, requiring more input variables, which makes it more sensitive to certain biases in iLOVECLIM climate-related to humidity in the AIS region does not influence ITM as much as in the BESSI case. For paleoclimate studies, using a physical-based model like BESSI helps to take into account the change of other factors besides temperature, such as insolation or humidity, and important processes like albedo feedback, which a simple parameterization scheme cannot capture well iLOVECLIM, such as humidity. Also, BESSI is more computationally expensive (30 years per minute for the T21 grid) than a parameterization like ITM. Adding BESSI might increase the energy consumption of iLOVECLIM, which has been its strong point as an EMIC (500~~  
715 ~~years per day). On the other hand, we can be more confident in its response to a change in climate since it explicitly simulates many processes, unlike ITM.~~

As any climate model, iLOVECLIM displays some biases which can be locally dominant (Heinemann et al., 2014). In this work, we investigate ~~three climate variables: precipitation, near-surface temperature, and relative humidity to document the bias the impact of these biases by using a simple delta method to correct the climate of iLOVECLIM in two polar ice sheet regions (see Appendix C). The results of Sect. 3.2.1 indicates that the climate in experiments with iLOVECLIM, compared to MAR, is warmer and less humid for both ice sheets, with a very low humidity for AIS. These biases strongly impact the performance of the snow model, resulting in overestimation of melts and excessive sublimation/evaporation rate. Therefore, the simulated SMB does not agree with MAR, particularly for AIS. This is unavoidable as as climate forcings indicate the substantial impacts of these biases on the SMB simulation of both BESSI and ITM. Particularly, the low short-wave radiation provided by iLOVECLIM is much less complex than state-of-the-art regional climate models such as MAR, leads to the missing representative of insolation change in ITM, as shown in Sect. 3.3.2. However, transient LIG climate forcings can be obtained with much more favorable computational efficiency thanks to such a simple model setup. Carrying out bias correction for some crucial atmospheric variables in iLOVECLIM can tackle the problems of unrealistic climate patterns, leading to a better performance of the snow model and ITM in the SMB simulation. For example, with a simple delta method to correct the bias in iLOVECLIM climate (see Appendix B), results of BESSI iLOVECLIM are improved for the present-day (Fig. B2) as well as the LIG (Fig. B1). With iLOVECLIM. The results of the SMB models are improved with the bias-corrected climate forcings. The results can be further improved with~~  
725 ~~precipitation, near-surface temperature, and relative humidity to document the bias the impact of these biases by using a simple delta method to correct the climate of iLOVECLIM in two polar ice sheet regions (see Appendix C). ## 5 Conclusions

This work examines the feasibility of ~~switching-replacing~~ the SMB scheme of the Earth system model of intermediate complex-  
740 ~~ity iLOVECLIM from a simple parameterization (ITM) to a physical-based by a physics-based~~ surface energy balance model (BESSI) for the purpose of improving the simulation of ice sheet-climate interaction. ~~BESSI exhibits good performance For this purpose, a comparison between BESSI and ITM stand-alone is carried out for different climate forcings and climate conditions. Both BESSI and ITM provide acceptable results~~ in the validation in the present-day period by MAR, a state-of-the-art regional

