Abstract. This study proposes using a data-driven statistical model to freeze errors due to differences in environmental forcing when evaluating surface turbulent heat fluxes from weather and climate numerical models with observations. It takes advantage of continuous acquisition over approximately ten years of near-surface sensible and latent heat fluxes (H and LE respectively) together with ancillary parameters over the supersite “Météopole” of the French national research infrastructure ACTRIS-
5 FR, located in Toulouse. The statistical model consists of several multi-layer perceptrons (MLPs) with the same architecture. Thirteen variables characterizing environmental forcing in the surface layer on an hourly timescale are used as input parameters to simultaneously estimate the observed H and LE . The MLPs are trained using 5-year observational data under a 5-fold cross-validation. The remaining data are used to test the estimates under unknown conditions. The performance of the statistical model ranges within the state-of-the-art surface parameterization schemes on hourly and seasonal time scales. It also has
10 a good generalization ability, but it hardly estimates negative H and large LE . A case study is conducted with data from a regional climate simulation. The statistical model is used to evaluate the simulated fluxes in the simulated environment to better examine the flaws of their numerical formulation throughout the simulation. Comparison of simulated fluxes with observed and MLP-based fluxes shows different results. According to MLP-based fluxes in the simulated environment, the land surface scheme of this climate model tends to underestimate large sensible heat flux. Thus, it incorrectly partitions between surface
15 heating and evaporation during the late summer. Our innovative method provides insight into different techniques for evaluating simulated near-surface turbulent heat fluxes when a long period of comprehensive observations is available. It can usefully support ongoing efforts to improve surface parameterization schemes.

1 Introduction

The surface sensible heat (H) and latent heat (LE) fluxes describe the surface-atmosphere exchanges of heat and moisture (Stull, 1988). They are major terms of the Surface-Energy-Budget (SEB) and key drivers of the atmospheric boundary layer (ABL) processes, such as turbulent mixing and convective cloud formation. Numerical models are important tools for weather forecasting and climate projection. Due to the coarse spatio-temporal resolution of operational weather and climate numerical models, the surface turbulent heat fluxes are computed with the help of surface parametrization schemes, which have different levels of sophistication. The correct formulation of turbulent heat fluxes by these schemes is then necessary for properly simulating the surface-atmosphere interactions. However, the representation of convection and surface processes are the two most important sources of systematic biases in numerical simulations (Zadra et al., 2018; Frassoni et al., 2023). Therefore, it is of paramount importance to develop improvements and evaluation is crucial to provide guidance.

The evaluation of surface turbulent fluxes is a real issue due to the number of factors that can explain the differences. These factors include inaccuracies in simulated weather conditions (such as cloudiness, temperature, wind, moisture, and surface stability), inconsistencies in landscape representation within the numerical model (e.g., vegetation and soil characteristics), the lack of representativeness of local measurements compared to the model grid scale, uncertainties in observations (Mauder et al., 2020), and finally, the parameterization of fluxes, which typically relies on Monin-Obukhov similarity theory (MOST, Monin and Obukhov, 1954). Various strategies using coupled numerical simulations have been proposed to reduce biases related to weather conditions, the scope of our proposed method here. These include investigating the relationships between surface heat fluxes and atmospheric variables pairwise (e.g., Zhou and Wang, 2016; Bastin et al., 2018) or focusing on clear-sky conditions (e.g., Arjdal et al., 2024). Another approach involves using the land surface model in offline mode (e.g., Liu et al., 2013), where turbulent heat fluxes are computed using input from observations or reanalysis. While these methods are encouraging, they have limitations that prevent drawing general conclusions.

In recent years, machine learning techniques have known a tremendous expansion in weather and climate sciences (de Burgh-Day and Leeuwenburg, 2023), driven by unrivalled results and infinite possibilities. Because of their ability to act as universal approximators (Cybenko, 1989; Hornik et al., 1989), Artificial Neural Networks (ANNs) have emerged as a powerful tool in machine learning for data-driven statistical modelling (Goodfellow et al., 2016). They can effectively model a broad range of complex relationships for quantitative approximations, such as multivariate classification and regression (Zhang, 2008; Kruse et al., 2013). ANNs are generally used to overcome the limitations of classical approaches. Several studies

have explored the use of ANN-based estimators for replacing numerical atmospheric models or some of their components (e.g., Bonavita and Laloyaux, 2020; Gentine et al., 2018; Knutti et al., 2003; Sarghini et al., 2003; Vollant et al., 2017). In the study of Abramowitz (2005), a trained ANN with observational data is used as a benchmark to objectively assess how well a land surface scheme should perform in estimating turbulent heat and net CO₂ fluxes. Recently, Leufen and Schädler (2019) estimated the scaling quantities needed in some surface parameterization schemes to calculate the momentum and sensible heat fluxes using an ANN-based model driven by meteorological factors. The ANN has learned from multi-year comprehensive data collected over several types of landscapes (grassland, forest, etc.). They obtained satisfying results when this ANN was implemented to replace the similarity functions in a one-dimensional stand-alone land surface model. In the field of hydrology, ANN-based models are increasingly being employed to estimate reliable evapotranspiration for near real-time monitoring of crop water demand (Kumar et al., 2011; Kelley et al., 2020; Kelley and Pardyjak, 2019). The growing availability of comprehensive data from atmospheric observatories offers an opportunity to explore ANN-based methods to better evaluate the numerical formulation of surface H and LE , particularly within the framework of full simulations, which is the ultimate goal of numerical models.

60

The Model and Observation for Surface-Atmosphere Interactions (MOSAI) project (Lohou et al., 2022) seeks to enhance the understanding of surface-atmosphere interactions. The key objectives are to address the issue of observations representativity and uncertainty, encourage the development of novel methods to better compare simulations with observations, and improve surface heat fluxes parametrization over heterogeneous surfaces. This paper is a contribution to the second objective. It proposes a novel method to diagnose the errors of numerical models in their formulations of H and LE . The idea is to exploit the capabilities of machine learning techniques on multi-years of continuous observational data, rather than performing a classical direct comparison of simulated against observed fluxes. It presents a pilot study that uses data collected during several years at a permanent French station, operational since June 2012, for evaluating turbulent heat fluxes in a climate numerical model over the period from 01 January 2012 to 31 December 2016. Section 2 presents the proposed evaluation approach, which involves using observational data to build a data-driven statistical model that approximates observed H and LE . The data and methods of our experimental setup are described in section 3. Section 4 discusses the performance of the data-driven model in observed conditions. In section 5, the data-driven model is applied to simulated conditions to better identify the flaws in the numerical formulation of turbulent heat fluxes. Finally, section 6 delivers a conclusion.

70

The surface turbulent heat fluxes are primarily governed by the net radiative flux (R_{net}), which is the algebraic sum of incoming (\downarrow) and outgoing (\uparrow) long-wave (LW) and short-wave (SW) radiations. Their magnitude is strongly linked to thermodynamic and dynamical conditions in the surface layer; a thin atmospheric layer immediately above the ground where turbulent fluxes are approximately constant. The flux H is responsible for removing/depositing heat from/to the ground, and
 80 LE is the energy exchanged through phase changes of water from liquid (or ice) to vapour. H and LE are therefore closely linked to the vertical gradients of temperature and humidity in the surface layer. The relative predominance between H and LE depends on surface characteristics (vegetation and soil moisture), LE is predominant over wet surfaces and vice versa. The solar heating and annual evolution of land cover induce diurnal and seasonal cycles of turbulent heat fluxes. Thus, the turbulent fluxes result from complex non-linear relationships between meteorological factors, surface cover and soil conditions.

85

The vast majority of numerical formulations of turbulent heat fluxes rely on the validity of MOST in the surface layer, which assumes horizontally homogeneous terrain, and fair and steady-state atmospheric conditions. The fluxes are then expressed in terms of the vertical gradient of the corresponding thermodynamic scalar (temperature for H and humidity for LE) in the surface layer, along with various parameters describing ground wetness and roughness. The weather and climate models
 90 usually apply MOST between the ground and the first atmospheric level above, considered as the top of the surface layer (Liu et al., 2013). However, the relevance of this theory in grid cells with heterogeneous land use is highly questionable.

Another fundamental relationship, usually used in numerical models, is the conservation of SEB as follows:

$$R_{net} = H + LE + G \quad (1)$$

95 where G is the ground heat flux. However, this conservation is rarely verified when H and LE are measured with an Eddy-Covariance (EC) method, the most recent and reliable technique (Mauder and Foken, 2004; Wolf et al., 2008; Aubinet et al., 2012). Indeed, the available energy $R_{net} - G$ is very often greater than the total turbulent flux $H + LE$, especially over a heterogeneous surface (Hu et al., 2021; Mauder et al., 2018; Foken et al., 2011). This imbalance can be quantified by the residual energy (RES).

