**Abstract.** Fertilised soils are a significant source of nitrous oxide (N<sub>2</sub>O), a highly active greenhouse gas and stratospheric ozone depleter. Nitrogen (N) fertilisers, while boosting crop yield, also lead to N<sub>2</sub>O emissions into the atmosphere, impacting global warming. We investigated relationships between mineral N fertilisation rates and additional manure amendment with different crop types through the analysis of abundances of N cycle functional genes, soil N<sub>2</sub>O and N<sub>2</sub> emissions, nitrogen use efficiency (NUE), soil physicochemical analysis and biomass production. Our study indicates that N<sub>2</sub>O emissions are predominantly dependent on the mineral N fertilisation rate and enhance with increased mineral N fertilisation rate. Crop type also has a significant impact on soil N<sub>2</sub>O emissions. Higher N<sub>2</sub>O emissions were attained with the application of manure in comparison to mineral fertilisation. Manure amendment also increased the number of N cycle genes that are significant in the variations of N<sub>2</sub>O. The study indicated that N<sub>2</sub>O emissions were mainly related to nitrification in the soil. Quantification of nitrogen cycle functional genes also showed the potential role of denitrification, comammox and DNRA processes as a source of N<sub>2</sub>O. Our study did not find soil moisture to be significantly linked to N<sub>2</sub>O emissions. Results of the study provide evidence that for wheat, a fertilisation rate of 80 kg N ha<sup>-1</sup> is closest to the optimal rate for balancing biomass yield, N<sub>2</sub>O emissions, and achieving high NUE. Sorghum showed a good potential for cultivation in temperate climate, as it showed similar biomass yield compared to the other crop types and fertilisation rates, but maintained low N<sub>2</sub>O emissions and N losses on mineral N fertilisation rate of 80 kg N ha<sup>-1</sup>.

## 1 Introduction

The rising demand for agricultural commodities and the management of agroecosystems are important factors contributing to global environmental problems. Increasing crop yield while reducing pollution from agricultural production is crucial (Abdalla *et al.*, 2019; Tilman *et al.*, 2011). Global food demand projections suggest a 50% increase in agricultural production by 2050 (compared to 2012) to feed the fast-growing human population (FAO, 2017). Enhancing agricultural production involves actions such as expanding agricultural land, applying more fertilisers, and using water resources and fertilisers more effectively

(Tian *et al.*, 2021). In today's agricultural practises, the applied N with fertilisation is often excessive for plant needs (Robertson and Vitousek *et al.*, 2009; Zhou *et al.*, 2016). About half of the applied N to the fields is not taken up by crops (Coskun *et al.*, 35 2017); which may lead to N loss in the surrounding environment. Main soil N loss mechanisms include denitrification, ammonia oxidation, N leaching, erosion of soil and ammonia (NH<sub>3</sub>) volatilisation (Thomson *et al.*, 2012). This results in adverse ecological impacts, such as eutrophication of aquatic ecosystems and increased gaseous emissions of N into the atmosphere (Cameron *et al.*, 2013; Liu *et al.*, 2017; Whetton *et al.*, 2022).

Fertilised soils are a significant source of nitrous oxide (N<sub>2</sub>O), contributing to the greenhouse effect and ozone depletion 40 (Ravishankara *et al.*, 2009; Shcherbak *et al.*, 2014). N<sub>2</sub>O has 273 times higher global warming potential than carbon dioxide (CO<sub>2</sub>) over a 100-year timescale (IPCC, 2021). Even without adding N fertiliser in the current season or year, background N<sub>2</sub>O emissions (BNEs) may still occur. BNEs are caused by different N sources, including residual N in the soil from previous years' N application, deposition from the atmosphere, biological N<sub>2</sub> fixation and mineralised N from plant residues (Gu *et al.*, 2007; Kim *et al.*, 2013, Abdalla *et al.*, 2022).

The key microbial processes leading to soil N loss are nitrification and denitrification (Thomson *et al.*, 2012). In agriculture, N fertilisers added to the soil can be lost due to these processes (Saud *et al.*, 2022). Nitrification was traditionally viewed as a two-step process carried out by separate functional groups of microorganisms, oxidising ammonium (NH<sub>4</sub><sup>+</sup>) sequentially to nitrite (NO<sub>2</sub><sup>-</sup>) and nitrate (NO<sub>3</sub><sup>-</sup>) under aerobic conditions (Kuypers *et al.*, 2018; Koch *et al.*, 2019; Nardi *et al.*, 2020). However, in 2015, a significant advancement in our understanding of nitrification occurred with the discovery that a single 50 microorganism, through the comammox (complete ammonia oxidation) process, can perform both nitrification steps (Daims *et al.*, 2015; Van Kessel *et al.*, 2015). Nitrification can reduce N availability for plant uptake by up to 50%, primarily due to NO<sub>3</sub><sup>-</sup> leaching and N<sub>2</sub>O emissions (Beeckman *et al.*, 2018). Synthetic fertilizers containing NH<sub>3</sub> offer an immediate substrate for ammonia oxidizers, thus accelerating the nitrification process (Ayiti & Babalola, 2022). Also, fertilizers that raise soil pH can significantly enhance the nitrification rate, as increasing soil pH from 4.8 to 6.7 can boost nitrification rates by 30 times 55 (DeForest & Otuya, 2020).

Denitrification is a microbially-catalysed process under oxygen-limited condition responsible for transforming NO<sub>3</sub><sup>-</sup> sequentially to gaseous forms of N: nitric oxide, N<sub>2</sub>O and atmospheric N (Philippot *et al.*, 2007; Zaman *et al.*, 2012). The input of N fertilisers affects the soil's mineral N pool by providing larger amounts of available N for nitrification and denitrification processes, contributing to N<sub>2</sub>O emissions (Engel *et al.*, 2010). Dissimilatory nitrate reduction to ammonium (DNRA) supplies 60 NH<sub>4</sub><sup>+</sup> to the soil, conserves bioavailable N and prevents the leaching of NO<sub>3</sub><sup>-</sup> (Bai *et al.*, 2020; Pandey *et al.*, 2020). DNRA competes with denitrification in NO<sub>3</sub><sup>-</sup>-reducing processes (Putz *et al.*, 2018). Similarly to denitrification and nitrification processes, DNRA can also be a source of N<sub>2</sub>O, although the quantities are modest (Rütting *et al.*, 2011; Stremińska *et al.*, 2012; Zaman *et al.*, 2012). Carbon to nitrogen ratio (C/N) and C/NO<sub>3</sub><sup>-</sup> are recognised as the main environmental factors controlling, which nitrate-reducing process is favoured as DNRA and denitrifying microbes compete for NO<sub>3</sub><sup>-</sup> and carbon 65 sources (Bai *et al.*, 2020). DNRA is dominant in the presence of a high C/N ratio and low NO<sub>3</sub><sup>-</sup> availability, while the denitrification process favours a low ratio of C/N and C/NO<sub>3</sub><sup>-</sup> (Bai *et al.*, 2020; Pandey *et al.*, 2020). These processes are

mediated by different functional marker genes, including archaeal, bacterial and comammox *amoA* genes for nitrification, *nrfA* genes for DNRA and *nosZ* clade I and II, *nirK*, *nirS* genes for denitrification (Zaman *et al.*, 2012; Hu *et al.*, 2015; Zhang *et al.*, 2021).

70 C3 photosynthesis, a dominant pathway among plants and found in wheat and barley, uses the Calvin-Benson pathway, while an alternative, the Hatch-Slack pathway, is used by C4 plants like sorghum and maize (Hibberd and Quick, 2002; Ehleringer and Cerling, 2002; Ehleringer, 1979; Ledvinka, 2022). In C3 plants, water loss through transpiration during CO<sub>2</sub> uptake is a risk in hot and water-limited conditions (Joshi *et al.*, 2022; Stevens *et al.*, 2022). However, C4 plants, with higher water use efficiency and greater tolerance to hot and dry environments, make the cultivation of sorghum and other drought-tolerant plants  
75 likely to expand in regions affected by droughts (Anderson *et al.*, 2020). Due to climate change, sorghum, as a resilient plant, is considered a novel crop for temperate Europe (Schaffasz *et al.*, 2019). Only a limited number of studies have compared N<sub>2</sub>O emissions between different crop species. Abdalla *et al.* (2022) found that crop type has significant effect ( $p < 0.05$ ) on the BNE values from soil. Furthermore, Bouwman *et al.* (2002) also found that crop type has a significant influence on N<sub>2</sub>O emissions. However, study including 372 sites showed that cover crops did not have significant ( $p > 0.05$ ) effect on direct N<sub>2</sub>O emissions  
80 (Abdalla *et al.*, 2019).