climate model that includes a full physical energy mass transfer scheme of the surface ,for two very different ice sheet climate  
745 conditions: GrIS and AIS. ~~Then, iLOVECLIM is used as BESSI's forcing for a paleoclimate simulation: For a paleoclimate~~  
~~study, the Last Interglacial period, climate fields simulated by an EMIC called iLOVECLIM are used as forcings for both~~  
~~SMB models.~~ iLOVECLIM displays a large-scale climate change consistent with the forcings that translate to SMB evolution  
in agreement with previous modeling work. Switching from MAR to iLOVECLIM highlights the strong influence of ~~climate~~  
~~forcing the climate forcings~~ on the simulation of ~~snow and the~~ SMB evolution. In particular, iLOVECLIM presents important  
750 bias that leads to some ~~large significant~~ misrepresentation of present-day SMB for both ~~Greenland and Antarctic ice sheets~~ GrIS  
and AIS. These unrealistic climate patterns hamper the performance of ~~BESSI~~ both BESSI and ITM, posing the need for bias  
correction of the climate fields in iLOVECLIM. The comparison between BESSI ~~forced by iLOVECLIM~~ and ITM during the  
Last Interglacial ~~indicates a strong suggests a stronger~~ sensitivity of ITM to the ~~temperature~~ climate conditions. The current  
SMB scheme of iLOVECLIM ~~also shows a strong dependence on the value empirical parameters, which means it can easily~~  
755 ~~be tuned, not physically constrained.~~ needs to be retuned for different climate forcings and study periods, which is not ideal  
for application in paleo studies. Also, the absence of sublimation/evaporation processes in ITM leads to the overestimation of  
runoff in order to provide SMB in an acceptable range. The results suggest BESSI can be used to replace ITM ~~in iLOVECLIM~~  
as this snow model maintains the low computational cost of ~~the parameterization SMB scheme whilst iLOVECLIM while~~  
providing more reliable results without the need to be retuned.

The In the following, we only detail the methodology used for surface energy and mass balance. Full details on the implementation of heat diffusion and snow mass compaction are given in Born et al. (2019).

### Surface energy balance

765 The exchange of energy between the surface (the top layer of the model) and the atmosphere results in the change of temperature in this layer ( $T_s$ ), influenced by the net solar flux  $Q_{SW}$ , the net long-wave radiation flux  $Q_{LW}$ , the sensible heat flux  $Q_{SH}$ , the latent heat flux  $Q_{LH}$ , the heat flux from the precipitation  $Q_{precip}$  and the melting flux  $Q_{melt}$  (when temperature reaches the melting point). This can be expressed as follows

$$\underbrace{c_{ice} m_{top} \frac{\partial T_s}{\partial t}}_{\text{surface}} = \underbrace{Q_{SW} + Q_{LW} + Q_{SH} + Q_{LH}} + \underbrace{Q_{precip} + Q_{melt}} \quad (\text{A1})$$

770 in which,  $c_i$  is the heat capacity of ice (2110 J kg<sup>-1</sup> K<sup>-1</sup> at -10°C) and  $m_{top}$  is the mass of the top layer in kg m<sup>-2</sup>.

<u>Stefan-Boltzmann constant</u>	<u><math>\sigma</math></u>	<u><math>5.670373 \times 10^{-8}</math></u>	<u>W m<sup>-2</sup> K<sup>-4</sup></u>

The net incoming solar radiation  $Q_{SW}$  is calculated from the albedo of the surface ( $\alpha_{snow}$  or  $\alpha_{ice}$ ) and the incoming shortwave radiation  $F_{SW}$  (Wm<sup>-2</sup>) available from the forcing:

$$\underbrace{Q_{SW}} = (1 - \alpha) F_{SW} \quad (\text{A2})$$

775 The albedo of ice  $\alpha_{ice}$  is fixed at 0.4 while the albedo of snow  $\alpha_{snow}$  is calculated considering the exponential decay with time since the last snowfall event (Oerlemans and Knap, 1998; Zolles and Born, 2021):

$$\alpha_{snow} = \alpha_{firn} + (\alpha_{freshsnow} - \alpha_{firn}) \exp\left(\frac{-N_{snowfall}}{t^*}\right) \quad (A3)$$

in which the albedo of firn  $\alpha_{firn}$  is 0.6, the albedo of the fresh snow  $\alpha_{freshsnow}$  is 0.82,  $N_{snowfall}$  is the number of days since the last snowfall event and  $t^*$  is the number of days for the fresh snow to reach firn condition. Depending on the temperature of the surface  $T_s$ ,  $t^*$  is set to 20 days for  $T_s < 273.15$  K or 5 days for  $T_s = 273.15$  K.

780 The difference between the upcoming long-wave radiation  $F_{LW}$  from the atmosphere (read from the input) and the emitted long-wave radiation flux is the net long-wave radiation  $Q_{LW}$ :

$$Q_{LW} = F_{LW} - \sigma \epsilon_s T_s^4 \quad (A4)$$

in which,  $\sigma$  is the Stefan-Boltzmann constant ( $5.670373 \times 10^{-8}$  W m<sup>-2</sup> K<sup>-4</sup>),  $\epsilon_s$  is the emissivity of the snow (0.98).