$$RES(\%) = 100 \cdot \frac{(R_{net} - G) - (H + LE)}{R_{net} - G} \quad (2)$$

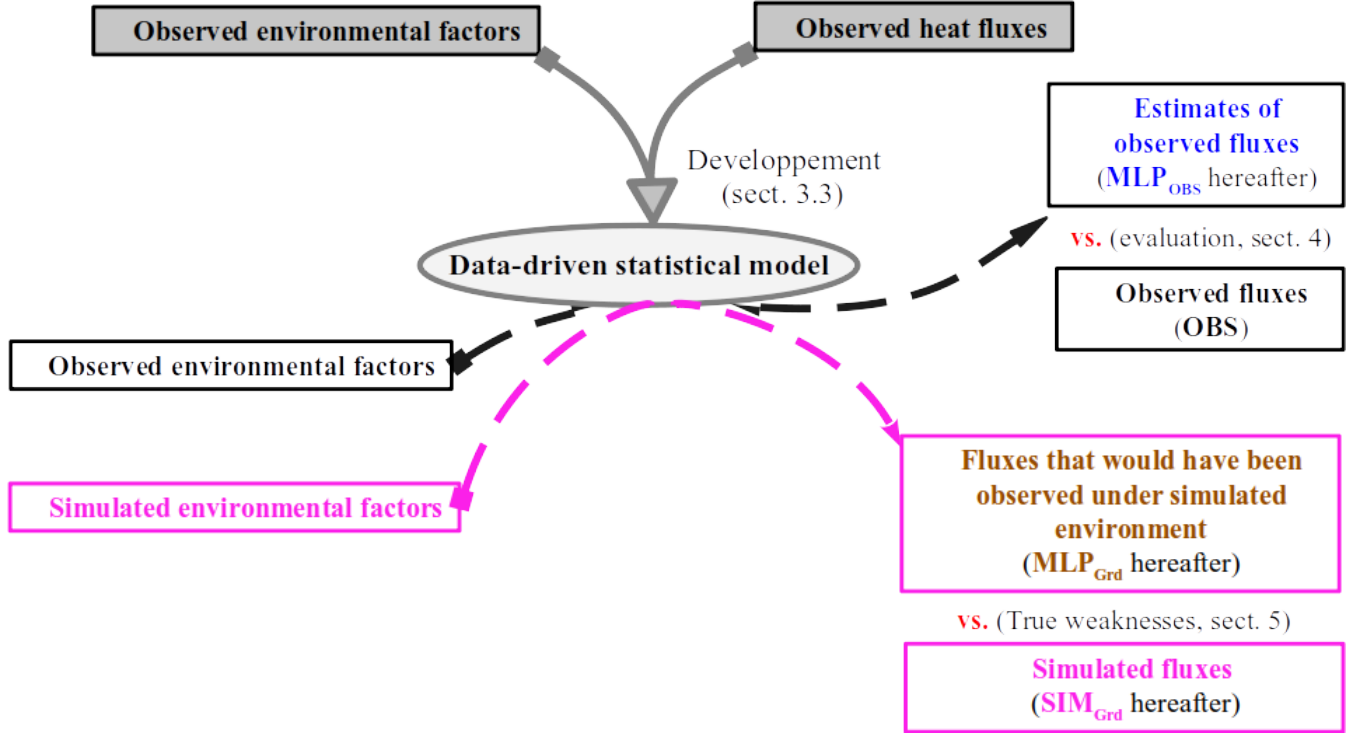

Figure 1. Schematic illustration of our proposed evaluation method. See the text for more details

Thus, the discrepancies in simulated and observed surface turbulent heat fluxes could stem from inconsistencies in surface representativeness, process parametrization, or observational and modeling biases. Therefore, a direct comparison is less useful in identifying the weaknesses of the surface parameterization scheme for the formulations of H and LE . The study by Abramowitz (2005), based on observational data, is a pioneer in using a data-driven statistical model to reliably assess land surface schemes. Inspired by the methodology of this study, we propose an evaluation approach specifically devoted to full numerical simulation that realistically represents the interplay between surface turbulent heat fluxes and environmental factors. This approach consists of two successive phases that are illustrated in Figure 1. At first, a long period of observations of turbulent heat fluxes and relevant environmental factors is needed to build a data-driven statistical model that approximates

observed heat fluxes. It can be regarded as a parameterization without any simplifying assumptions. Then, the application of this statistical model to the simulated environment generates the fluxes that would have been observed under this environment from a statistical point of view. Thus, by comparing simulated heat fluxes with corresponding statistically-based fluxes for the same environment, the biases from other components of the numerical model are frozen. This allows us to better isolate the weaknesses in the formulations of H and LE , or due to the surface parameters and characteristics. The problems of observation representativeness and uncertainty are not addressed here. However, RES will be used as an indicator of the reliability of the observation in our analysis. The use of an indicator of the representativeness of observation is also in development but is out of the scope of this paper.

3 Experimental setup

3.1 Observational data

This pilot study is based on high-temporal-resolution data gathered over several years at the Météopole (43.57°N, 1.374°E, 157 m above sea level, Etienne, 2022), a measurement site hosted by the Centre National de Recherches Météorologiques (CNRM) in Toulouse, France. This site, operated by Météo-France, is part of the Aerosol, Clouds and Trace Gases Research Infrastructure in France (ACTRIS-FR). The observation facility consists of several co-located ground-based instruments installed in a large grass field. Starting from 24 November 2012, the surface energy budget and the corresponding environmental forcing (soil and overlying meteorological conditions) are continuously documented through a comprehensive set of measurements; the most relevant for our study are listed in Table 1. In addition to turbulent fluxes H and LE , these include the four components of the radiative budget, ground heat flux G , air temperature (T) and relative humidity (RH) at two conventional heights 2 and 10 m above ground level (agl), surface pressure (SP) and rainfall (RR), and soil volumetric water content (SWC). The surface and soil temperature are also measured at the Météopole station, but there is a lack of data before 12 July 2015. We then decided not to use these measurements to avoid limiting the number of samples, which is crucial when building a data-driven statistical model. Sensitivity analysis indicates no significant loss of key information concerning the variability in H and LE .

135

The fluxes H and LE are measured with the EC method (Aubinet et al., 2012) by high-frequency measurements (20 Hz) of three-dimensional components of the wind, T and water vapour specific humidity (q) with a sonic anemometer and a rapid

hygrometer mounted at 3.7 magl. Eventually, EddyPro 7 software (<https://www.licor.com/env/support/EddyPro/software.html>) is utilized to compute turbulent heat fluxes at a half-hour temporal resolution. Each of these observed fluxes is accompanied by a quality flag by Mauder and Foken (2004) that ranks the measurement into three categories: 0 for high quality, 1 for suitable to be used for research and 2 for that should not be used. Besides, the rapid hygrometer’s accuracy (licor 7500 open-path) is highly degraded in wet conditions (fog or rain event). Therefore, the turbulent fluxes are normally not estimated under these conditions, based on the sensor detection of rainfall occurrence. However, wrong measurements could still be performed, as an accumulation of liquid water persists on the sensor.

The environmental parameters are originally acquired every 1-min and finally archived as half-hourly averages, matching the temporal resolution of turbulent fluxes. Jomé et al. (2023) analyzed the contribution of the surrounding land cover types to the turbulent heat fluxes measured at the Météopole station. It was found that the contribution of grass cover ranges between 80 to 90 %, with the remaining contribution coming mostly from urbanized areas. The observational data from the Météopole station are freely available via the AERIS platform (<https://www.aeris-data.fr/>). This database undergoes several quality controls and is regularly updated after an annual exercise.

Table 1. Observational data from the Météopole station used in this study. A negative height corresponds to a soil depth.

Variables	height of acquisition (m a.g.l)
Surface upward/downward long/short-wave components	10
Turbulent heat fluxes (H and LE) and horizontal wind components (u , v)	3.7
Air temperature (T) and relative humidity (RH)	2 and 10
surface pressure (SP) and rainfall (RR)	-
Ground heat flux (G)	-0.05
Soil volumetric water content (SWC)	at 16 levels, the first at -0.1

This study is based on the data collected until 23 : 30 UTC 31 December 2022, which represents nearly 10 consecutive years of monitoring. The corresponding database contains 117782 half-hours for which the required measurements (Table 1) are simultaneously available, i.e., almost 66.5 % of the samples expected since 00 : 00 UTC 24 November 2012. The lack of data is mainly due to the absence of observed turbulent fluxes, mostly under wet conditions. Since the quality and amount of the data on which the data-driven statistical model is built determines its performance, several considerations were applied to select the samples with the most reliable measurements. Firstly, only H and LE with the quality flag 0 or 1 (Mauder and Foken, 2004) were selected. Due to the strong evolution of continental turbulent heat fluxes throughout the day, several authors preferred to evaluate numerical simulations under well-established diurnal cycles (e.g. Román-Cascón et al., 2021). For the final selection,

we then considered sampling on a daily scale. The half-hourly data included in our analyses are collected during the diurnal cycles (starting at 00 : 00) that fulfil the following three conditions: (i) it is described by at least half of the expected samples (i.e., 24/48 of pre-selected samples), (ii) the daily cumulative rainfall is less than 5 mm and (iii) all the items of Pearson's correlation coefficient matrix between H , LE and SW^{\downarrow} are greater than 0.6. The two last criteria are a compromise to preserve a reasonable number of samples while reducing the amount of data possibly impacted by wet conditions. This leaves us with 80683 half-hourly samples (around 69 % of all available samples), documenting 2274 diurnal cycles. Figure 2a shows the distribution of these samples per year, and Figure 2b presents the distribution of the corresponding diurnal cycles per month. None of these diurnal cycles was fully sampled, the rate of data availability is around 74 % on average. The annual cycles from 2015 to 2021 are relatively well sampled. The selected diurnal cycles are homogeneously distributed throughout each year, meaning that the four typical seasons (winter, spring, summer, and autumn) are represented well. There are no selected samples from June to September 2022 (Figure 2b) due to missing data of LW^{\uparrow} .

3.2 Numerical model data

To test our proposed evaluation method, we used data from an existing climate simulation, carried out with the Regional Earth system model of the Institut Pierre Simon Laplace (RegIPSL). Within the settings of this model, the land surface model ORCHIDEE (ORganising Carbon and Hydrology In Dynamic EcosystEms, Krinner et al., 2005) provides the bottom boundary conditions for the continental surface to the atmospheric model, WRF v3.7.1 (Weather Research and Forecasting, Skamarock et al., 2008). The simulation has been carried out within the framework of the Mediterranean Coordinated Regional Climate Downscaling Experiment (Med-CORDEX) initiative (Ruti et al., 2016) and the European Climate Prediction System (EUCP) H2020 project (Coppola et al., 2020). It covers the Euro-Mediterranean area with a horizontal resolution of 20 km on a Lambert-conformal projection and spans from 1st January 1979 to 31 December 2016. The atmospheric vertical column was discretized by 46 hybrid sigma-pressure levels (full eta levels), with 16 levels roughly in the first 2 kmagl. The soil column, which extends to 2 m below the ground, was subdivided by 11 nodes, with seven nodes located within the first 15 cm. For more details, the reader can refer to the studies of Guion et al. (2022) which used this climate simulation to assess the impact of droughts and heat waves on vegetation and wildfires in the western Mediterranean, and of Shahi et al. (2022) which used the RegIPSL model to analyze the added value of a convective-permitting climate simulation over the Iberian Peninsula.

Figure 2. (a) Number of remaining half-hourly samples and diurnal cycles per year after the selection over the period from 24 November 2012 at 00 : 00 to 31 December 2022 at 23 : 30 (see text for details), and (b) monthly distribution of these diurnal cycles. The rate of availability is the ratio of the selected half-hourly samples (second column) over the number of samples which fully describe the corresponding diurnal cycles (48 times the third column). The data of the five most covered years (in bold (a), with a black cross at the bottom (b)) composed the learning set, the other years are used as the test set.