Previous studies on long-term fertilisation experiments have mostly focused on fertilisation's yield effects and changes in soil organic matter (Cvetkov and Tajnšek, *et al.*, 2009; Hijbeek *et al.*, 2017; Káš *et al.*, 2010; Spiegel *et al.*, 2010; Tajnšek *et al.*, 2013). Improved management of arable soils holds significant potential for mitigating greenhouse gas emissions, as agroecosystems contribute ca 66% of total anthropogenic N<sub>2</sub>O emissions (Davidson and Kanter, 2014; Paustian *et al.*, 2016; Shen *et al.*, 2021). Efficient mitigation of N loss requires a comprehensive understanding of microbial processes related to  
85 N<sub>2</sub>O emissions in agricultural soils (Davidson and Kanter, 2014; Shen *et al.*, 2021).

The general objectives of the study were to evaluate temporal patterns of gaseous N loss, link N-cycle processes with abundances of functional N cycle genes in arable soil, and evaluate the performance of different crops (including novel crop in Northern Europe) in terms of biomass production and N<sub>2</sub>O emissions under mineral and organic fertilisation. The following  
90 hypotheses were tested: (1) crop type significantly affects N<sub>2</sub>O emissions; (2) nitrification is the primary pathway of soil N<sub>2</sub>O production due to aerobic conditions; (3) in arable soil, low soil moisture results in reduced N<sub>2</sub>O losses; (4) amendment of manure fertiliser increases soil N<sub>2</sub>O emissions and affects the abundances of functional N cycle genes.

## 2 Material and methods

### 2.1 Field experiment description

95 The field study was conducted on the International Organic Nitrogen Long-term Fertilisation Experiment (IOSDV; Internationaler Organischer Stickstoff Dauerdüngungs Versuch) experimental field. The experimental site is located near Tartu, southern Estonia, Northern Europe (58°22'30" N, 26°39'48" E). The experiment was set up as a three-field crop rotation

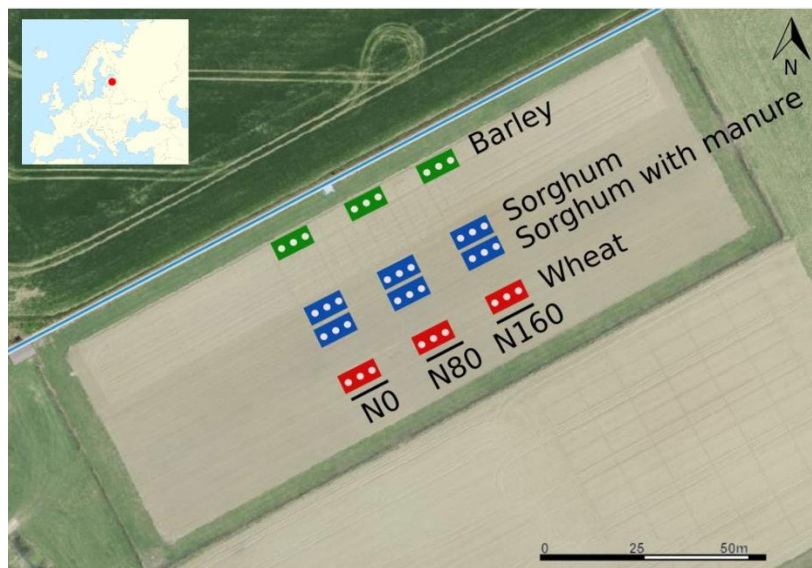

experiment in 1989 to investigate the long-term effects of mineral and organic fertilisation on crop responses of various crops and soil properties.

100 In 2022, the average temperature in the area was  $-2.0$  °C in winter,  $4.6$  °C in spring,  $18.1$  °C in summer and  $7.2$  °C in autumn. The mean annual precipitation was  $531$  mm (Republic of Estonia Environment Agency, 2023) in 2022. A climate diagram for the area during the study period is in Figure S1 in the Supplementary materials.

The soil type is *Stagnic Luvisol* combined with *Fragic Glossic Retisol* (IUSS WG WRB 2015). The thickness of the humus layer is  $27$ - $32$  cm. Soil texture by FAO classification is sandy loam:  $57.86\%$  sand ( $>0.063$  mm),  $33.58\%$  silt ( $0.063$ – $0.002$  mm) and  $8.55\%$  clay ( $<0.002$  mm). Soil bulk density was in range of  $1.5$  to  $1.6$  g cm<sup>-3</sup> with slightly lower values for manure treatment plots. The average pH levels in spring 2022 were  $5.4$  for barley plots,  $5.3$  for wheat plots,  $5.6$  for sorghum plots without manure amendment, and  $6.2$  for sorghum plots with manure amendment.

The experiment was organised into 12 plots in a systematic block design (Figure 1) with three sampling spots per plot. Every plot was  $50$  m<sup>2</sup> in size. The crop species studied were spring barley (cultivar “Elmeri”), sorghum (*Sorghum bicolor* x *Sorghum* 110 *sudanense*, cultivar “SUSU”), and spring wheat (cultivar “Mistral”). Initially, the crop rotation was potato–spring wheat–spring barley (Astover *et al.*, 2016). In 2019, potato was replaced with sorghum-sudangras hybrid.

The fertiliser treatment consisted of mineral N fertilisation and mineral fertilisation with farmyard manure amendment. All fertilisation treatments are applied continuously from year 1989, when the experimental site was established. Three mineral N fertiliser treatment rates were studied:  $0$ ,  $80$  and  $160$  kg N ha<sup>-1</sup>. The farmyard manure rate added to the sorghum plots was  $40$  115 t ha<sup>-1</sup> of manure ( $231.2$  kg N ha<sup>-1</sup>). The mineral fertiliser applied was ammonium nitrate (NH<sub>4</sub>NO<sub>3</sub>) and organic fertiliser was farmyard manure. The farmyard manure was cattle dung with straw bedding, freely fermented before use 6-8 months in heap. The chemical properties (C, N, P, K) of manure added in 2022 and during the last ten years are presented in Table S1 in the Supplementary materials. The farmyard manure treatment with mineral fertilisation was applied only to sorghum. Manure treatment is amended with solid farmyard manure ( $40$  t ha<sup>-1</sup>) in every third year before sorghum/potato. The main management 120 activities and timing in the field are displayed in Table S2 in Supplementary materials.

**Figure 1:** Satellite view of the study site with study plots (from Maa-amet). Each plot constituted of three sampling spots indicated as white dots. N0 – 0 kg N ha<sup>-1</sup>, N80 – 80 kg N ha<sup>-1</sup>, N160 – 160 kg N ha<sup>-1</sup> as mineral fertiliser.

## 2.2 Gas sampling for N<sub>2</sub>O flux analyses

The field study was conducted during the growing season from April 2022 to October 2022. Sampling took place on 15 different dates, starting on April 27<sup>th</sup> and ending on October 12<sup>th</sup> (every week until the end of June and then twice a month until the end of September). Gas samples for N<sub>2</sub>O flux analysis were collected on all fifteen fieldwork days. N<sub>2</sub>O gas sampling was carried out using the static chamber method (Hutchinson and Livingston, 1993). Polyvinyl chloride chambers (Ø 50 cm, volume 65 L) were placed on top of the collars during the gas sampling. Chamber extensions were used for some treatments of sorghum on four occasions as the chambers alone were too small to accommodate the growing crops. Pre-vacuumed 50 ml glass vials were used for gas sampling. Gas samples were collected at 20 minutes intervals for one hour (0, 20, 40, 60 min). The concentration of N<sub>2</sub>O in the collected air was measured in the Biogeochemical Cycling Research Laboratory in the Department of Geography, University of Tartu, with the gas chromatograph Shimadzu GC-2014 (Kyoto, Japan), equipped with electron capture and flame ionisation detectors (Poole, 2015).