785 The turbulent sensible heat flux  $Q_{SH}$  equals to the difference between the temperature of the air  $T_{air}$  and that of the surface layer  $T_s$  multiplied by a coefficient  $D_{sh}$  (15 W m<sup>-2</sup> K<sup>-1</sup>):

$$Q_{SH} = D_{sh}(T_{air} - T_s) \quad (A5)$$

The turbulent latent heat flux  $Q_{LH}$  depends on the difference between the water vapor pressure of the air  $e_{air}$  and of the surface layer  $e_s$ , the surface pressure  $p_{air}$  from input and a coefficient  $D_{lh}$ :

$$Q_{LH} = \frac{D_{lh}}{p_{air}}(e_{air} - e_s) \quad (A6)$$

790 with  $D_{lh} = 0.622 r_{lh/sh} \frac{D_{sh}}{c_{air}} (L_v + L_m)$  (A7)

where  $r_{lh/sh}$  is the ratio of the exchange rates between the latent heat and sensible heat (equal to 1.0 in this work),  $c_{air}$  is the heat capacity of the air (1003 J kg<sup>-1</sup> K<sup>-1</sup> at 0°C) whilst  $L_v$  and  $L_m$  are latent heat of vaporization and melting, respectively ( $2.5 \times 10^6$  J kg<sup>-1</sup> and  $3.34 \times 10^5$  J kg<sup>-1</sup>). Details of the turbulent sensible and latent heat fluxes calculation methods are available in Zolles and Born (2021).

795 Based on the air temperature ( $T_{air}$ ), BESSI classifies total precipitation as snow ( $T_{air} \leq 273.15$  K) or rain ( $T_{air} > 273.15$  K). When snow/rain falls, the air temperature is transported to the surface. Hence, the equations of heat flux from the snow/rain are:

$$Q_{precip,s} = m_{precip} c_i (T_{air} - T_s) \quad (A8)$$

$$Q_{precip,r} = m_{precip} c_w (T_{air} - 273.15) \quad (A9)$$

800 where  $m_{precip}$  is the mass of precipitation (kg m<sup>-2</sup> d<sup>-1</sup>) and  $c_{water}$  is heat capacity of water (4181 J kg<sup>-1</sup> K<sup>-1</sup> at 25°C).

The model uses an implicit scheme, for which the energy fluxes are calculated first, then the energy required to heat the top layer to the melting point. As the temperature of the surface cannot exceed the melting point, the remaining energy is considered as energy available to melt snow/ice  $Q_{melt}$  (Eq. (A1)). The main parameters of the model are presented in Table A1.

## 805 Surface mass balance

Surface mass balance SMB is an important element of the ice sheet mass balance, apart from the ice discharge and basal melting. In BESSI, SMB is calculated as the remaining mass of total precipitation from runoff and sublimation/evaporation processes:

$$SMB = m_{precip} - (m_{runoff} + m_{sub}) \quad (A10)$$

810 In BESSI, the incoming precipitation (rain/snow) accumulates first on the surface (Fig. 1). Generally, the precipitation adds snow mass to the top snow layer ( $T_{air} < 273.15$  K) or liquid mass to the water content of the surface ( $T_{air} > 273.15$  K). As more snow accumulates in the top layer, BESSI generates new snow layers below to prevent the mass of the layer from exceeding the maximum threshold ( $500 \text{ kg m}^{-2}$ ). The mass of the new layer is set at  $300 \text{ kg m}^{-2}$ , and the old layer keeps the remaining mass, continuing to accumulate snow. Depending on the precipitation and the temperature, up to 15 layers can be  
815 formed. When more than one layer exists, the masses of these layers are shifted down to leave space for the new forming layer. In contrast, when  $Q_{melt}$  is available, the snow column melts from the top. To prevent the mass of the surface layer from sinking below the minimum threshold ( $100 \text{ kg m}^{-2}$ ), BESSI merges this layer with the next one. After the merging, the masses of the layers below are shifted up. In case  $Q_{melt}$  is enough to melt all the snow layers, ice starts to melt, adding water to the runoff.