The landscape in ORCHIDEE was categorized into 13 main classes including bare soil and 12 Plant Functional Types (PFTs: eight for forests, two for grasslands and two for croplands). The total proportion of the grid cell occupied by each class remained constant throughout the simulation. Nonetheless, for PFTs, the proportion effectively occupied by vegetation was allowed to vary and the non-occupied fraction was defined as bare soil (Ducharne et al., 2018; Alléon, 2022). The bare soil fraction is assumed to contain the urbanized areas. For simulating the surface processes, ORCHIDEE requires several environmental parameters including surface precipitation, downward *SW* and *LW* as well as air temperature, humidity, and wind just above the ground. These were taken at the lowest vertical level of WRF, located within 20 magl. The near-surface turbulent heat fluxes are computed using bulk aerodynamic formulations (Ducoudré et al., 1993; Krinner et al., 2005; Alléon,

2022) in an implicit surface-atmosphere coupling (Polcher et al., 1998). Several other useful parameters are also computed, such as surface temperature (T_S), surface albedo and emissivity, which are needed to calculate the upwelling components of the radiative budget. The calculations are performed at the grid cell scale, by aggregating its landscape into three soil tiles: one for the forest, one for grass and crops, and one for the bare soil. The aerodynamic parameters of the grid cell correspond to the
200 averaged parameters weighted by the effective areal fraction of each soil tile.

The raw output data of this climate simulation have been post-processed, and only a variety of specific variables describing atmospheric and land surface conditions have been archived for further uses. These include atmospheric variables on half-eta levels (M) such as q , potential temperature (θ) and horizontal wind components (u and v). The surface data involve skin
205 temperature T_S , SP , precipitation rate, H and LE , the four components of the radiative budget, and the underground liquid water content. The most conventional meteorological variables, such as T and RH at 2 m agl are also available. The data were stored at a 3 –hour temporal resolution for all variables except for the underground liquid water content. Specifically, the turbulent heat and radiative fluxes are 3 –hour time-centered averages, labeled at 01 : 30, 04 : 30, 07 : 30, 10 : 30, 13 : 30, 16 : 30, 19 : 30 and 22 : 30 UTC. Meanwhile, atmospheric variables at half-eta levels q_M , u_M and v_M , as well as those near
210 the surface T_S , SP , T_{2m} and RH_{2m} , are nearly instantaneous at 00 : 00, 03 : 00, 06 : 00, 09 : 00, 12 : 00, 15 : 00, 18 : 00 and 21 : 00 UTC. The underground water content is archived daily and consists of the height of liquid water within various sublayers, each containing one node.

215 It would be very interesting to extract the simulation data at a grid cell with a landscape composition that resembles the landscape contribution to the turbulent heat fluxes measured at the Météopole station, as found by Jomé et al. (2023). This grid cell should also be geographically close to the station to preserve the local behaviour of atmospheric forcing. However, for all the grid cells located within a distance 60 km to the station coordinates (e.g., 3 times the simulation horizontal resolution), at least 50 % of the surface is covered by crops and forest PFTs. The areal fraction of grass PFTs ranges between 10 – 21 %.

220 The simulation data are then extracted at the two nearest grid cells to the Météopole site, as usually done. Figure 3 shows their landscape composition. The proportion of bare soil and crops are respectively greater and smaller in the closest grid cell (Grd1, Figure 3b). Only the simulation covering the period from 01 January 2012 (the first year of heat fluxes measurements at the Météopole station) to 31 December 2016 is considered. This period coincides with the selected observation period from 24 November 2012. For consistency with radiative and heat fluxes, the time-centered average of q_M , θ_M , u_M , v_M , T_S , SP ,

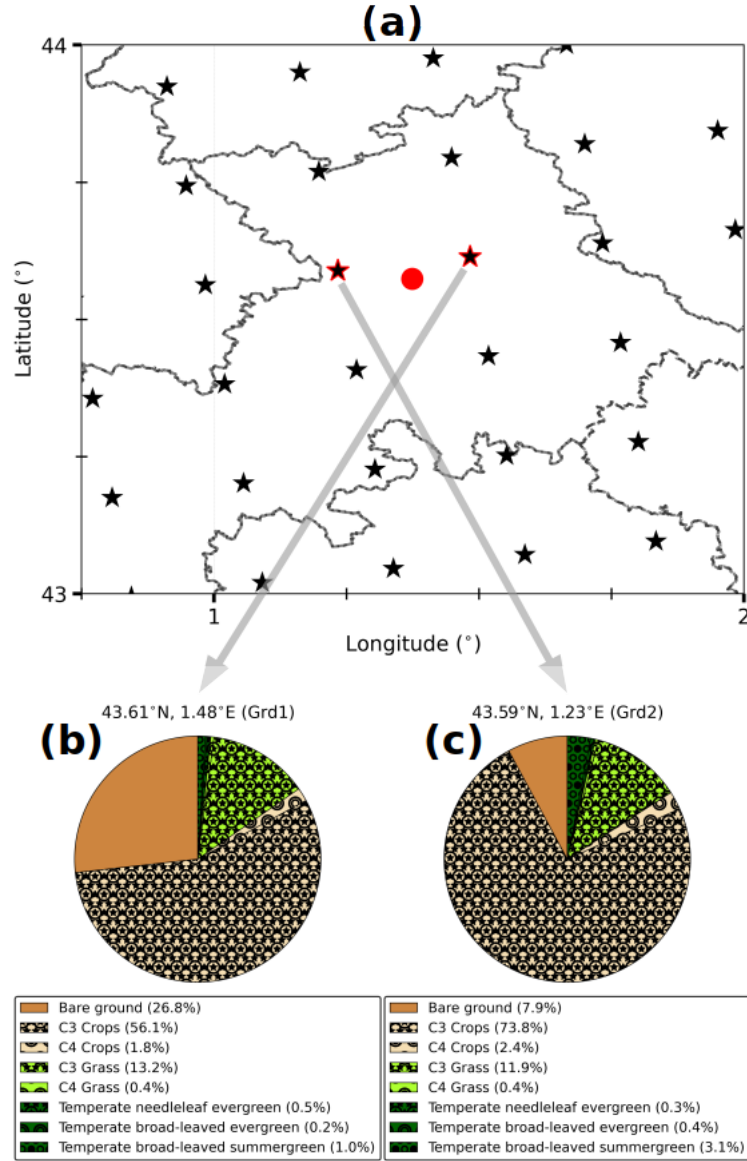

Figure 3. (a) The RegIPSL grid mesh (black stars) around the geographical location of the Météopole site (red circle). The dashed lines indicate the administrative subdivisions. The two nearest grid cells (Grd1 and Grd2) are highlighted with red edges. (b) and (c) Landscape composition in these two grid cells, Grd1 (b) being the closest.

225 T_{2m} and RH_{2m} are used. The SWC at the soil nodes is calculated as the ratio of liquid water height over the thickness of the corresponding sublayer. For each node, the value of SWC at a given day is assigned to every 3 hourly timestamp of that day. Similarly to the selected observational data, the days with cumulative rainfall exceeding 5 mm were excluded, reducing the

simulation data by around 15 %.

230 3.3 The data-driven statistical model

Since the fluxes H and LE are continuous variables, our problem is formulated as multivariate regression settings. There are several ways to perform regression with ANNs. The easiest is to exploit the most basic ANN, the feed-forward network also known as the multi-layer perceptron (MLP). Due to its exceptional ability to approximate complex multivariate functions, MLP has become the most widely used type of ANN. Accordingly, our data-driven statistical model is built using MLP. This
235 section begins by briefly introducing this type of ANN. Subsequently, the implementation of the statistical model with half-hourly observational data is detailed. Finally, the challenges involved in its application to the data from climate simulation are outlined.

3.3.1 The multi-layer perceptron

The elementary unit of ANNs is the mathematical neuron (Rosenblatt, 1960), which is illustrated in Figure 4. It is a numerical computational unit that receives information through synaptic connections characterized by weights (w), and provides a
240 response using an activation function (f) and a bias (b), as follows:

$$o = f(b + \sum_{j=1}^N w_j \cdot x_j) \quad (3)$$

where N is the number of input variables. In general, the input data of f and its output range within $[-1, 1]$. The neuron's behaviour, either linear or non-linear, is defined by its activation function. Although there are many types of activation
245 functions, sigmoid-like functions (e.g. logistic and hyperbolic tangent) and the identity function are commonly used for regression (Zhang, 2008).

The MLP is a supervised ANN, which consists of fully interconnected neurons organized in successive layers (see Figure 5 for illustration). These layers include an input layer to receive the predictors, an output layer to get the outcome, and at least
250 one intermediate layer between them, the so-called hidden layer(s). There is one neuron per input and output variable. The neurons in the input layer just carry the data without any calculations. The hidden layer(s) form the computational core of MLP. Although the topography of hidden layers (number of layers and neurons) has an impact on the network's capability to approximate the relationships, there is not yet a universal rule defining the most suited for a given problem. Thus, finding

an appropriate configuration for hidden layers (number of layers and neurons) is generally a non-trivial and uphill task with
 255 expensive computational costs.

Figure 4. Schematic illustration of a mathematical neuron (adapted from Zhang, 2008): x_i, w_i correspond respectively to its numerical inputs and synaptic weights, whereas o is the response based on its activation function (f) and bias (b). This latter is schematized by an input variable with a value and weight equal to $+1$ and b respectively.

As a supervised ANN, MLP acquires knowledge about its task through a learning stage. During this stage, the network is provided with examples of paired predictors and desired outputs, and its weights and biases adjust accordingly. The MLP understanding of the physics laws then entirely relies upon the quality and amount of data on which it has learned. Thus, the
 260 more consistent examples, the more chances of the MLP being accurate over unseen input data. The learning data is usually separated into two disjoint subsets: training and validation. The MLP weights and biases are updated using a backpropagation optimization technique which minimizes an error metric calculated on the training data, between the MLP outputs and the desired values. The Mean-Square-Error (MSE) is the common error metric (Zhang, 2008) for regression. In general, there are three modes in which backpropagation optimization may be applied: (i) the 'online' mode in which the network weights and
 265 biases are updated for each example in the training set, (ii) the 'batch' mode in which all the training data are considered at once, and (iii) the 'mini-batch' mode which is a mixture of the two first and achieves their advantages while limiting their inconveniences; the training data is subdivided into a smaller fixed number of samples (the mini-batch) which are used for modifying weights and biases. The default mini-batch size is 32. Another key parameter of the learning stage is the number of training data passages through the network, also called epochs (Chicco, 2017; Zhang, 2008; Kruse et al., 2013). Indeed,
 270 with small epochs, the network would not understand the complexity of the data, leading to an underfitting. By contrast, too high epochs may lead to overfitting; the network would capture all the details of the training data while performing badly on unknown data. The validation data serve to assess the network performance during the updating of its weights and biases. Thus, a fairly large number of epochs can be envisaged to avoid underfitting and the learning is early stopped when the

performance over the validation set no longer improves, preventing overfitting.