## 2.3. Soil sampling and physicochemical analyses

Soils were sampled for chemical and microbiological analyses six times (April 27<sup>th</sup>, May 9<sup>th</sup>, June 2<sup>nd</sup>, July 7<sup>th</sup>, September 2<sup>nd</sup>, October 12<sup>th</sup>). Soil sampling was conducted after gas sampling. Soil samples were collected close to collars with a soil probe from the top 10 cm of the soil. Three auger samples from each point (both bulk and rhizosphere soil were sampled) were

140

collected for one composite sample for chemical and microbiological analyses. All in all, 216 samples were collected for chemical analyses and 144 samples for microbial analyses. Until chemical and microbiological analyses, samples were stored at +4 °C and -20 °C, respectively. In addition to soil sampling, soil temperature (°C) at a 10 cm depth was measured with a temperature logger (Comet Systems Ltd., Rožnov pod Radhoštěm, Czech Republic) and soil moisture ( $\text{m}^3/\text{m}^3$ ) was recorded using water content reflectometers (model CS615, Campbell Scientific Inc., Logan, UT, USA). The soil samples were analysed for total carbon ( $\text{C}_{\text{tot}}$ ), total nitrogen ( $\text{N}_{\text{tot}}$ ), nitrate-nitrogen ( $\text{NO}_3^-$ -N), and ammonium-nitrogen ( $\text{NH}_4^+$ -N) concentrations in the Soil Science and Agrochemistry Laboratory of Estonian University of Life Sciences.  $\text{N}_{\text{tot}}$  and  $\text{C}_{\text{tot}}$  analyses were done by Dumas method (International Organization for Standardization, 1998) with dry combustion on a VarioMAX CNS elemental analyser (ELEMENTAR, Elementar Analysensysteme GmbH, Langenselbold, Germany).  $\text{NO}_3^-$ -N analyses were done according to EPA (United States Environmental Protection Agency) method 9056: determination of inorganic anions by ion chromatography.  $\text{NH}_4^+$ -N analyses were done according to Thermo Fisher Application Note 141 (AU204: Determination of Inorganic Cations and Ammonium in Environmental Waters Using a Compact Ion Chromatography System) using ion chromatography. Soil pH was measured using a glass-electrode pH meter in a water solution of 1:2.5. Total phosphorus (P) and potassium (K) concentration in manure were determined through acid digestion using a sulfuric acid solution (van Reeuwijk, 2002).

The hot-water extractable C (HWEOC) represents the readily mineralising C fraction and was determined on dry soil samples by a modified method of Haynes and Francis (1993) in two steps. In the first step the soil was shaken with deionized water at room temperature for 1 h. After that the soil suspension put into the thermostat at 80 °C for 16 h. The mixture was centrifuged for 10 min at 8000 rpm and filtered through a 0.45- $\mu\text{m}$  membrane filter (25-mm diameter, nylon, Agilent®). The HWEOC concentration was determined from the extracts by the VarioMaX CNS analyzer (ELEMENTAR, Elementar Analysensysteme GmbH, Langenselbold, Germany).

## 2.4 Total biomass

The total biomass (above- and below-ground) was measured at the maturity phase on the harvest day of each crop (Supplementary Table S2). The above-ground biomass was cut from the ground level in a 0.2  $\text{m}^2$  area near each collar. The belowground biomass samples were taken with a soil auger ( $\text{Ø}$  34 cm). Frasier *et al.* (2016) provides a more detailed description of the method used for below-ground biomass measurement. The sampling depth extended to the plowing depth, where most of the roots are found, up to a depth of 18 cm. Samples were stored at +4 °C until the roots were washed on a sieve (mesh size 0.5 mm).

Dry matter yield was determined after drying the biomass (including roots) at 70 °C to constant weight. The straw and grains were separated before weighing as air dry. The biomass (straw, grain, roots) were milled and the  $\text{N}_{\text{tot}}$  content was determined by the Dumas method with dry combustion on a VarioMAX CNS elemental analyser (ELEMENTAR, Elementar Analysensysteme GmbH, Langenselbold, Germany).

## 175 **2.5 Soil microbial analyses**

### **2.5.1 DNA extraction**

DNA was extracted from 0.25 g of soil samples using the DNeasy® PowerSoil® Pro Kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. The difference from the instruction was the homogenisation of samples with homogeniser, Precellys 24 (Bertin Technologies, Montaigne-le-Bretonneux, France), for 20 s at the rate of 5000 rpm. The concentration and  
180 quality of the extracted DNA were evaluated with an Infinite 200 M spectrophotometer (Tecan AG, Männedorf, Switzerland). The extracted DNA was stored in a freezer at  $-20^{\circ}\text{C}$ .

### **2.5.2 Quantification of gene copies using qPCR**

Quantification of the 16S rRNA genes of bacteria and archaea, along with the quantification of nitrification (bacterial, archaeal,  
185 and comammox *amoA*), denitrification (*nirS*, *nirK*, *nosZI*, and *nosZII*) and DNRA (*nrfA*) genes was done using quantitative polymerase chain reaction (qPCR). qPCR reactions were performed by The Rotor-Gene Q thermocycler (Qiagen). The reaction mixture of 10  $\mu\text{L}$  consisted of extracted DNA (1  $\mu\text{L}$ ), gene-specific forward and reverse primers, Maxima SYBR Green Master mix reagent (5  $\mu\text{L}$ ; Thermo Fisher Scientific, Waltham, MA, USA) and distilled water. Each sample was amplified two times. All of the qPCR assays included two DNA-free negative control samples. Details on thermal cycling conditions and used  
190 primers are added in Table S3 in Supplementary Materials. The Rotor-Gene® Q software v. 2.0.2 (Qiagen) and LinRegPCR v. 2020.2. were used to assess the qPCR results. The amount of gene copies was calculated using standard curve ranges, and results were presented in gene copies per gram of dry matter (copies/g dw). Espenberg *et al.* (2018) provides a more detailed description of the used qPCR methodology.

## 195 **2.6 Statistical analyses and modelling**

Statistical software programs Statistica (v. 7.1) and R (v. 4.0.4) were used for statistical analyses and visualising the data. Principal component analysis (PCA) were conducted on soil physicochemical parameters and microbiological data (abundance of functional marker genes) with the “FactoMineR” (Lê *et al.*, 2008) and “factoextra” (Kassambara *et al.*, 2020) packages in the software R. Analysis of variance (ANOVA) with post-hoc Tukey HSD test was used (cumulative  $\text{N}_2\text{O}$  emission values are  
200 meeting the assumptions of parametric test) to find statistically significant differences between different fertilisation rates, use of manure and crop types.

Spearman's rank correlation coefficient measured the association between  $\text{N}_2\text{O}$  and  $\text{N}_2$  emissions, gene abundances and environmental factors. Random Forest classification analysis was conducted using Boruta v. 8.0 (Kursa and Rudnicki, 2010) to identify the gene parameters that best predicted  $\text{N}_2\text{O}$  fluxes.

205 Nitrogen use efficiency (NUE, kg DM kg<sup>-1</sup> N<sup>-1</sup>) was calculated as the biomass production per unit of N applied (Pandey *et al.*, 2001; Supplementary Methodology S1). The N<sub>2</sub> emissions were estimated from the measured N<sub>2</sub>O emissions using the N<sub>2</sub>:N<sub>2</sub>O ratio, which was calculated as proposed in the DAYCENT model (Parton *et al.*, 2001), with the equations described in Del Grosso *et al.* (2000) (Supplementary Methodology S2), where the ratio N<sub>2</sub>:N<sub>2</sub>O is a function of the content of NO<sub>3</sub><sup>-</sup> in the soil, CO<sub>2</sub> emissions, and water-filled pore space (WFPS). The change of soil N content (kg N ha<sup>-1</sup>) was calculated according  
210 to Sainju (2017), as the difference between the initial and final soil total N contents (Supplementary Methodology S3). N losses are calculated by subtracting N outputs and change of soil N content from N inputs (Sainju, 2017; Escuer-Gatius *et al.*, 2022; Supplementary Methodology S4).

Linear mixed-effects model (LMM) was used to investigate differences in N<sub>2</sub>O emissions and gene parameters between different crop types and fertilisation rates using the R package “nlme.” For N<sub>2</sub>O emissions and gene parameters, temporal  
215 (sampling dates) effect was used as random effect. The Kruskal–Wallis test and the post-hoc Tukey HSD test were used to compare the N<sub>2</sub>O and gene parameter (not meeting the assumptions of parametric test) values between different crop types and fertilisation rates. Due to limited number of observations in the case of total dry weight biomass, N content in biomass, and cumulative N<sub>2</sub> emissions, LMM was not possible to apply for statistical differences between different fertilisation rates and crop types.