The water resulting from melt and rain is retained by the snow column up to 10% of its pore volume. The excess water  
820 percolates through the snow column, either refreezing due to low temperatures or leaving the lowest layer as runoff. The energy for refreezing, according to the assumption that the snow and the liquid water inside the snowpack are in thermodynamic equilibrium (Born et al., 2019), is calculated as:

$$Q_{refreezing} = c_i m_s (273.15 - T_{snow}) \quad (A11)$$

in which  $T_{snow}$  is the temperature of the snow layer where the process takes place. Refreezing can occur anywhere among the  
825 snow layers, unlike melt, which happens only at the top.

The resulting amount of water from processes of rain, melt, and refreezing that leaves the bottom layer is considered as runoff:

$$\frac{\partial m_{runoff}}{\partial t} = m_{rain} + m_{melt} - m_{refreezing} \geq 0 \quad (A12)$$

830 Sublimation/Evaporation, depending on the humidity of the air, is converted from the turbulent latent heat flux  $Q_{LH}$  to mass as:

$$\frac{\partial m_{sub}}{\partial t} = -\frac{Q_{LH}}{L_v + L_m} \quad (\text{A13})$$

Positive values indicate sublimation/evaporation happens, subtracting mass from SMB. On the contrary, deposition/condensation occurs, adding mass to SMB.

## **Appendix B: Evaluation metrics for BESSI-MAR and ITM-MAR with MAR as climate forcing**

835 The goodness-of-fit metrics used to evaluate ~~BESSI performance behaviors of BESSI-MAR and ITM-MAR~~ for the present-day climate condition are presented in the following. The coefficient of determination  $R^2$  is calculated as:

$$R^2 = 1 - \frac{\sum_i^n (X_{BESSI_i} - X_{MAR_i})^2}{\sum_i^n (X_{MAR_i} - \bar{X}_{MAR})^2} \frac{\sum_i^n (X_{BESSI_i} - X_{MAR_i})^2}{\sum_i^n (X_{MAR_i} - \bar{X}_{MAR})^2} \quad (\text{B1})$$

in which  $(X_{BESSI_i} - X_{MAR_i})$  is the difference between the climatological annual mean value of the same variable of ~~two models BESSI-MAR and MAR~~ for the grid cell  $i$ .  $\bar{X}_{MAR}$  indicates the spatial mean value of MAR of 43-year-mean result.

840 The Root Mean Squared Errors (RMSE) is defined as:

$$RMSE = \sqrt{\frac{1}{n} \sum_i^n (X_{BESSI_i} - X_{MAR_i})^2} \quad (\text{B2})$$

Here,  $n$  is the total number of the grid points of each ice sheet domain: ~~7,667-665~~ for GrIS and 11,217 for AIS, which is also the case for Eq. ~~A1- B1. The same equations are applied to ITM-MAR.~~

~~For a better intercomparison of different variables, we used Normalised RMSE, defined as:-~~

$$845 \quad \underline{NRMSE = \frac{1}{\sigma_{MAR}} \sqrt{\frac{1}{n} \sum_i^n (X_{BESSI_i} - X_{MAR_i})^2}}$$