275

Thus, the implementation of MLP can be split into three main points:

- (i) Define a set of relevant predictors based on the variables to be approximated.
- (ii) Select a learning data such that it would contain sufficient examples to statistically describe the relationships between predictors and targeted variables.
- 280 – (iii) Find suitable MLP setting (topology of hidden layer(s), activation function, etc.) through sensitivity experimentation.

Before processing with MLP, data should be scaled (i) for consistency with f and (ii) to circumvent the relevance of variables due to their magnitude. Moreover, the backpropagation algorithm is stochastic, which often leads to variability in the final weights and biases of MLP each time the network is retrained with the same data. Indeed, the final state may correspond to a local minimum of the error metric (Zhang, 2008). Although the difference between the MLP outputs is usually slight, it
285 can be annoying not to get the same results. The ensemble learning approach (Ganaie et al., 2022) may limit the instability of the MLP-based estimates and get closer to the optimal estimate. Instead of training a single MLP, this approach involves training multiple MLPs and then averaging their outputs for regression problems. One of the standard strategies for generating these MLPs is bagging (Breiman, 1996; Khwaja et al., 2015); a base MLP is trained on a redistributed version of the original training or learning set.

290

3.3.2 Implementation

In this work, each MLP is implemented using Tensorflow-Keras (version 2, Abadi et al., 2016), a Python library specifically designed for ANNs, known for its user-friendly interface. Unless otherwise mentioned, the default parameters are used. The three points mentioned above are addressed as follows:

- 295 – (i) As MLP predictors, we use 13 variables that can be derived from observational and simulation data while still having the same physical meaning. Their formulations are shown in Table 2. Indeed, H and LE are theoretically quasi-constant within the surface layer and strongly related to near-surface radiative, thermodynamic, and dynamical forcing. Moreover, their relative predominance is controlled by the wetness of the uppermost part of the soil. In numerical simulations, the atmospheric level just above the ground is usually the top of the surface layer. Therefore, considering the observed
300 variables in Table 1 and the variables from the simulation that have been archived, we derived a set of 9 physical

variables that may analogously summarize the environmental forcing in the surface layer. They include the radiative energy governing surface processes (R_{net}), the meteorological conditions in the surface layer (θ_{sl} , $\Delta\theta$, q_{sl} , Δq , u_{sl} , v_{sl} , Δ_U) and the moisture in the uppermost soil layer (SM). Eventually, 4 trigonometric temporal coordinates are added to describe seasonal (d_x , d_y) and diurnal (h_x , h_y) cycles. Under the observed environment, SM is defined by SWC_{-10cm} (the first depth of soil moisture measurements) and the meteorological variables are calculated assuming that the surface layer always extends above 10 magl. For the simulated environment, SM then corresponds to $SWC_{-12.3cm}$ (the nearest node to the measurement depth). Diagnostic variables derived from numerical simulation (T_{2m} , RH_{2m}) are susceptible to contain bias due to the interpolation technique and the inconsistency of terrain elevation. To avoid these uncertainties, the meteorological variables are taken directly at the first half-eta level ($M=1$, around 8 magl) as much as possible. In both observed and simulated environments, Δ_U is calculated assuming a null horizontal wind speed at the ground. Due to missing data, the sunrise hour required to compute h_x and h_y was retrieved using the astral package (version 3.0), and rounded to the nearest half hour.

- (ii) To train the statistical model over as many multivariate cases as possible, the half-hour observational data from the five most covered years (Figure 2) were gathered as the learning set. The remaining data was reserved for assessing its ability to generalize, it will be referred to as the test set.
- (iii) Since H and LE are complementary fluxes and to avoid excessive sensitivity experiments in the search for a relevant architecture for MLP, the neurons in the output layer were set to 2, one for each flux. Following the literature (Kumar et al., 2011; Leufen and Schädler, 2019; Kelley and Pardyjak, 2019; Kelley et al., 2020), hyperbolic tangent and identical functions were used as the activation functions for neurons of the hidden and output layers, respectively. The weights and biases optimization was carried out with the Adam-amsgrad backpropagation algorithm (Kingma and Ba, 2017; Reddi et al., 2018) in a default mini-batch mode, and MSE was chosen as the error to minimize. Based on preliminary results, we opted for the same strategy of network training used by Leufen and Schädler (2019). The network update stops at most after 1000 epochs. Otherwise, the update is stopped early if the MSE on the validation data does not improve after 50 successive epochs, and then the network state is finally set to the epoch with the best MSE.

The input and output data are scaled to the interval $[0, 1]$ similarly to Leufen and Schädler (2019) as follows:

$$\tilde{x} = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (4)$$

Table 2. The 13 MLP input variables, derived from observational data and their equivalent extracted from RegIPSL data. dd , Δh and N_y included in the expressions of the temporal coordinates respectively are the Julian date, hours relative to sunrise on dd and number of days in the year.

where x_{min} and x_{max} correspond to the extreme values. They are set to the theoretical values of the trigonometric functions (e.g., -1 and 1 respectively) for the four temporal coordinates. For the other nine physical parameters, these values are set so that the resulting interval strictly holds both the observational and RegIPSL data (see Figure A1).

330

The MLP base architecture used in this study involves two hidden layers with 4 and 3 neurons, respectively (Figure 5). It was found through several series of sensitivity experiments with the learning set (not shown). A bagging-based strategy was used to account for the strong inter-annual variability of H and LE in their statistically-based estimates. Indeed, a 5-fold cross-validation (Andersen and Martinez, 1999) with year-wise data splitting was applied to the learning set to generate 55
335 bagged MLPs. Cyclically, the data from one year were used as the validation set whilst the others composed the training set, and, 11 MLPs were trained by randomly initializing weights and biases along with a shuffling of the training data before composing mini-batch subsets. In this way, each example in the learning set was at least once used as validation or training

data. Even though the number 11 was arbitrarily chosen based on the available computing resources, it ensures the repeatability of estimates. Thus, the statistically-based estimates of observed fluxes are the average across the individual MLP outputs. In the following, we refer to these as MLP-based fluxes or estimates.

Figure 5. Architecture of MLP used in this study. The input variables are described in table 2.

3.3.3 Application to data from numerical model

The MLP-based model is built using half-hour observational data to take advantage of more samples. After that, it will be applied to the 3-hour simulation data to provide H and LE that are likely to be observed in the simulated environment. This assumes that simulated and observed environments share a common space, and the learning data represents that space. On one hand, the difference in temporal resolution could introduce artificial errors that might impact both the statistical model's performance and comparison results. These potential impacts are discussed at the beginning of section 5. On the other hand, if the simulated environment does not have similar structures (distribution and interval ranges of input variables) to the observations, the statistical model may perform poorly. Indeed, MLP has a good interpolation capability, but may not correctly extrapolate beyond the ranges of values it has learned (Bonnasse-Gahot, 2022). Yet, for four of the nine physical

variables (Δ_θ , Δ_q , u_{sl} and v_{sl}) the simulation data spread beyond the observed values (Figure A1). A rigorous application of machine learning techniques requires the use of transfer learning to mitigate performance loss when trained ANN is applied to data originating from another source (Day and Khoshgoftaar, 2017). Since the observed H and LE associated with the simulated environment are unknown, the most challenging transfer learning approach, unsupervised domain adaptation, would normally be used in our case. Numerous methods are available for achieving unsupervised domain adaptation. We tried the easiest and most popular methods over the simulation input data, such that correlation alignment (Sun et al., 2015), feature augmentation (Daumé III, 2009), subspace alignment (Fernando et al., 2013), transfer component analysis (Pan et al., 2011) and feature selection (Uguroglu and Carbonell, 2011) as implemented in ADAPT library (version 0.4.2, de Mathelin et al., 2023). Either, we get unreasonable fluxes, particularly in stable conditions, or the fluxes vary from one method to another, so it is hard to conclude the most suitable. The most sophisticated methods require the use of an encoder, which may be an ANN, with the laborious and time-consuming task of finding its appropriate configuration. Further investigations are then needed to find a suited unsupervised domain adaptation method, but that is beyond the scope of this paper.

At this stage, our proposed evaluation method does not yet include any transfer learning method. Under the traditional assumption that training and testing data come from the same distribution and input space (Aggarwal, 2014), the MLP-based statistical model is directly applied to simulation data. Nonetheless, to gain insight into performance loss, the relative contribution of each predictor to flux estimates is calculated using the SHapley Additive exPlanations (SHAP) algorithm (Lundberg and Lee, 2017). SHAP is attractive because it unifies several common methods for interpreting the approximation with ANN. It is based on the game theory approach; for an individual game (MLP outputs), contributions (called SHAP values) are assigned to each player (predictor). The average of the SHAP absolute value in several instances is then used to measure the predictor influence. The higher the corresponding SHAP value, the more the input variable contributes on average.

4 Assessing the data-driven statistical model

As mentioned previously, the MLP-based H and LE are the average over the outputs of 55 MLPs trained with the learning set. The key objective in machine learning is generalization, which means that the data-driven model should perform well under known and unknown conditions. This section discusses the performance of our statistical model on learning and test sets.

Figure 6. Half-hourly MLP-based estimates of observed sensible heat flux ($MLP_{OBS} H$, a and b), latent heat flux ($MLP_{OBS} LE$, c and d) and total turbulent heat flux ($MLP_{OBS} H + LE$, e and f) with observed input data against observed fluxes (OBS), for learning (a, c and e) and test (b, d and f) sets. The values at the top of each panel correspond to Root-Mean-Square Error (RMSE) and Pearson's correlation coefficient. The lines in red and orange represent the linear regression and identical fits, respectively. The axis labels are colored according to the schematic illustration in Figure 1 (right side).