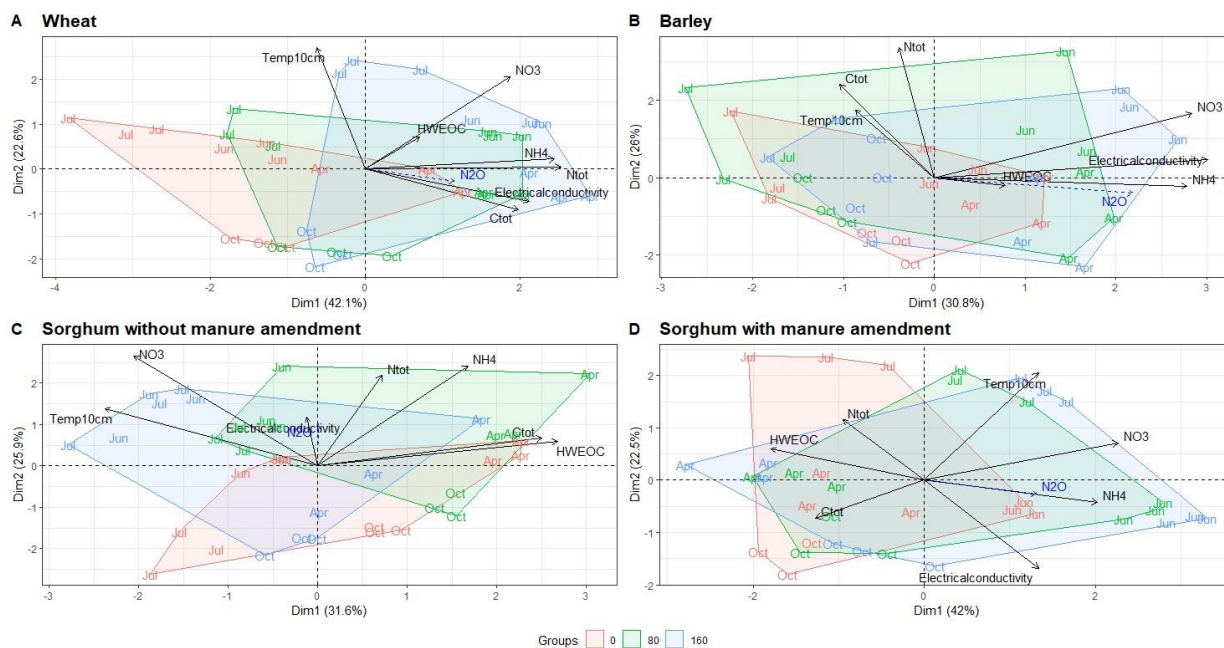

## 220 3 Results

### 3.1 Soil physicochemical characteristics and biomass production

The NH<sub>4</sub><sup>+</sup>-N content in soil decreased on most of the plots at the beginning of the study period, while NO<sub>3</sub><sup>-</sup>-N content was increasing (Supplementary Figure S2). Fertilised plots had higher soil N<sub>tot</sub>, C<sub>tot</sub>, NO<sub>3</sub><sup>-</sup>-N and NH<sub>4</sub><sup>+</sup>-N content compared to non-fertilised plots according to the principal component analysis (PCA) (Figure 2; Supplementary Figure S2 and Figure S3). For  
225 sorghum without manure amendment plots (Figure 2C), NO<sub>3</sub><sup>-</sup>-N and NH<sub>4</sub><sup>+</sup>-N contents were more different from each other compared to sorghum with manure amendment plots, where NO<sub>3</sub><sup>-</sup>-N and NH<sub>4</sub><sup>+</sup>-N contents were relatively similar (Figure 2D). HWEOC concentrations were higher in sorghum plots with farmyard manure amendment compared to sorghum plots without manure amendment.

Soil moisture ranged from 0.02 m<sup>3</sup>/m<sup>3</sup> to 0.32 m<sup>3</sup>/m<sup>3</sup> with an average of 0.23 m<sup>3</sup>/m<sup>3</sup> over the study period (Supplementary  
230 Figure S4). There were no significant correlations between soil moisture and N<sub>2</sub>O emissions (Supplementary Table S4). Soil moisture was not significantly linked to gene copy numbers across all crop types, except *nirS*. A climate diagram for the area during the study period is presented in Figure S1 in the Supplementary materials.

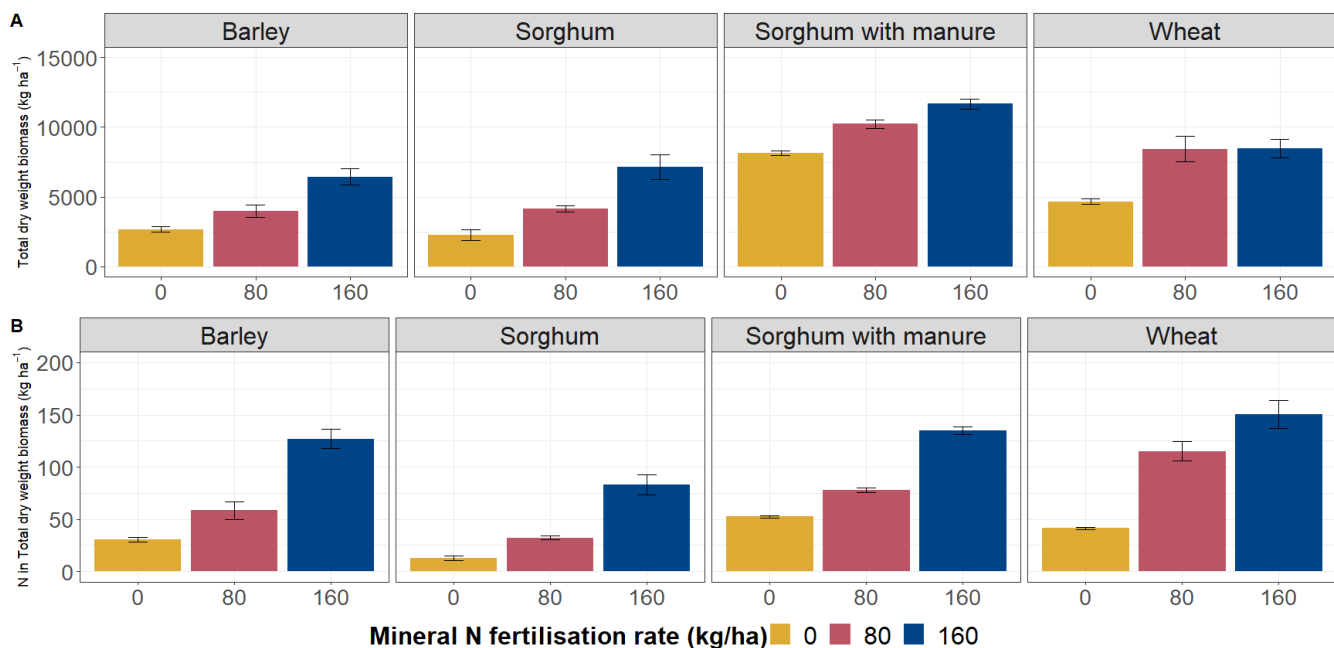

235 **Figure 2:** Principal components analysis (PCA) ordination plots demonstrate the grouping of fertilisation rates according to physicochemical parameters for different crop type. N<sub>2</sub>O is added as a supplementary variable. The month indicates the sampling time. Abbreviations: Ctot – total carbon content of soil; Ntot – total nitrogen content of soil; HWEOC – hot-water extractable organic carbon.

240 The total dry biomass of barley ranged between 2.6 to 6.4 t ha<sup>-1</sup>, and wheat between 4.6 to 8.5 t ha<sup>-1</sup> depending on the mineral N fertilisation rate (Figure 3). For sorghum without manure amendment, the total dry biomass varied between 2.3 and 7.1 t ha<sup>-1</sup>, and for sorghum with manure amendment, the total dry biomass varied between 8.2 and 11.7 t ha<sup>-1</sup>.

The biomass production was higher per unit area of crop growth with higher fertiliser input (Figure 3A). Total biomass was significantly positively correlated with N<sub>tot</sub> (p<0.01), C<sub>tot</sub> (p<0.05) and NO<sub>3</sub><sup>-</sup>-N (p<0.001) levels in soil (Supplementary Table 245 S5). Also, higher N fertilisation rate caused an increase in N content in the crop biomass (Figure 3B).