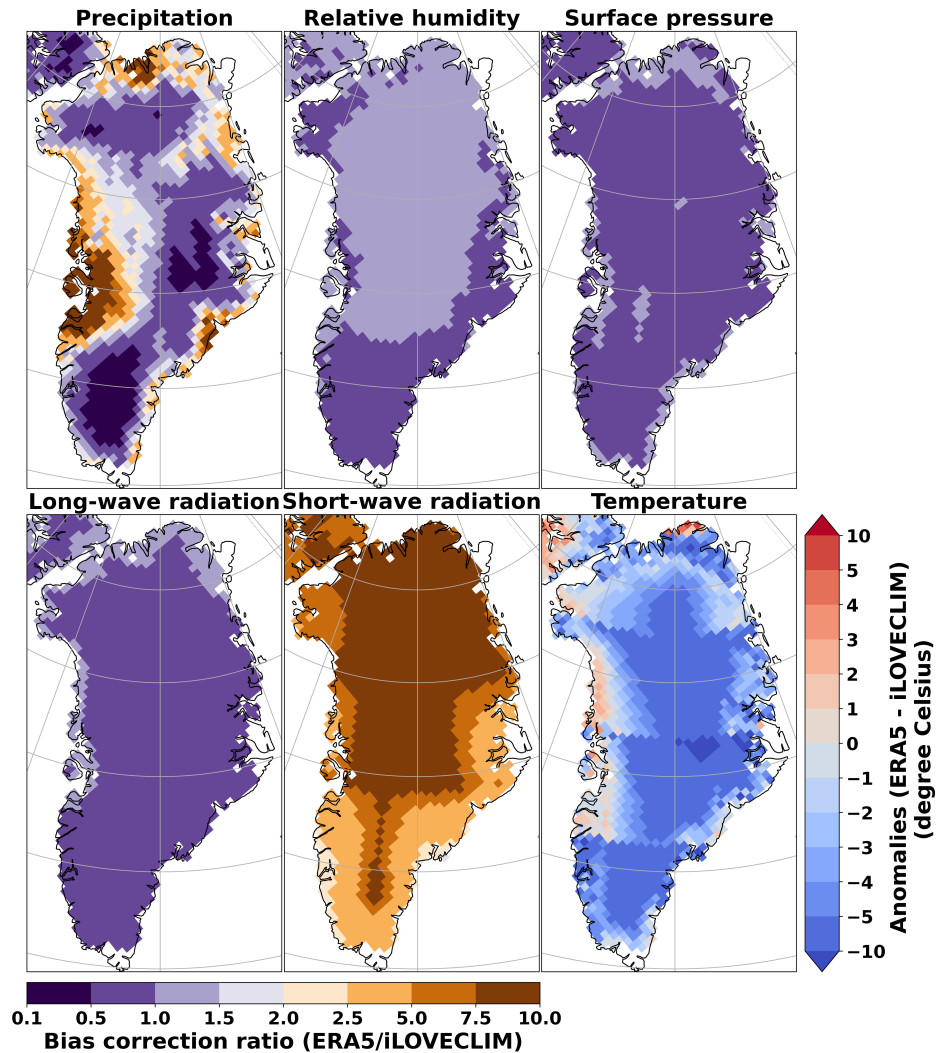

~~with  $\sigma_{MAR}$  is the standard deviation of MAR model climatological annual mean output.~~

## **Appendix C: ~~Additional plots~~**

### **B1 ~~ITM with $e = -40 \text{ W m}^{-2}$~~**

## **Appendix C: Bias correction procedure for iLOVECLIM**

850 ~~To illustrate the dependence of ITM on its empirical parameters, we carry out a LIG simulation with a lower value of  $e$  parameter in Eq. (15) by using  $e = -40 \text{ W m}^{-2}$ . The results are presented in Fig. B1. As expected, ITM with a lower  $e$  value simulates less melt for regions with large temperature changes during the LIG (GrIS).~~

**Figure C1.** Comparison Mean values of ITM bias correction factors of different value of parameter  $e$  and BESSI with original and bias-corrected iLOVECLIM in terms of the annual mean total SMB anomalies (in  $\text{Gt yr}^{-1}$ ) between LIG and pre-industrial respect to ERA5 for (a) Greenland and (b) Antarctica.

### C1 Bias correction method for iLOVECLIM

To investigate the influence of bias-corrected the climate biases in iLOVECLIM on BESSI 's performance and ITM behaviors, we use the delta method to correct the bias in iLOVECLIM by using these biases with ERA5 (Muñoz-Sabater et al., 2021), a reanalysis climate data, as reference.

Comparison of BESSI iLOVECLIM and ITM of different value of parameter  $e$  in terms of the annual mean total SMB anomalies (in  $\text{Gt yr}^{-1}$ ) between LIG and pre-industrial for (a) Greenland and (b) Antarctica.