Figure 6 compares half-hourly MLP-based fluxes (MLP_{OBS}) against their observed values (OBS), for learning and test sets (left and right panels, respectively). It shows H and LE (top and middle panels respectively) and the total turbulent heat flux $H + LE$ (bottom panels). Overall, the root-mean-square-errors (RMSE) range between $20 - 30 \text{ Wm}^{-2}$ and the Pearson's correlation coefficients (r) are greater than 0.95, indicating an excellent agreement between estimated and observed fluxes. Interestingly, $H + LE$ is particularly well approximated, despite not being a direct output of MLPs. Furthermore, the RMSE increases by less than 20% and the correlation is almost the same from learning to test data. Hence, under both known and unknown observed conditions, the statistical model performs similarly on average, demonstrating a fairly good generalization ability. Besides this good performance, some noticeable shortcomings appear in both the learning and test sets. On the one hand, $MLP_{OBS} H$ is bound to about -50 Wm^{-2} , while values below -100 Wm^{-2} are observed (Figure 6a and b). On the other hand, $MLP_{OBS} LE$ tends to underestimate observed LE above 200 Wm^{-2} (Figure 6c and d), especially for the test set. This indicates that the statistical model struggles to estimate large LE and negative H , which are associated with highly unstable and stable surface layer regimes, respectively.

Figure 7. Cumulative density functions (CDFs) of RES (eq. 2) calculated with half-hourly observed turbulent heat fluxes (OBS , in black) and competing MLP-based estimates (MLP_{OBS} in blue) for learning set (a) and test set (b) in Figure 6.

Figure 7 shows the cumulative distribution functions (CDFs) of RES (eq. 2) calculated with half-hourly observed $R_{net} - G$ together with OBS and MLP_{OBS} fluxes. For both learning and test sets (Figure 7 a and b resp.), CDFs of OBS and MLP_{OBS} are close but the MLP underestimates the strong (negative or positive) RES values. Although the sample size is different for these two sets, their CDF curves look quite similar, implying that they are individually representative of the main local

characteristics of energy imbalance. Closer inspection showed that the statistical model provides smoothed fluxes that preserve the striking relationship between $OBS\ H + LE$ and $R_{net} - G$ (not shown). This smoothing is the main cause of intermittent departures between the CDF curves. Overall, the CDFs are smaller than 0.15 for RES lower than 20 % indicating that both $OBS\ H + LE$ and $MLP_{OBS}\ H + LE$ are smaller than $R_{net} - G$ in the majority of cases. This tendency is systematic for large $H + LE$ (not shown). Thus, the statistical model carries the limitations of observed turbulent heat fluxes. The representativeness of turbulent heat fluxes measured at the permanent Météopole site on the coarser horizontal scale of numerical models is being examined as part of the MOSAI project (e.g. Jomé et al., 2023).

Figure 8 shows the composite seasonal cycles of OBS and MLP_{OBS} fluxes for the learning and test sets (left and right panels, respectively). The observed $H + LE$ presents similar seasonal cycles for both sets, with a peak from April to September (Figure 8c and f). However, observed H and LE do not typically present the same seasonal cycle. Indeed, from April to September, H (LE) is on average stronger (weaker) in the learning set than in the test one. In the learning set, LE predominates over H from March to June, with the reverse occurring from July to October (Figure 8a and b). Whereas in the test set, the predominance of H starts later in August, since LE slowly decreases from May to July (Figure 8d and e). The inter-annual variability presented in Figure A2 explains this disparity. Indeed, the year 2022 presents a seasonal cycle that differs from the one of other years, which different vegetation dynamics, driven by different atmospheric conditions, may explain. This highlights the importance of covering several annual cycles to well train the MLPs.

Overall, the MLP_{OBS} fluxes correctly reproduce the observed seasonal cycles along with day-to-day variability for both learning and test sets. This is particularly true for the total turbulent heat flux (Figure 8c and f). Interestingly, the relative predominance between H and LE is remarkably well replicated in the two sets. In the learning set, the absolute difference between estimated and observed fluxes remains smaller than $5\ \text{Wm}^{-2}$ for all the fluxes. However, in the test set, striking differences appear between May and September, when the total turbulent heat flux is at its maximum. Indeed, while the $MLP_{OBS}\ H + LE$ is quite similar to observations (Figure 8f), the $MLP_{OBS}\ H$ overestimates observations (Figure 8d), by more than $10\ \text{Wm}^{-2}$ in June and July, and, the $MLP_{OBS}\ LE$ underestimates observations, by more than $14\ \text{Wm}^{-2}$ from July to September (Figure 8e). This likely comes from the fact that the MLPs have learned respectively weaker LE and stronger H on average (Figures 8 and A2).

Figure 8. Composite monthly averages of observed and (*OBS* in black) and MLP-based (*MLP_{OBS}* in blue) sensible heat flux (H , a and d), latent heat flux (LE , b and e) and total turbulent heat flux ($H + LE$, c and f) for the learning and test sets (left and right panels, respectively). The solid lines represent the means and the error bars correspond to 10 and 90th percentiles, calculated by gathering the daily averages of half-hourly samples in Figure 6.

In conclusion, the statistical model, constructed with half-hourly observational data, provides highly consistent estimates of observed H and LE . It especially approximates quite well the total flux $H + LE$. The non-closure of SEB embedded in the observed fluxes is also reproduced, but lightly reduced for the strongest values. Its performance in terms of RMSE and linear correlation ranges within the best reported by the literature on surface parametrization schemes (e.g. Liu et al., 2013; Leufen and Schädler, 2019; Román-Cascón et al., 2021). In particular, the relative predominance between heating and evaporation is faithfully reproduced at the seasonal scale. The most fundamental local links between turbulent fluxes and environmental factors seem to be well captured by the data-driven model. However, it shows limitations with estimating large LE and negative H , and does not well generalize in the spring and summer months. Likely, the limited number of samples

435 in the learning set and/or the MLP input variables do not fully convey the strong inter-annual variability of turbulent heat fluxes.

Increasing the learning data at the expense of the test data does not noticeably improve the generalization ability of the statistical model (not shown). Moreover, uncertainties will always remain when the statistical model is applied to unseen data and cannot be assessed in the absence of corresponding observations, as is the case for numerical simulations. By
440 convention, 30-years of observational data is required for good climatological coverage, while around 10-years are currently available at the Météopole permanent site. The spring and summer seasons are usually characterized by intense vegetation activity. Moreover, the relationship between surface latent heat flux and soil moisture could be modulated by the state of the vegetation (e.g. Román-Cascón et al., 2020). However, the MLP input variables lack a key factor that could capture vegetation dynamics, such as the leaf area index (*LAI*). Adding such a parameter to the input variables would provide a more robust
445 description of the annual variability of surface turbulent heat fluxes. This is likely to enhance the generalization ability of the statistical model, especially during the spring and summer seasons.

5 Using the data-driven statistical model to evaluate simulated surface turbulent heat fluxes

The simulated surface turbulent heat fluxes from 01 January 2012 to 31 December 2016, by the RegIPSL model, are evaluated
450 in this section. The benefits of our proposed evaluation approach, compared to the traditional direct comparison between observed and simulated time series, are discussed.

For as much consistency as possible with the archived simulation data, 3- hour 'adapted' observational data (*OBS'*, 15739 samples in total from November 2012 to December 2022) were derived from half-hour observations (see Table 1). Indeed,
455 *SWC*, *H*, *LE* and the four radiative fluxes were time-centered averaged on a 3 –hr window, to get the same timestamps. The timestamp is excluded when more than half of the expected half-hour data (e.g., 3 out of 6) are missing. Half-hour data at these timestamps are used directly when available for the other variables (*T*, *RH*, *SP*, *u*, and *v*). If not available, *T*, *RH*, and *SP* values are obtained through linear interpolation, while *u* and *v* are taken from the nearest half-hour. First, the sensitivity of the data-driven model's performance to changes in temporal resolution and the effects of simulated data extending beyond the
460 learning range is assessed. Then, the data-driven model is applied to evaluate the simulated heat fluxes over the common period.

5.1 Impact of temporal resolution and extrapolation on flux estimates using the data-driven model

Table 3 shows the RMSE, r, and linear regression coefficients (slope and intercept) obtained when all MLP_{OBS} H and LE from November 2012 to December 2022 are compared with their target values, for both the adapted 3 hour OBS' and the
465 half-hour OBS from which OBS' was derived. Figure 9 shows their composite diurnal cycles, for the sub-periods during which the fluxes are weaker (November, December, January, and February), stronger with a predominance of LE (March, April, May, and June) and stronger with a predominance of H (July, August, September, and October). RMSE of $MLP_{OBS'}$ improves by 4 Wm^{-2} data, and the other parameters in Table 3 remain the same, between OBS and OBS' datasets. The composite diurnal cycles of the observed fluxes and the MLP-based estimates for both temporal resolutions align closely with
470 each other. This indicates that the mismatches between half-hour and coarser 3-hour time resolutions do not significantly affect the performance of the statistical model.

Table 3. Comparison of Root-Mean-Square-Error, linear correlation and the linear regression fitting coefficients (slope and intercept) when applying the MPL-based statistical model to half-hour raw and to 3-hour average observational data. The statistical model has been constructed using the half-hour sampling of the learning set (Figure 2a).

		H	LE
RMSE (Wm^{-2})	half-hour	22.1	20.5
	3-hour	17.8	16.6
Correlation	half-hour	0.97	0.96
	3-hour	0.97	0.97
Slope	half-hour	0.95	0.91
	3-hour	0.97	0.93
Intercept	half-hour	2.98	2.98
	3-hour	1.71	1.68

Figure 10 presents averages of SHAP absolute value for each input variable across the trained MLPs, for the MPL-based H
475 and LE for learning and test sets (in Figure 6) and simulated environments at Grd1 and Grd2. The variables are ranked on the y -axis in descending order according to their values at Grd1, the nearest geographical grid cell. Note that, SHAP value increases with the variable relative contribution of the input variable. Thus, this figure allows for discussion of performance loss due to extrapolation, e.g., when the input data extends beyond the learning interval.

Figure 9. Composite diurnal cycles of half-hour and 3-hour observed heat fluxes (OBS and OBS' in black) and their competing MLP-based estimates (MLP_{OBS} and $MLP_{OBS'}$ respectively, in blue), for H (top panels) and LE (bottom panels), by splitting the annual cycle into 3 typical sub-periods (see the text for more details). They are calculated based on diurnal cycles where at least 6 out of 8 expected OBS' are available (approximately 85% of all selected diurnal cycles).