250

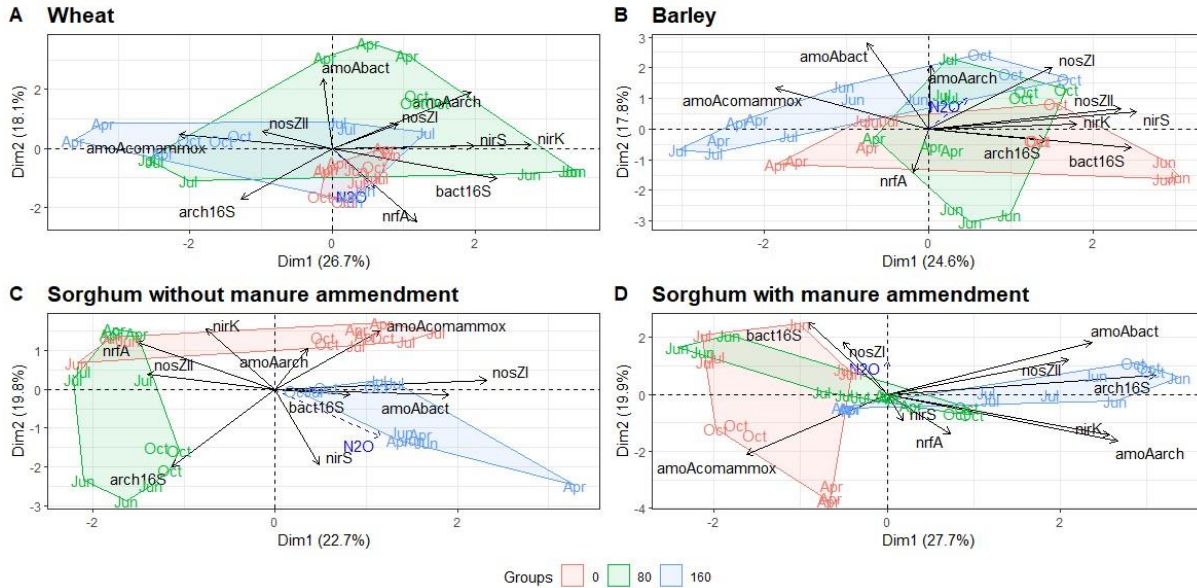

**Figure 3:** Total dry weight biomass (aboveground + belowground) produced per unit area according to crop types and fertilisation rates. Error bars show standard errors.

255 The highest values of nitrogen use efficiency (NUE) were obtained from wheat plots, and the lowest from sorghum plots. The average NUE of wheat plots at fertilisation rate 80 was 0.84, and at rate 160, it was 0.64. For sorghum plots with manure amendment, NUE at mineral N fertilisation rate 0 was 0.15, at rate 80 was 0.16, and at rate 160 was 0.25. For sorghum plots without manure amendment, the average NUE at fertilisation rate 80 was 0.12, and at rate 160, it was 0.25. The NUE for barley plots at fertilisation rate 80 was 0.35, and at fertilisation rate 160, it was 0.45. The highest estimated N losses occurred on  
 260 sorghum plots with manure amendment (Supplementary Table S6). In general, wheat plots at different fertilisation rates lost more N compared to sorghum plots without manure amendment. The lowest estimated N losses occurred on barley plots.

### 3.2 Nitrogen cycle genes

The abundances of N cycling genes on plots with different fertilisation rates and crop species show different patterns throughout the study period (Supplementary Figures S5, S6, S7, and S8). The principal component analysis (PCA) of the N  
 265 cycle genes abundances showed differences between sites with different fertilisation rates (Figure 4). There were greater differences in gene abundances between three different mineral N fertilisation rates in sorghum plots compared to barley and wheat plots (Figure 4). For sorghum without manure amendment (Figure 4C), archaeal 16S rRNA and *nosZII* gene abundances were highest for fertilisation rate 80 compared to rate 0 ja 160 ( $p < 0.001$ ), but for sorghum with manure amendment (Figure

270 4D), the highest archaeal 16S rRNA and *nosZII* gene abundances were for fertilisation rate 160 compared to rate 0 ( $p < 0.001$ ) and 80 ( $p < 0.05$ ). For all sorghum plots, comammox *amoA* gene abundance was highest on non-fertilised plots. However, fertilised wheat and barley plots had higher comammox *amoA* gene abundance compared to non-fertilised plots.

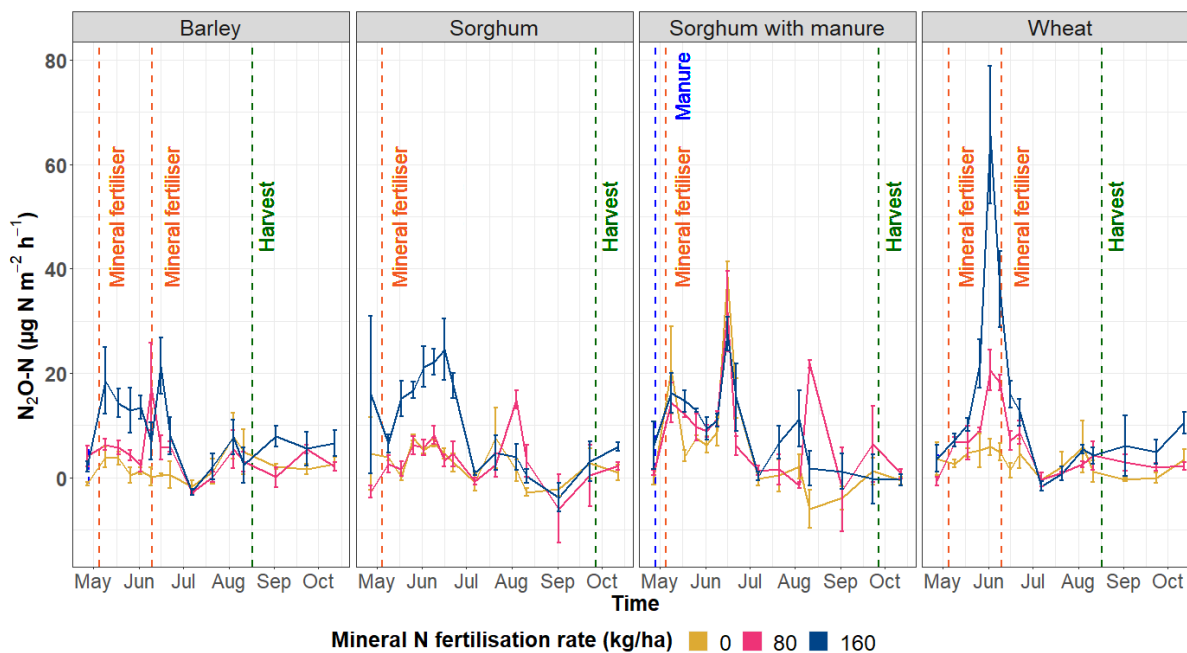

275 **Figure 4:** Principal components analysis (PCA) ordination plots demonstrate the grouping of fertilisation rates according to functional marker genes abundances for different crop type. N<sub>2</sub>O is added as a supplementary variable. The month shows the sampling time. Abbreviations: *bact16S* – bacterial 16S rRNA gene; *arch16S* – archaeal 16S rRNA gene; *amoAbact* – bacterial *amoA* gene; *amoAarch* – archaeal *amoA* gene; *amoAcomammox* – comammox *amoA* gene.

### 280 3.3 N<sub>2</sub>O emissions

The N<sub>2</sub>O emissions over the course of the study period show that different fertilisation rates influence N<sub>2</sub>O emissions, and the highest N<sub>2</sub>O emissions tend to be emitted from the highest N fertiliser treatment (160 kg N ha<sup>-1</sup>) (Figure 5). N<sub>2</sub>O emissions among all crop species tended to be higher during the first part of the study period (spring and early summer). Taken together, the highest average N<sub>2</sub>O emissions for barley plots were measured in the middle of May, for sorghum plots without and with manure in the middle of June, and for wheat plots at the beginning of June.