Input for BESSI includes near-surface temperature, precipitation, surface pressures, humidity, and short-/long-wave radiation  
 860 in daily time ~~steps~~step. For temperature, the bias-corrected data is obtained as follows:

$$T'_{iLC} = T_{iLC} + (\overline{T_{ERA5}} - \overline{T_{iLC}}) \quad (C1)$$

in which,  $T'_{iLC}$  is the bias-corrected daily temperature of *iLOVECLIM*,  $T_{iLC}$  is the origin daily output of *iLOVECLIM*,  $(\overline{T_{ERA5}} - \overline{T_{iLC}})$  is the differences in the daily climatological mean temperature of the period 1979-2021 between ERA5 and *iLOVECLIM*.

865 For other input variables, the bias correction is carried out as:

$$X'_{iLC} = X_{iLC} \times \frac{\overline{X_{ERA5}}}{\overline{X_{iLC}}} \frac{\overline{X_{ERA5}}}{\overline{X_{iLC}}} \quad (C2)$$

in which,  $X'_{iLC}$  is the bias-corrected daily data of *iLOVECLIM*,  $X_{iLC}$  is the origin daily output of *iLOVECLIM*,  $\overline{X_{ERA5}}$  and  $\overline{X_{iLC}}$  is the daily climatological mean data of the period 1979-2021 correspondent to the reference (ERA5) and *iLOVECLIM*.

In order to avoid extreme value, we set a threshold for the ratio  $\frac{\overline{X_{ERA5}}}{\overline{X_{iLC}}} \frac{\overline{X_{ERA5}}}{\overline{X_{iLC}}}$  to be in the range 0.1 ~~-10.0-~~

870 ~~We present the result of the bias correction for present-day climate in Fig. B2. For the Greenland ice sheet (Fig. B2a), bias-corrected BESSI-*iLOVECLIM* displays better SMB patterns than the original version with BESSI-MAR as a reference. Similarly, the unrealistic negative SMB in the center of the Antarctic ice sheet is also removed with the bias correction (Fig. B2a)-~~

~~Assuming the biases are constant with time, we run bias-corrected BESSI-*iLOVECLIM* for the LIG with the same bias-corrected~~  
 875 ~~factors obtained from present-day simulations. The results to 10.0. For relative humidity, the range is set to 0.15 to 1.0. These bias correction factors are presented in Fig. B1 (also in Supplementary Fig. S5). Compared to the pre-industrial simulation of the same model, bias-corrected BESSI-*iLOVECLIM* simulates more melt than the origin model version during the LIG in GrIS. For AIS, not much differences are observed between the two versions of BESSI-*iLOVECLIM*. C1 for GrIS and Fig. C2 for AIS.~~