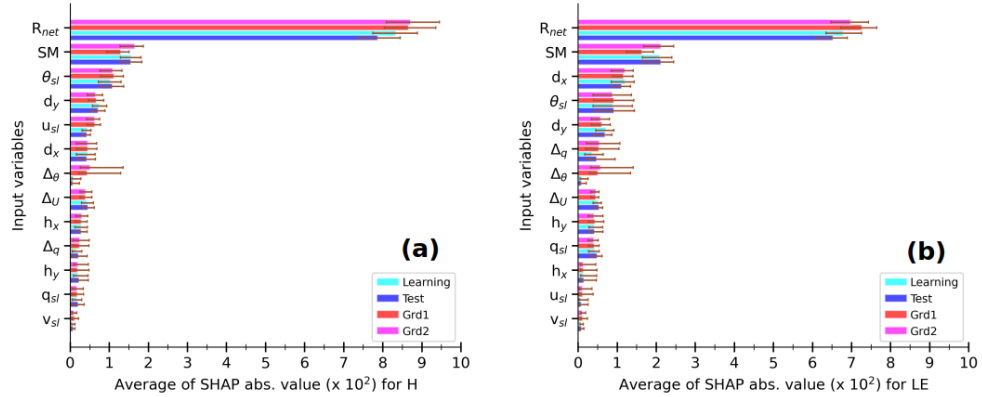

Figure 10. Averages of SHAP absolute value for each input variable in MLP-based estimates of H (a) and LE (b) within the simulated environment at Grd1 and Grd2, and the observed environment of learning and test sets, according to the caption. For a given MLP, the SHAP absolute values are calculated for each estimate and then averaged over the samples of each data set. The colored bars indicate the median values, and the error bars correspond to the minimum and maximum values across the 55 trained MLPs that compose the statistical model. In each panel, the input variables are ranked in descending order under the simulated environment at Grd1.

Regardless of the environment, R_{net} is by far the most contributing variable, followed by SM and θ_{sl} for both H and LE estimates. Thus, the trained MLPs composing the statistical model clearly understood that the net radiative budget at the surface is the primary driver of turbulent heat fluxes and that the soil wetness is a crucial factor for the partitioning

between heating and evaporation. This probably explains the better agreement between observed and MLP_{OBS} at coarser
485 time-scales, seasonal and 3-hr, since the noise in the observational data is reduced. The importance of the other variables
varies with the environment, the grid cells and the fluxes. Notably, Δ_θ is one of the least influential variables under observed
conditions, unlike in the simulated environment. This demonstrates that the statistical model takes into consideration changing
environmental contexts. Overall, the aggregated contribution of the three physical variables (Δ_θ , u_{sl} and v_{sl}) whose simulated
values spread beyond the learning interval is overall smaller than 20 % of the aggregated contribution of R_{net} , SM and θ_{sl} .
490 Therefore, we hypothesize a modest loss of performance due to extrapolation when the statistical model is directly applied to
data from the RegIPSL model.

5.2 Evaluating the simulated heat fluxes using the data-driven model

Remember that MLP-based fluxes are approximations of observed fluxes in a given environmental forcing (see section 4).
495 When applied to simulation, they correspond to the fluxes that would have been measured if the simulated conditions were
effectively observed. In the following, OBS' data (e.g., 3-hour time-centered averages) are used as observed conditions. They
are referred to as OBS for simplicity.

The scatter plots in Figure 11 illustrate the consistency of the MLP-based fluxes in the simulated environment. They also
500 highlight errors resulting from disparities in observed and simulated environmental forcing. It compares 3-hourly MLP-based
fluxes with environmental conditions at Grd1 (MLP_{Grd1}) against the corresponding 3-hour fluxes (OBS left panels) and
MLP-based fluxes in observed conditions (MLP_{OBS} , right panels). It only includes the timestamps between 24 November
2012 to 31 December 2016 for which both simulated and corresponding OBS are available, accounting for around 50 % of the
whole simulation data. In each panel, the flux varies within the same interval range, between -50 and 400 Wm^{-2} for H and
505 LE , and between -50 and 500 Wm^{-2} for $H + LE$. Moreover, the correlation coefficient is greater or equal to 0.9, indicating
that the variability in MLP_{Grd1} fluxes is consistent with OBS and MLP_{OBS} . These findings also hold for the second grid cell
(Figure A3). Hence, the disparities between simulated and observed fluxes mostly lie in their magnitudes. Since the difference
is much more pronounced for large fluxes, the divergence would occur mainly during daylight hours. The MLP_{Grd1} H and
 $H + LE$ are stronger than observed. The same tendency has been found when comparing simulated R_{net} to observation (not
510 shown).

Figure 11. Comparison of 3-hour MLP-based fluxes in the simulated environment at Grd1 (MLP_{Grd1}) against 3-hour observations (OBS , left panels) and MLP-based fluxes in the associated environment (MLP_{OBS} , right panels) at Météopole site, for H (a, b), LE (c, d) and $H + LE$ (e, f). The data includes only 3-hour timestamps between 24 November 2012 and 31 December 2016, for which both simulation and observational data are available. The values at the top of each panel correspond to the number of samples (N), Root-Mean-Square-Error ($RMSE$) and Pearson's correlation coefficient (r). The lines in red and orange represent the linear regression and identical fits, respectively. The axis labels are coloured according to the schematic illustration in Figure 1.

Figure 12 compares 3-hour simulated heat fluxes at Grd1 (SIM_{Grd1}) to OBS and MLP_{Grd1} (left and right panels, respectively) at the same timestamps as in Figure 11. The scatter is considerably reduced with a better alignment along the linear regression fit when the MLP_{Grd1} are used as the reference values instead of OBS . These changes agree well with a reduction of uncertainties, particularly those related to the disparities in environmental conditions. The non-closure of SEB for MLP-based fluxes may (Figure 7) explain the imperfect fit between $SIM_{Grd1} H + LE$ and corresponding MLP_{Grd1} . This suggests that substantial uncertainties remain. Nonetheless, comparing with MLP_{Grd1} better highlights the shortcomings of the surface scheme than a direct comparison with OBS , as the bias in R_{net} is frozen. According to the MLP_{Grd1} , the surface scheme tends to quasi-systematically underestimate large H (Figure 12a and b). This tendency is more pronounced for Grd2 (Figure A4), which comprises a smaller fraction of bare soil and a larger cropland fraction, which enhances evaporation. Whereas, the simulated environment promotes overestimating large observed H (Figures 11 and A3, a and b), mostly due to higher R_{net} and weaker SM . Thus, by using the statistical model, we can detect that the R_{net} overestimation compensates and hides an underestimation of H in RegIPSL. This underestimation can be due may be due to i) incorrect surface land use (with crop instead of grass and bare soil instead of urban area) and ii) inadequate formulations of fluxes.

Additionally, SIM_{Grd1} and SIM_{Grd2} differ very slightly. As a result, the direct comparison with observations leads to nearly similar RMSE and correlation. Meanwhile, using MLP-based fluxes shows a larger departure for Grd2, since its landscape induces slightly drier soil on average (Figure A1i). Thus, formulations of H and LE in ORCHIDEE appear to lack sensitivity to soil wetness.

Another key advantage of our method is that data on any simulation timestamps can be used for comparison, since the availability of observations at the same timestamps is no longer necessary. The statistical significance of the results is thus enhanced. Overall, including all the timestamps between 01 January 2012 and 31 December 2016 in the comparison does not change a lot the previous finding that the surface scheme struggles with large H (Figure A5).

The seasonal cycles of SIM_{Grd1} and SIM_{Grd2} , OBS , MPL_{OBS} and $MLP-MPL_{Grd1}$ and MPL_{Grd2} for H , LE and $H + LE$ in Figure 13 show the following:

- Simulated fluxes during the spring and summer seasons (from April to August) are the most tricky to evaluate because of significant differences in environmental forcing between simulation and observations. The direct comparison between

Figure 12. Comparison of 3-hour simulated fluxes at Grd1 (SIM_{Grd1}) with observed at the Météopole site (OBS , left panels) and MLP-based estimates in simulated environment (MLP_{Grd1} , right panels) for H (a and b), LE (c and d) and $H+LE$ (e and f). The data correspond to the same timestamps as in Figure 11. The values at the top of each panel correspond to the number of instances (N), Root-Mean-Square-Error ($RMSE$) and Pearson's correlation coefficient (r). The lines in red and orange represent the linear and ideal fits, respectively. The axis labels are colored according to the schematic illustration in Figure 1.

simulation and observations is mainly hampered by the systematic bias in simulated R_{net} (Figure A6). This overestimation of R_{net} is no doubt due to more short-wave radiation reaching the surface caused by a lack of low clouds in numerical simulation, as found in several modelling studies over mid-latitude (e.g. Cheruy et al., 2014; Bastin et al., 2018; Chakroun et al., 2018). Moreover, comparing SIM_{Grd} fluxes against MLP_{Grd} seems to mitigate the effect of the SEB non-closure in observations. Indeed, the data-driven model tends to underestimate strong values of RES (section 4, Figure 2). Hence, if its effect was so strong the $MLP_{Grd} H + LE$ would have been much weaker than the $SIM_{Grd} H + LE$, which is not necessarily the case (Figure 13).

- Strikingly, the partitioning between H and LE in June, July, and August differs between SIM_{Grd} and MLP_{Grd} . The fraction of grid cell effectively occupied by vegetation (crops and grass) is at its maximum during the summer months. Hence, the larger R_{net} in the simulation mainly leads to higher simulated LE than observed. Whereas, this stronger energy is converted into higher H and weaker LE by the statistical model to mimic what it has learned from observations. This is somewhat consistent with the fact that urban surfaces are not represented in ORCHIDEE and are replaced by bare soil, which evaporates more than impervious surfaces.
- As mentioned above, the simulated heat fluxes are not very sensitive to soil wetness, whilst the MLP-based estimates are. Hence, the two grid cells show important differences for the MLP-based fluxes while not for the simulated fluxes. On average, the soil at Grid2 is drier between May and September (Figure A7), which explains the relatively higher $MLP_{Grd2} H$ and lower $MLP_{Grd2} LE$ during this period, compared with MLP_{Grd1} fluxes. The same results are found when all the diurnal cycles of the model sample data are considered (Figure A8). This deficiency opens an avenue for improvements in ORCHIDEE.