285

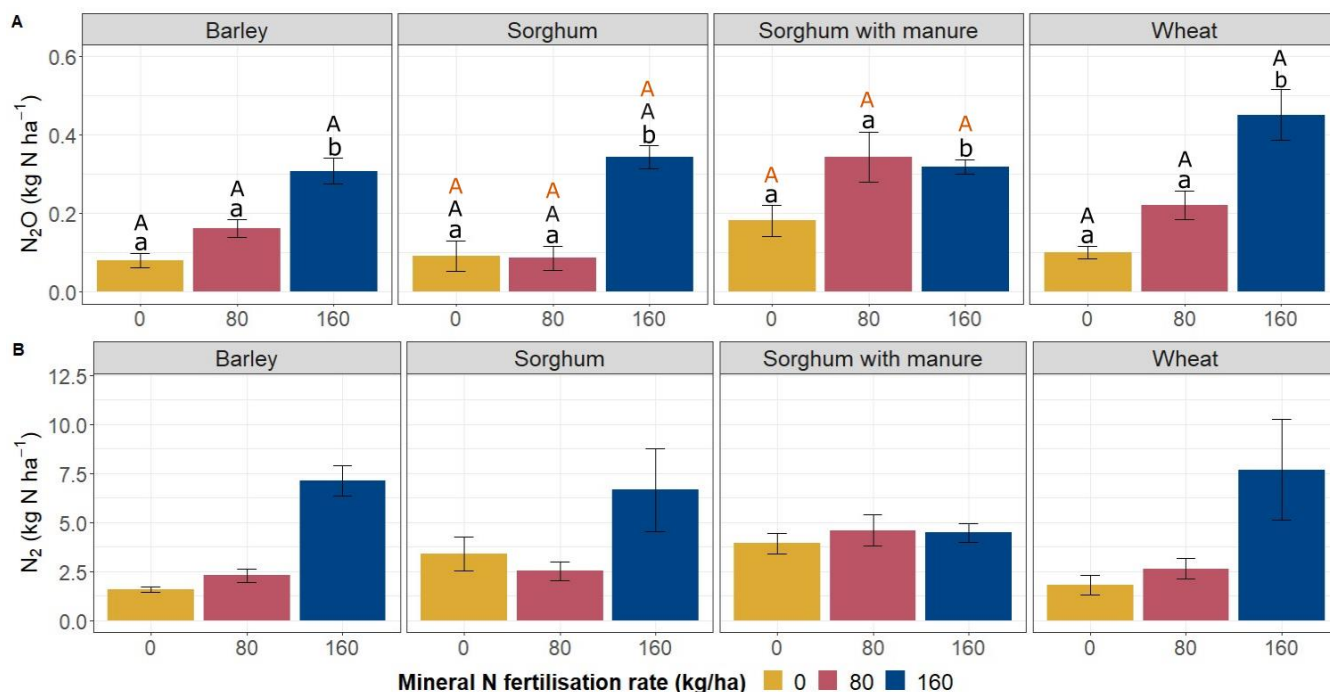

**Figure 5:** N<sub>2</sub>O emissions ( $\mu\text{g N m}^{-2} \text{h}^{-1}$ ) according to crop types and fertilisation rates during the study period.

290 Throughout the study period, cumulative N<sub>2</sub>O and N<sub>2</sub> emissions were highest in plots with the highest fertilization rate, except  
 295 sorghum plots with manure amendment (Figure 6A, B). For wheat and barley plots, there is a clear pattern of increasing N<sub>2</sub>O  
 emissions with increasing fertilisation rates.

For barley plots, cumulative N<sub>2</sub>O emissions did not significantly differ between fertilisation rates 0 and 80 (Figure 6A).  
 However, N<sub>2</sub>O emissions on barley plots were significantly higher at fertilisation rate 160 than at rate 0 and 80 ( $p < 0.05$ ).

295 Similarly, for wheat plots, cumulative N<sub>2</sub>O emissions were also significantly higher at fertilisation rate 160 compared to rates  
 0 ( $p < 0.05$ ) and 80 ( $p < 0.05$ ); however, fertilisation rates 0 and 80 did not significantly differ from each other. For plots with  
 sorghum without manure, cumulative N<sub>2</sub>O emissions at fertilisation rate 160 were significantly higher compared to fertilisation  
 rates 0 ( $p < 0.05$ ) and 80 ( $p < 0.05$ ). For sorghum with manure plots, cumulative N<sub>2</sub>O emissions at fertilisation rate 160 was  
 significantly different compared to fertilisation rate 0 ( $p < 0.05$ ) and 80 ( $p < 0.05$ ).

300 For barley and wheat plots, the cumulative N<sub>2</sub> emissions were higher at fertilisation rate 160 compared to rates 0 and 80 (Figure  
 6B). For sorghum plots, cumulative N<sub>2</sub> emissions emitted from all three fertilisation rates were similar.

**Figure 6:** Cumulative N<sub>2</sub>O and N<sub>2</sub> emissions according to crop types and fertilisation rates. Error bars show standard errors. Letters above the boxes indicate statistically significant differences at significance level  $p < 0.05$  according to a post-hoc Tukey HSD test. Lowercase letters indicate comparisons within crop types. Uppercase letters indicate comparisons of the same fertilisation rate between different crop types: orange uppercase letters represent comparisons between sorghum without manure amendment and sorghum with manure amendment; black uppercase letters represent comparison between barley, wheat and sorghum without manure amendment.

### 3.4 Relationships between environmental parameters, gene abundances and ratios, and N emissions

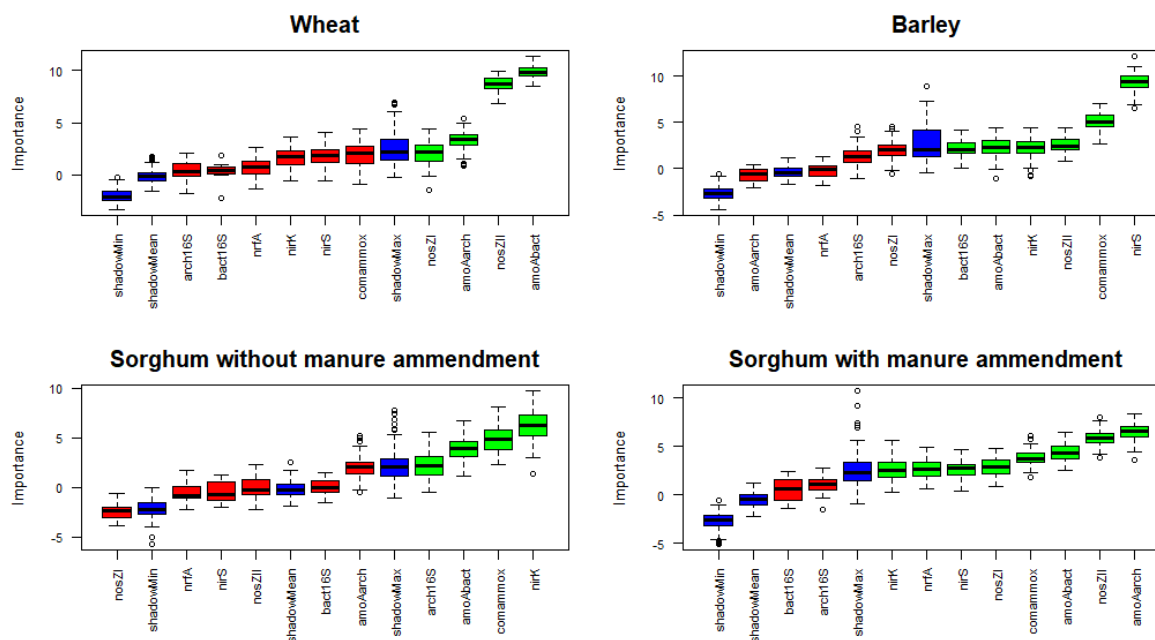

Mineral N fertilisation rate ( $p < 0.001$ ) and crop type ( $p < 0.05$ ) significantly influenced N<sub>2</sub>O emissions on plots with only mineral N fertilisation (Table 1A). Manure amendment ( $p < 0.05$ ) and mineral N fertilisation rate ( $p < 0.05$ ) had a significant impact on N<sub>2</sub>O emissions from sorghum plots (Table 1B).

325 **Table 1:** Results of ANOVA testing the effects of **(A)** mineral N fertilisation rate and crop type on cumulative N<sub>2</sub>O fluxes on plots with barley, wheat and sorghum without manure amendment, **(B)** mineral N fertilisation rate and manure amendment on cumulative N<sub>2</sub>O fluxes on sorghum plots with and without manure amendment. Significance is indicated as \*\*\* – 0.001; \*\* – 0.01; \* – 0.05; ns – not significant.

<b>A</b>	<b>Df</b>	<b>F value</b>	<b>Pr (&gt;F)</b>	<b>B</b>	<b>Df</b>	<b>F value</b>	<b>Pr (&gt;F)</b>

Residuals	22			Residuals	14		

330 Random Forest classification analysis for the N<sub>2</sub>O emissions from wheat plots considered bacterial *amoA*, archaeal *amoA*,  
*nosZI* and *nosZII* genes relevant (Figure 7). For barley plots, bacterial *amoA*, comammox *amoA*, bacterial 16S rRNA, *nirK*,  
*nirS* and *nosZII* were deemed as important genes in the variations of N<sub>2</sub>O emissions. For sorghum without manure amendment  
plots, bacterial *amoA*, comammox *amoA*, archaeal 16S rRNA and *nirK* genes were considered important for the N<sub>2</sub>O emissions.  
For sorghum with manure amendment plots, archaeal *amoA*, bacterial *amoA*, comammox *amoA*, *nirK*, *nirS*, *nosZII*, *nosZI* and  
335 *nrfA* genes were considered important for the N<sub>2</sub>O emissions.