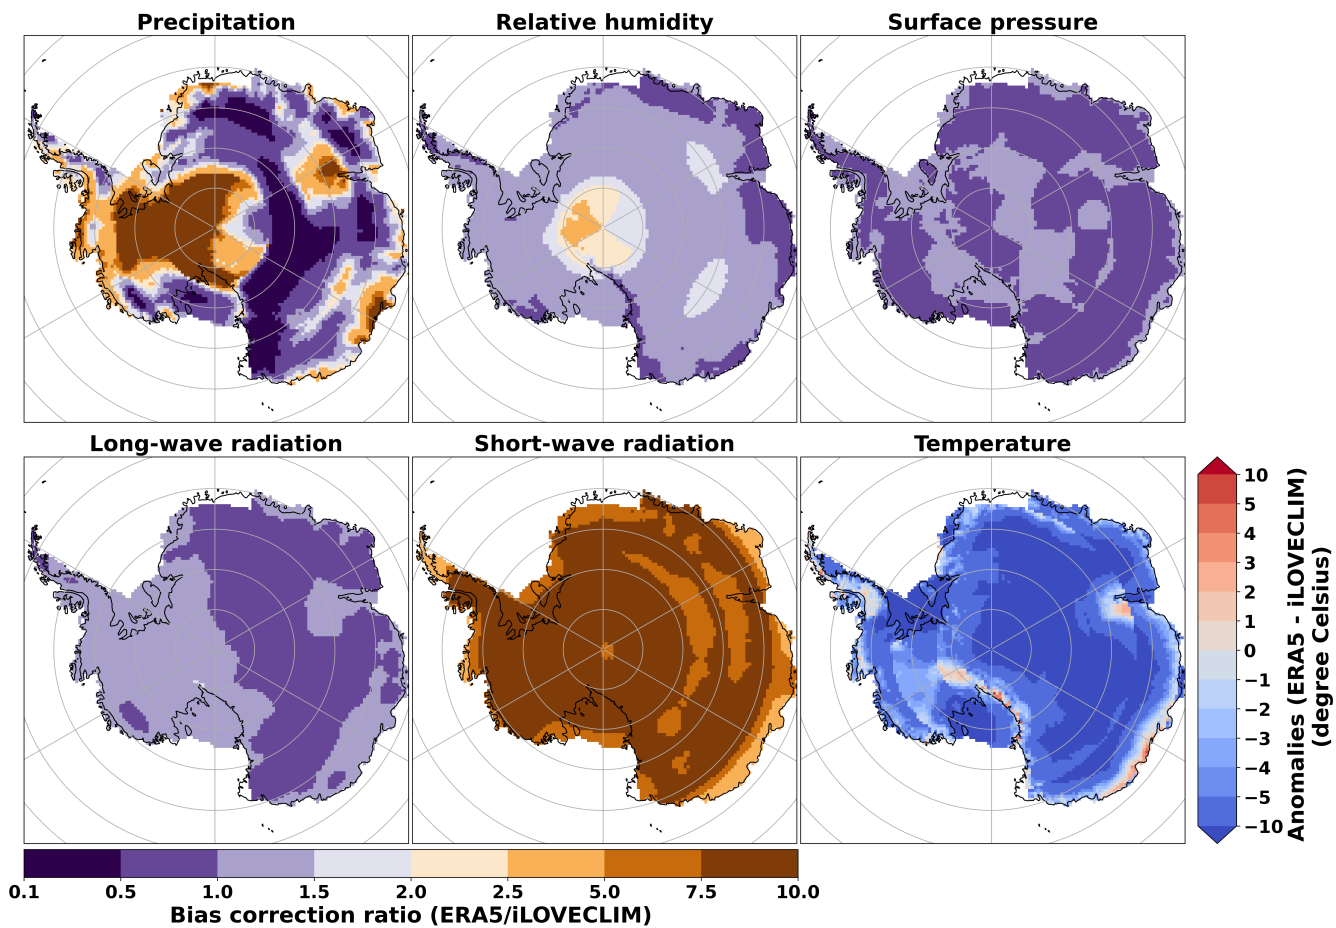

Figure C2. [Mean values of bias correction factors of iLOVECLIM respect to ERA5 for Antarctica.](#)

880 *Data availability.* Archiving of source data of the figures presented in the main text of the manuscript is underway. Data will be made publicly available upon publication of the manuscript on the Zenodo repository with digital object identifier 10.xxxx/zenodo.xxxxxxx. They are temporarily available for review purposes upon request.

*Code availability.* BESSI version used in this work will be made publicly available upon publication of the manuscript on the Zenodo repository with digital object identifier 10.xxxx/zenodo.xxxxxxx.

885 *Author contributions.* TKDH and AQ designed the study with contributions from CD and DMR. AB provided the source code of the BESSI model. All authors contributed to the analysis of the results. TKDH performed the simulations and wrote the manuscript with comments from AQ, CD, AB and DMR.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* Thi-Khanh-Dieu Hoang was supported by the CEA NUMERICS program, which has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No 800945. The authors would like to thank Xavier Fettweis, Charles Amory and Cécile Agosta for providing the data of MAR for GrIS and AIS. We also acknowledge the Institut Pierre Simon Laplace for hosting the iLOVECLIM model code under the LUDUS framework project (<http://forge.ipsl.jussieu.fr/ludus>, last access: 23 February 2024).