There is clear evidence that the simulated H and LE are highly biased from late spring to late summer. This is undoubtedly due to an inappropriate representation of land cover and inaccurate weather conditions. Our statistical model also shows low generalization ability during this period (Figure 8), illustrating the challenge of using environmental variables to parameterize surface turbulent heat fluxes that include contributions from heterogeneous patches. However, using the statistical model shows consistent differences between the two grid cells, which are not as evident when using observations. The MLPs were trained on observed fluxes involving contribution from urban land use types, whereas urban areas were replaced by bare soil in the version of ORCHIDEE used in the RegIPSL model. Yet, bare soil heats the atmosphere less than impervious surfaces such

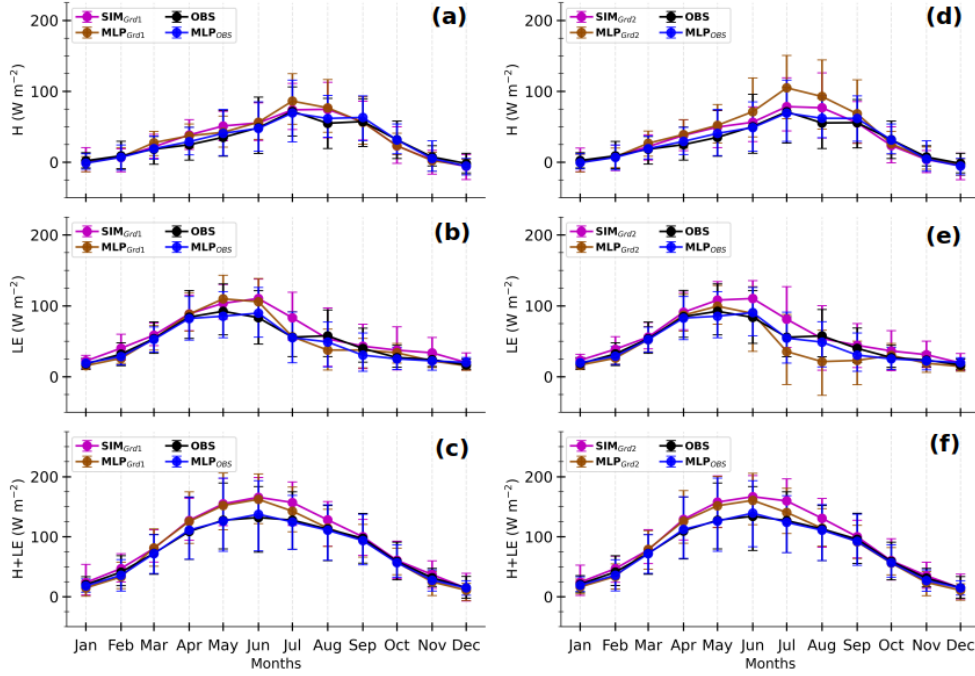

Figure 13. Composite monthly averages of heat fluxes simulated at Grd1 and Grd2 (SIM_{Grd1} and SIM_{Grd2} in left and right panels respectively), MLP-based estimates for their respective environments (MLP_{Grd1} and MLP_{Grd2}), observed at the Météopole site (OBS) and MLP-based estimates in the observed environment (MLP_{OBS}) for H (a and d), LE (b and e) and $H + LE$ (c and f). The curve colours are according to the schematic illustration in Figure 1. The solid lines correspond to the means and the error bars represent 10 and 90th percentiles, calculated by gathering daily averages using 3-hour data. Only, the timestamps between 01 December 2012 and 31 December 2016, for which both simulation and observational data are available, have been considered. The days involving less than 6 timestamps were excluded.

as urban areas. This likely explains why the surface scheme tends to underestimate large H and, conversely, overestimate the associated LE when evaluated in the simulated environment using the data-driven model. Since bare soil typically evaporates less than vegetated areas, the errors are relatively smaller for the nearest grid cell, likely due to its higher proportion of bare soil. This limitation in the land surface scheme likely contributes to a misrepresentation of the intense convective heating of the atmosphere by the surface during the summer. Efforts are ongoing to improve the representation of urban areas in ORCHIDEE (e.g., Lalonde et al., 2024).

6 Conclusions

The representation of surface processes, especially the formulation of surface turbulent heat fluxes H and LE is the second most important source of biases in the numerical weather and climate simulations. However, it is very challenging to unambiguously quantify this error with the existing evaluation methods. In the framework of the MOSAI project (Lohou

et al., 2022), this study proposes a different evaluation approach when a long period of comprehensive observational data is available. Based on the observations, a data-driven statistical model is first developed to approximate observed H and LE with
580 near-surface environmental factors as inputs. The data-driven model is then applied to the simulated environment to generate possibly observed fluxes under this environment. By comparing the simulated fluxes against their statistically-based estimates, the evaluation is performed in the environment as seen by the numerical model.

A demonstration study was carried out with about 10 consecutive years of observational data acquired at one of the permanent
585 French instrumented sites of the ACTRIS-FR research network. The data-driven model is a collection of several multi-layer perceptrons, trained on the data of the 5 most covered years after cleaning. Thirteen variables characterizing the environmental forcing in the surface layer are used as inputs to simultaneously provide estimates of observed H and LE . The analysis of variables contribution showed that the estimates are largely based on three classical physical parameters, namely the surface net radiative flux, the mean potential temperature of the surface layer and the wetness of underlying soil. This opens
590 the possibility to reduce the number of input parameters. Overall, the statistically-based fluxes under observed conditions are rather consistent with the observed fluxes for known and unknown cases by the MLPs. Similar to the observed fluxes, the estimated fluxes do not close the Surface-Energy-Budget, but reduce its impact. Nevertheless, it does not correctly approximate negative H and tends to underestimate large LE . Moreover, its ability to generalize is altered from spring to late summer, likely because the leading input parameters do not fully describe the strong inter-annual variability in this period.
595 This limitation can probably be overcome by adding a typical vegetation parameter (e.g. LAI) to the inputs.

The data-driven model was subsequently applied to a regional climate simulation performed with the RegIPSL model to freeze the uncertainties which may come from the inaccuracy of simulated environmental forcing. The simulation data were extracted at the two nearest grid cells to the station. The comparison between simulated and observed fluxes gives the error resulting
600 from the compensation between the components of the numerical model. The noticeable difference is found from late spring to late summer, in agreement with the previous studies. Overall, both simulated H and LE are stronger than observed, in consistency with stronger net radiative flux. The comparison of simulated and statistically-based heat fluxes in the simulated environment revealed that the numerical formulation of fluxes combined with the inconsistency of surface characteristics in the grid cells mainly cause an underestimation of large H and an overestimation of associated LE , which were hidden by the
605 overestimation of R_{net} . Moreover, the partitioning between heating and evaporation is not properly sensitive to soil moisture.

By circumventing the challenge of comparing the turbulent heat fluxes from different environments, our evaluation method offers promising perspectives for adequate evaluation of the surface parametrization schemes. The ACTRIS-FR network offers the possibility of applying this methodology to other supersites where the variables required for this analysis have been also
610 measured for several years, allowing investigation in different types of surfaces and climates. The ReOBS approach (Chiriaco et al., 2018) has been applied to these long-term colocated multi-variables datasets, which eases their use for different applications.

At this early stage, our proposed approach firstly focused on discrepancies in environmental forcing between simulation and
615 observation. However, the non-closure of SEB and the representativeness of in-situ measurements at the horizontal resolution of the numerical models are also key sources of uncertainties. Hence, our evaluation method should be further refined to address these two challenges, ensuring a better agreement with the simplifying assumptions used in the numerical models. Thanks to the MOSAI project, the Toulouse region benefited from a one-year enhanced observation period, which would allow a more detailed regional-scale characterization of the representativeness of the fluxes measured at the Météopole permanent
620 station (Jomé et al., 2023). For instance, the input variables for the data-driven model could incorporate a description of land use composition. In addition, this model may learn to estimate observed fluxes that verify the closure of SEB (e.g., Hu et al., 2021), usually applied in numerical models. There is also a need to include a transfer learning strategy to prevent the possible deterioration of performance when the data-driven model is applied to situations with the leading input variables ranging out of its known domain. Besides, this novel approach could be used to evaluate community numerical simulations like reanalysis
625 and to revisit intercomparison of land-surface schemes.

Data availability. The data from the Météopole are freely available on AERIS platform (<https://www.aeris-data.fr/>). The source for RegIPSL data is indicated in the acknowledgements.

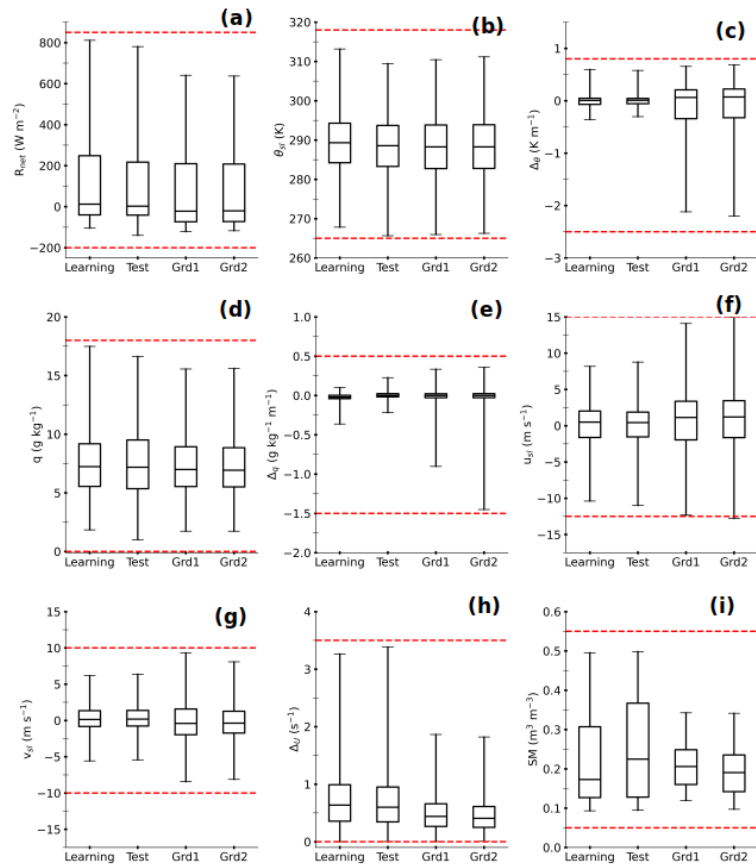

Figure A1. Box plots summarizing the interval ranges of the nine physical variables used as input to our MLP-based statistic model (Table 2). The corresponding data sets are indicated on the x -axis. The whiskers represent the minimum and maximum values of each data set. The horizontal dashed red lines indicate the extreme values used for scaling.

Figure A2. Composite monthly averages of observed sensible heat flux (H , a), latent heat flux (LE , b) and total turbulent heat flux ($H + LE$, c) for each year included in the observational data, calculated from the daily averages of half-hourly samples. The years of learning and test sets are in solid and dashed lines, respectively. The thick lines correspond to the means on each subset, and the error represents the 10 and 90th percentiles.