340

**Figure 7:** Results of feature selection in predicting the genes that are important in the variations of N<sub>2</sub>O emissions. Important factors are indicated in green, unimportant factors in red, and shadow variables (the random shadow copies of features (noise) will be created to test the feature against those copies to determine if it is better than the noise, and therefore significant) in blue. Abbreviations: bact16S – bacterial 16S rRNA gene; arch16S – archaeal 16S rRNA gene; amoAbact – bacterial *amoA* gene; amoAarch – archaeal *amoA* gene; amoAcomammox – comammox *amoA* gene.

The relationships between gene abundances and N<sub>2</sub>O emissions showed that the ratio of *amoA/nir* was in a significant positive correlation with N<sub>2</sub>O emissions ( $\rho=0.20$ ;  $p<0.001$ ). Furthermore, the ratio of *nosZ/nir* was also significantly positively correlated with N<sub>2</sub>O emissions ( $\rho=0.21$ ;  $p<0.001$ ). *nirS* genes were positively correlated with N<sub>2</sub>O emissions over all crops species plots ( $\rho=0.19$ ;  $p<0.05$ ). N<sub>2</sub>O emissions from barley plots had also a strong positive correlation with *nirS* gene abundance ( $\rho=0.58$ ;  $p<0.001$ ). On wheat plots, *nosZII* genes were negatively correlated with N<sub>2</sub>O emissions ( $\rho=-0.46$ ;  $p<0.01$ ). The correlation matrix is provided as Table S7 in Supplementary materials.

The relationship between N<sub>2</sub> emissions and *nrfA* genes showed that N<sub>2</sub> emissions were negatively correlated to *nrfA* genes over all crop types ( $\rho=-0.39$ ;  $p<0.05$ ). *nosZII* genes were positively correlated with N<sub>2</sub> emissions on plots with wheat ( $\rho=0.85$ ;  $p<0.01$ ).

## 4 Discussion

Mineral N fertilisation positively influenced biomass increase in all three crop types (Figure 3A), with similar findings  
360 observed in other IOSDV experiments by Csitári *et al.* (2021) and Tajnšek *et al.* (2013). The results also showed a significant  
positive correlation between biomass production and soil  $\text{NO}_3^-$ -N,  $\text{C}_{\text{tot}}$  and  $\text{N}_{\text{tot}}$  content, explaining higher biomass production  
in fertilised soil, as N limitation is the most influential factor constraining crop growth (Mengel and Kirkby, 2001).  
Furthermore, increasing mineral N fertilisation led to higher N accumulation in the biomass (Figure 3). The higher N content  
in biomass can be explained by applying N at rates that exceed crop needs for optimal yield, leading to an increase in crop  
365 protein content (Serret *et al.*, 2008; Mengel and Kirkby, 2001).

The sorghum plots without fertilisation yielded  $2.3 \text{ t ha}^{-1}$ , while those with only manure amendment produced an additional  
 $5.9 \text{ t ha}^{-1}$  of total dry biomass (Figure 3A), consistent with the results from Spiegel *et al.* (2010).  $\text{N}_{\text{tot}}$  and  $\text{C}_{\text{tot}}$  were also higher  
on sorghum plots with manure amendment compared to plots with only mineral fertilisation (Figure S3), which can explain  
higher biomass production. The positive effect of manure amendment could be attributed to increased availability of nutrients.  
370 Meta-analysis by Hijbeek *et al.* (2017), covering 20 long-term experiments (including the IOSDV experimental site used in  
our study) in Europe, reported that organic input does not necessarily guarantee increased crop yields. Although Hijbeek *et al.*  
(2017) also found that in specific cases, like spring sown cereals and sandy soils, the use of organic inputs led to an increase  
in crop yield.

In various ecosystems, N cycle genes have been linked to  $\text{N}_2\text{O}$  emissions (Butterbach-Bahl *et al.*, 2013; Espenberg *et al.*, 2018;  
375 Harter *et al.*, 2014). The significant positive correlation between the ratio of *amoA/nir* and  $\text{N}_2\text{O}$  emissions ( $\rho=0.20$ ,  $p<0.001$ )  
in our study indicates that nitrification potential was higher than denitrification potential and thereby  $\text{N}_2\text{O}$  emissions were  
mainly related to nitrification in the soil. Previous studies have also used the ratio of *amoA* to *nir* genes to study N-cycle  
processes (Kazmi *et al.*, 2023; Tang *et al.*, 2018; Zhu *et al.*, 2018). Additionally, an initial decrease in  $\text{NH}_4^+$ -N content in soil  
was observed, suggesting  $\text{NH}_4^+$  consumption (nitrification) and mineral N uptake by plants (Supplementary Figure S2). A  
380 simultaneous increase in  $\text{NO}_3^-$ -N accompanied by a decrease in  $\text{NH}_4^+$ -N was recorded, likely resulting from the nitrification  
production process.

*nirS* genes exhibited a positive correlation with  $\text{N}_2\text{O}$  emissions across all crops species plots ( $\rho=0.19$ ;  $p<0.05$ ), suggesting that  
while nitrification is predominant, denitrification is also evident. This finding aligns with results from several other agricultural  
studies, which also reported a significant positive correlation between *nirS* genes and  $\text{N}_2\text{O}$  emissions (Castellano-Hinojosa *et al.*  
385 *et al.*, 2020; Cui *et al.*, 2016). Additionally, the ratio of *nosZ* to *nir* genes (*nosZ/nir*) was positively correlated with  $\text{N}_2\text{O}$  emissions  
( $\rho=0.21$ ,  $p<0.001$ ). It highlights the importance of complete denitrifiers that have a capacity to convert  $\text{N}_2\text{O}$  to  $\text{N}_2$ . Since  $\text{N}_2\text{O}$   
emissions are increasing with a high abundance of the *nosZ* gene, this positive correlation may be also related to  $\text{N}_2\text{O}$  emissions  
being emitted from nitrification.

For all plots, one or more functional marker genes related to nitrification and denitrification were identified as important in the  
390 variations of  $\text{N}_2\text{O}$  emissions (Figure 7), emphasizing the significance of both processes in  $\text{N}_2\text{O}$  emissions. Comammox was

also recognized as an important process in N<sub>2</sub>O emissions, except in wheat plots, indicating its potential important role. Additionally, Li *et al.* (2019) demonstrated an order of magnitude higher abundance of comammox *Nitrospira* clade A compared to ammonia-oxidizing archaea and ammonia-oxidizing bacteria in fertilised agricultural soil. More functional marker genes show significance in the variations of N<sub>2</sub>O with manure compared to other treatments (Figure 7), indicating that a greater number of N cycle processes are relevant in plots with manure. Additionally, *nosZI*, *nosZII* and *nirS* genes were identified as important in the variations of N<sub>2</sub>O emissions for sorghum with manure amendment, but not for only mineral fertiliser sorghum plots, which indicates significance of denitrification in these plots. Previous studies also suggest a higher denitrification potential from manure treatment, highlighting the importance of denitrifying microorganisms in manure-fertilised plots (Clark *et al.*, 2012; Wan *et al.*, 2023). The increased denitrification rate in manure-amended plots may be due to improved soil water retention promoting denitrification and increased availability of labile C content, which is the energy source for denitrifiers (Lazcano *et al.*, 2021; Rayne and Aula, 2020). Our results also support higher labile C content in plots with manure amendment (Figure 2). Furthermore, sorghum with manure plots were the only plots where the *nrfA* gene was identified as an important gene in N<sub>2</sub>O emissions, suggesting that manure amendment is likely enhancing the rate of DNRA process.

The negative relationship between *nrfA* gene and N<sub>2</sub> emissions is suggesting that the DNRA process is not contributing to N<sub>2</sub> emissions. The DNRA process, which is mediated by *nrfA* gene, is beneficial as it supplies NH<sub>4</sub><sup>+</sup> to the soil and conserves bioavailable N (Bai *et al.*, 2020; Pandey *et al.*, 2020). In addition, significant positive correlation between *nosZII* genes and N<sub>2</sub> emissions on plots with wheat indicates that there is likely a potential production of N<sub>2</sub> due to high abundance of *nosZII* genes that reduce N<sub>2</sub>O into inert N<sub>2</sub>. It is also supported by negative correlation between *nosZII* genes and N<sub>2</sub>O emissions ( $\rho=-0.46$ ;  $p<0.01$ ) on wheat plots. It indicates *nosZII* genes role in reducing N<sub>2</sub>O emissions (Graf *et al.*, 2014). Jones *et al.* (2014) demonstrated that the abundance and phylogenetic diversity of *nosZII* community is an important factor driving the soil's N<sub>2</sub>O sink capacity.