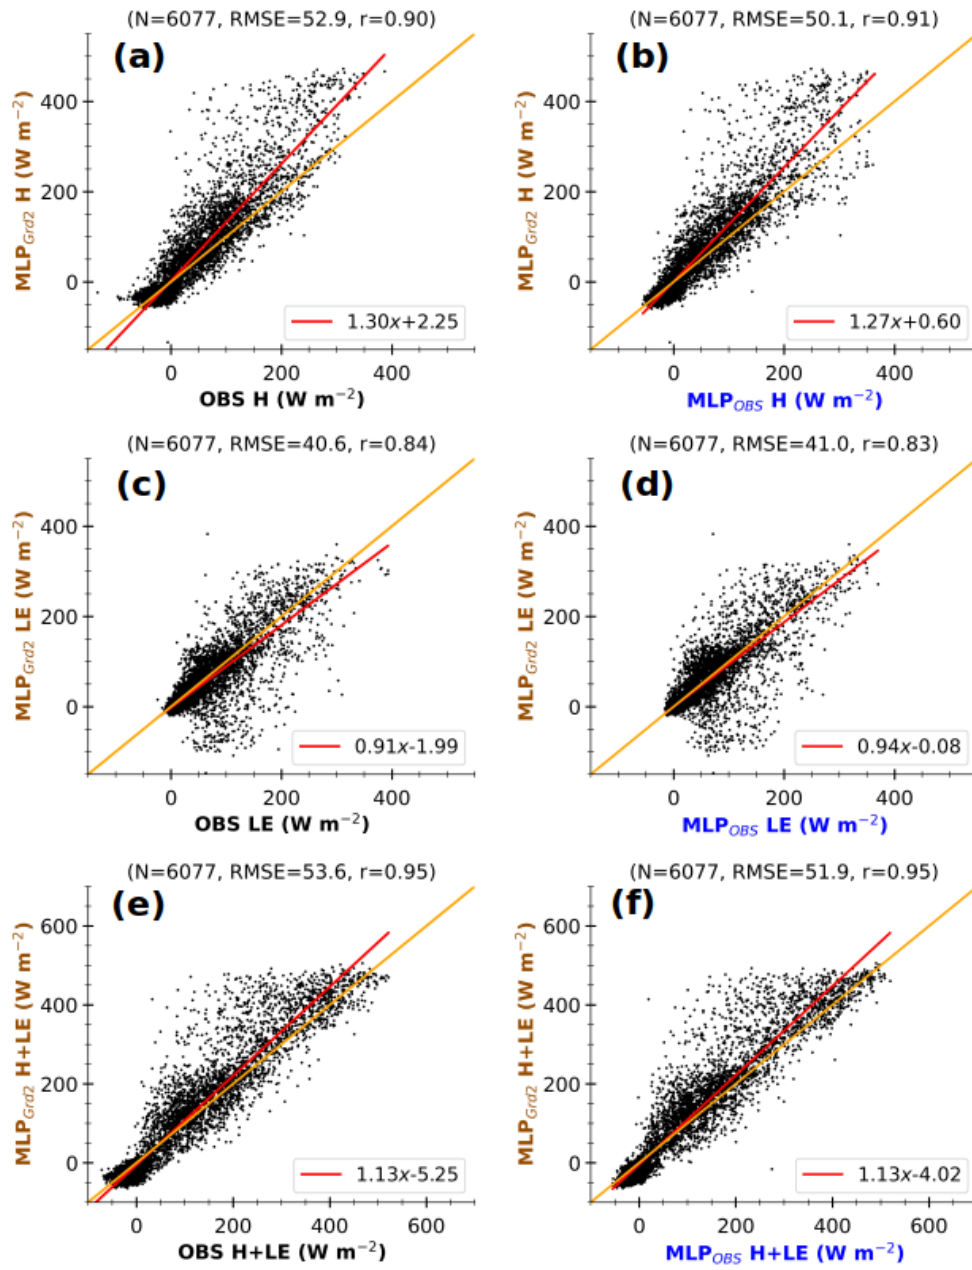

Figure A3. Same as in Figure 11 but for Grd2.

Figure A4. Same as in Figure 12 but for Grd2.

Figure A5. 3-hour simulated sensible heat flux (H , a and d), latent heat flux (LE , b and e) and total turbulent heat flux ($H + LE$, c and f) at Grd1 (left panels) and Grd2 (right panels) against corresponding MLP-based estimates in simulated environment. All the selected timestamps from 01 January 2012 to 31 December 2016 are considered here. The values at the top of each panel correspond to the number of samples (N), Root-Mean-Square-Error ($RMSE$) and Pearson's correlation coefficient (r). The lines in red and orange represent the linear and ideal fits, respectively. The axis labels are colored according to the schematic illustration in Figure 1.

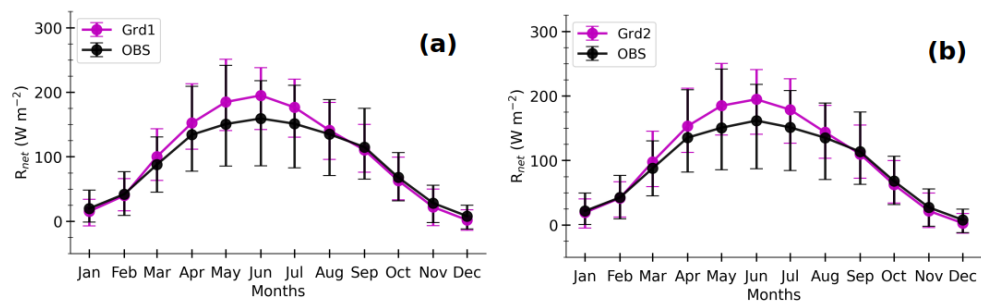

Figure A6. Composites monthly averages of simulated surface net radiative flux (R_{net} , magenta lines) at Grd1 (a) and Grd2 (b) and that of their respective observations at Météopole (black lines). They are computed as in Figure 13.

635

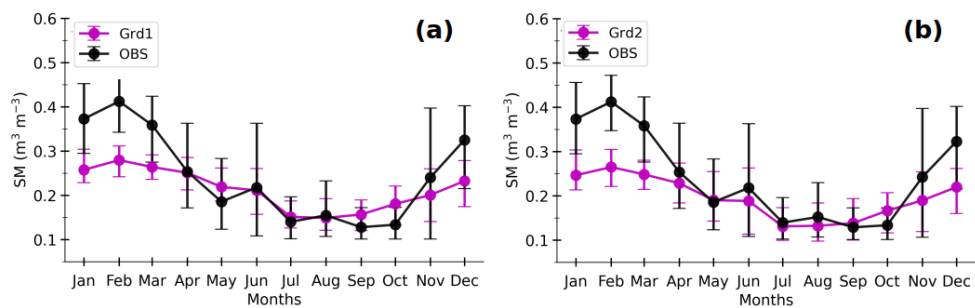

Figure A7. Same as in Figure A6 but for soil wetness (SM).

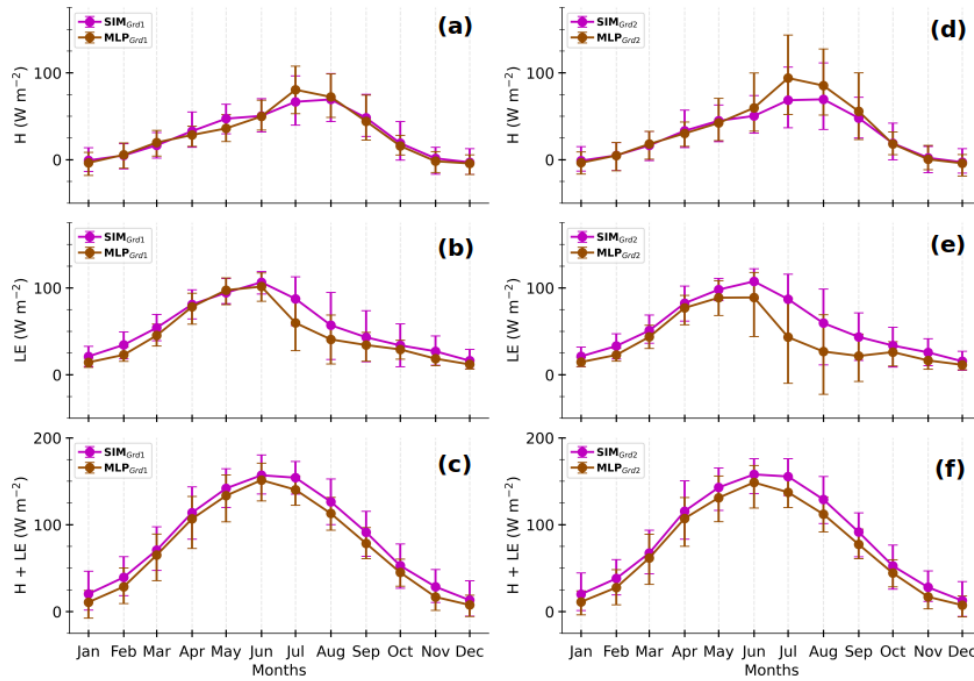

Figure A8. Composites monthly averages of simulated H (a and d), LE (b and e) and $H + LE$ (c and f) at Grd1 and Grd2 (SIM_{Grd1} and SIM_{Grd2}, lines in magenta) together with that of MLP-based estimates under simulated environment (MLP_{Grd1} and MLP_{Grd2} lines in brown). The solid lines correspond to the means and the error bars represent the 10 and 90th percentiles, calculated by gathering the daily averages of 3-hourly data. All the selected diurnal cycles from 01 January 2012 to 31 December 2016 are considered here.

Author contributions. MZ, SB and MC elaborated the methodology with contributions from CM and LB. GC and SB provided the observational and climate simulation data respectively. MZ processed the data and prepared the paper with contributions from all the co-authors.

640 *Competing interests.* The authors declare that they have no conflict of interest.

Acknowledgements. The MOSAI (Model and Observation for Surface-Atmosphere Interactions) project was founded by the French Agence Nationale de la Recherche (ANR) under grant agreement no. 216875. The RegIPSL simulation was granted access to the HPC resources of

IDRIS under the allocation 2019-0227 attributed by GENCI (Grand Équipement National de Calcul Intensif). Thanks to ESPRI-IPSL and LATMOS IT department for access to the computational and storage infrastructures.