Agricultural soils typically act as a source of N<sub>2</sub>O (Davidson and Kanter, 2014), as shown in this study. The three mineral N fertilisation rates investigated influenced N<sub>2</sub>O emissions, with N<sub>2</sub>O emissions increasing with higher mineral N application rate for all three crop species (Figure 5, 6A). This can be attributed to higher available N levels with increased fertilisation rates for processes contributing to N<sub>2</sub>O emissions (Engel *et al.*, 2010), as N<sub>2</sub>O emissions showed a strong positive correlation with both NO<sub>3</sub><sup>-</sup>-N and NH<sub>4</sub><sup>+</sup>-N levels in soil. Prior studies have also highlighted a positive relationship between soil N<sub>2</sub>O emissions and mineral N content (Sosulski *et al.*, 2014; Yao *et al.*, 2009; Yuan *et al.*, 2022). Furthermore, among the investigated factors, the mineral N fertilisation rate was the primary determinant of cumulative N<sub>2</sub>O emissions (Table 1), indicating that soil N<sub>2</sub>O emissions are mainly linked to the excess N added with mineral fertiliser in the cropping system (Supplementary Table S6). However, it is important to consider that the sample replicates may not be fully statistically independent, as the experiment involved only one plot per treatment combination (crop type × fertilisation rate), with three samples taken within the same plot.

Our study found that both crop type and mineral N fertilisation rate significantly influence cumulative N<sub>2</sub>O emissions, with mineral N fertilisation rate having a stronger effect (Table 1). It suggests that N<sub>2</sub>O emissions from soil are more closely related

425 to the excess N in the cropping system than the crop type. Some studies have also shown a significant effect of crop type on  
N<sub>2</sub>O emissions (Bouwman *et al.*, 2002; Kaiser and Ruser, 2000). However, study including 372 sites also showed that cover  
crops did not have significant ( $p>0.05$ ) effect on N<sub>2</sub>O emissions (Abdalla *et al.*, 2019). Manure amendment significantly  
impacted N<sub>2</sub>O emissions (Table 1B). Additionally, mineral fertiliser plus manure amendment showed higher soil N<sub>2</sub>O  
430 the cropping system in mineral fertiliser plus manure plots compared to mineral fertiliser-only plots (231.2 kg N ha<sup>-1</sup> was  
added extra), enhancing N<sub>2</sub>O production. In addition to providing nitrifiable N compounds, manure incorporation improves  
soil conditions for nitrification and denitrification by increasing moisture and adding C to the soil (Chadwick *et al.*, 2000).  
While the increase in moisture with manure was not detectable from our study, it may be explained by the slow evolution of  
soil properties over previous years in the 33-year-long fertilisation experiment. Moreover, manure can enhance the activity of  
435 soil microbes, oxygen consumption, and the development of anaerobic zones in the soil, favouring denitrification (Akiyama  
and Tsuruta, 2003).

Soil microbial processes leading to N<sub>2</sub>O production are influenced by soil water content, as it directly affects oxygen  
availability for nitrification and denitrification processes. The recorded lowest soil moisture contents for barley and wheat  
plots on 7th of July (Supplementary Figure S4) likely explain the lowest N<sub>2</sub>O emissions on that date (Figure 5). Previous  
440 studies on N<sub>2</sub>O emissions and soil moisture dynamics have reported similar trend (Yamulki *et al.*, 1995; Yuan *et al.*, 2022).  
Additionally, Thapa *et al.* (2017) reported a reduction in N<sub>2</sub>O emissions from wheat fields, which could be due to soil salinity  
interfering with nitrification and denitrification processes (Dang *et al.*, 2016). Dry soils may lead to microorganisms  
experiencing cell dehydration and increased soil salinity, hindering soil microbial activity and, therefore, the production of  
gaseous N emissions (Haj-Amor *et al.*, 2022; Schimel *et al.*, 2018). Although our study did not find significant correlations  
445 between soil moisture and N<sub>2</sub>O emissions or most of the functional marker genes.

Considering climate changes and population growth, N<sub>2</sub>O management should be aligned with the future need to increase crop  
yield and sustain rapidly increasing human population. Biomass production increased with fertilisation rate (Figure 3), except  
for wheat plots. In our study, the biomass production on wheat plots between fertilisation rates 80 kg N ha<sup>-1</sup> and 160 kg N ha<sup>-1</sup>  
had very similar biomass values. However, long-term fertilisation experiments (IOSDV) by Káš *et al.* (2010) achieved highest  
450 wheat yields from N fertilisation rate of 160 kg N ha<sup>-1</sup>. Our study shows increasing N<sub>2</sub>O emissions at higher fertilisation rate  
on wheat plots (Figure 6A), indicating potential overfertilisation and suggesting fertilisation rate at 80 kg N ha<sup>-1</sup> as the optimal  
fertilisation rate. In addition, the highest nitrogen use efficiency (NUE) was observed at fertilisation rate 80 kg N ha<sup>-1</sup> for  
wheat (NUE = 0.84), indicating a balance between low N<sub>2</sub>O emissions and high yield. In India, Chaturvedi *et al.* (2006)  
conducted similar fertilisation experiments with N fertilisation rates of 0, 25, 50, 75, 100, and 125 kg N ha<sup>-1</sup>, and identified  
455 the highest N input rate as optimal.

On fertilisation rate of 160 kg N ha<sup>-1</sup>, N<sub>2</sub>O emissions significantly increased compared to lower rates, but this rate also results  
in higher total dry biomass (Figure 3; Figure 6). The fertilisation rate of 80 kg N ha<sup>-1</sup> for sorghum plots with only mineral N

fertiliser amendment appears optimal with low N<sub>2</sub>O emissions and N losses (Supplementary Table S6). However, in sorghum plots without manure amendment, NUE values are low (160 kg N ha<sup>-1</sup> NUE = 0.25; 80 kg N ha<sup>-1</sup> NUE = 0.12).

## 460 5 Conclusions

The results of our study (part of the 33 year old IOSDV experiment) showed that the mineral N fertilisation rate was the dominant factor determining cumulative N<sub>2</sub>O emissions. Crop type also had a significant effect on N<sub>2</sub>O emissions in this study. The study observed an increase in N<sub>2</sub>O emissions with an elevated mineral N fertilisation rate, attributed to higher NO<sub>3</sub><sup>-</sup>-N and NH<sub>4</sub><sup>+</sup>-N levels in fertilised soil. These findings supported our hypothesis of higher N<sub>2</sub>O emissions on sorghum plots under  
465 mineral fertiliser plus manure treatment compared to only mineral fertiliser treatment. Additionally, the number of N-cycle genes that are significant in the variations of N<sub>2</sub>O emissions also increased with manure amendment.

N<sub>2</sub>O emissions were mostly caused by nitrification with potential contribution from denitrification, comammox and DNRA processes. Plots with manure amendment exhibited a greater impact of N-cycle microbial processes on N<sub>2</sub>O emissions,  
470 compared to plots with other crop types. Soil moisture showed no correlation with N<sub>2</sub>O emissions and most of the functional marker gene abundances. Nonetheless, the lowest N<sub>2</sub>O emissions and functional marker gene abundances were recorded during periods of low soil moisture, suggesting a decrease in N<sub>2</sub>O under such conditions.

For wheat, a high NUE value and low N<sub>2</sub>O emissions, coupled with relatively high crop yield, suggest that a fertilisation rate of 80 kg N ha<sup>-1</sup> is optimal. Similarly, in sorghum plots with only mineral N fertiliser amendment, a fertilisation rate of 80 kg  
475 N ha<sup>-1</sup> resulted in low N<sub>2</sub>O emissions and N losses considering comparable biomass production with other crop types.

**Author contributions.** ME, AA, and ÜM designed the experiment and developed the methodology. LK and JEG carried out the fieldwork. LK analysed the results, performed data visualization, and wrote the original manuscript. JEG and ME participated in data analyses and assisted with paper editing. All authors were involved in revising the paper for submission  
480 and contributed to its improvement.

**Competing interests.** The contact author has declared that none of the authors has any competing interests.

**Acknowledgements.** We thank Triin Teesalu for assisting with soil sampling for chemical analyses. Thanks to Tõnu Tõnutare  
485 and Kristi Kõva for conducting soil chemical analysis. We would also like to acknowledge Avo Toomsoo for operating the fertilisation experiment and maintenance of the study field.

**Financial support.** The study was supported by the Estonian Research Council (grants number PRG352 and PRG2032), European Research Council (ERC) under the grant agreement No 101096403 (MLTOM23415R), European Commission

490 through the HORIZON-WIDERA ‘Living Labs for Wetland Forest Research’ Twinning project No 101079192 and the European Regional Development Fund (Centres of Excellence EcolChange, TK131, and AgroCropFuture, TK200).
