32 **Abstract**

33 Mandatory use of low-sulfur fuel according to global sulfur limit regulation has
34 reduced the emissions of SO₂ and PM significantly on ships, while it also leads to very
35 large uncertainty on volatile organic compounds (VOCs) emission. Therefore, on-board
36 test of VOCs from 9 typical cargo ships with low-sulfur fuels in China were carried out
37 in this study. Results showed that emission factor of VOCs (EF_{VOCs}) varied largely from
38 0.09 to 3.01 g kg⁻¹ fuel, with domestic coastal cargo ships (CCSs) had the highest level,
39 followed by inland cargo ships (ICSs) and ocean-going vessels (OGVs). The switch of
40 fuels from heavy fuel oil (HFO) to diesel increased EF_{VOCs} by 48% on average, which
41 enhanced both O₃ and secondary organic aerosol (SOA) formation potentials, especially
42 for OGVs. Besides, the use of low-sulfur fuels for OGVs also lead to significant
43 increase of naphthalene emission. These indicated the implementation of globally ultra-
44 low-sulfur oil policy in the near future needs to be optimized. Moreover, aromatics were
45 the most important common contributors to O₃ and SOA in ship exhausts, which need
46 to be controlled with priority. It was also found that benzene, toluene, and ethylbenzene
47 ratio of 0.5:0.3:0.2 on average could be considered as a diagnostic characteristic to
48 distinguish ship emission from other emission sources.

49 **Keywords:** cargo ships, low-sulfur fuel, VOCs, ozone, secondary organic aerosol

50 **1. Introduction**

51 Maritime transport accounts for more than 80% of global trade by volume (United
52 Nations Conference on Trade and Development, 2020), leading to significant
53 environmental and health effects (Corbett et al., 2007;Liu et al., 2016;Wang et al.,
54 2021a). As a non-ignorable anthropogenic emission source of air pollutants, shipping
55 emission has caused more and more attentions in recent decades. However, most of the
56 previous studies focus on primary pollutants, such as SO₂, NO_x, CO_x, HC, particulate
57 matter (PM) and its components, particulate number (PN), etc. (Zhang et al.,

58 2022b;Santos et al., 2022;Zhou et al., 2019b;Chu-Van et al., 2017;Reda et al.,
59 2015;Buffaloe et al., 2014;Beecken et al., 2014;Moldanova et al., 2013;Fu et al.,
60 2013;Moldanova et al., 2009;Lack et al., 2009;Lack et al., 2008). Only few studies
61 estimate the influence of ship exhaust on secondary photochemical oxidation products,
62 such as O₃ and secondary organic aerosol (SOA), and concern their relative precursors
63 (Jonson et al., 2009;Song et al., 2010;Lang et al., 2017;Wu et al., 2019;Wang et al.,
64 2019;Wu et al., 2020). Results from these limited studies show that the ozone formation
65 potential (OFP) and secondary organic aerosol formation potential (SOAFP) of
66 shipping emissions are much greater than from on-road vehicles due to their higher
67 VOCs emission factors and normalized reactivities (Wu et al., 2019;Wu et al., 2020).
68 Therefore, the neglect of secondary pollutants such as O₃ and SOA would vastly
69 underestimate the actual influence of shipping emissions on environment air.

70 Volatile organic compounds (VOCs) are typical O₃ and SOA precursors. Generally
71 speaking, alkanes, alkenes, aromatics and carbonyls with carbon number > 6 in VOCs
72 can form SOA (Grosjean, 1992;Grosjean and Seinfeld, 1989). While O₃ is formed from
73 the photochemical interactions of volatile organic VOCs and oxides of nitrogen (NO_x),
74 with alkenes having the highest Maximum Incremental Reactivity (MIR), followed by
75 aromatics and OVOCs (Carter, 1994). Typical aromatics, alkenes, and alkanes are the
76 most concerned VOCs from diesel exhausts. For example, Previous studies find that
77 aromatics and alkanes contribute most to SOAFP from diesel exhaust, with single-ring
78 aromatics such as toluene, benzene and xylene et al. are the most contributors (Gentner
79 et al., 2012;Che et al., 2023). Wang et al. (2020) point out that naphthalene, butene,
80 toluene, benzene, and dodecane et al. are the most contributors to OFP from exhausts
81 of diesel trucks. Besides, OVOCs such as formaldehyde, acetaldehyde, and
82 benzaldehyde also have high ozone formation potentials (Yao et al., 2015;Wang et al.,
83 2020). Even though concentrations of PM_{2.5} decreased rapidly in recent years, O₃
84 presented continuous upward trends in most of China (Lu et al., 2020). More and more
85 strict limitations of VOCs have been applied to the main sources such as industrial

86 emission, vehicle exhaust etc., while VOCs from shipping haven't gained much
87 attention. Most of previous studies just give the characteristics of total non-methane
88 hydrocarbons (NMHCs) from ships, but not specific VOC species (Cooper, 2003;Zhang
89 et al., 2016a). Only few studies have reported the VOCs emission factors (EFs) and
90 their composition from specific type of ships under specific operating conditions (Wu
91 et al., 2020;Wang et al., 2020;Wu et al., 2019;Xiao et al., 2018;Zetterdahl et al.,
92 2016;Huang et al., 2018b;Cooper et al., 1996). The limited measured VOCs data cannot
93 reflect the actual situation of shipping emissions. More on-board VOCs measurement
94 for typical ships with representative fuels under different operating conditions need to
95 be carried out, especially after the implementation of low-sulfur fuel policies.

96 According to the International Maritime Organization (IMO), the maximum fuel
97 sulfur content has been set to be 0.5% (m/m) worldwide by 2020, and 0.1% (m/m) in
98 emission control areas (ECAs). The Chinese government also has set the coastal ECAs
99 that require the sulfur content of 0.5% (m/m) since 2019, and 0.1% (m/m) in inland
100 ECAs since 2020 (Ministry of Transport of the People's Republic of China, 2018). The
101 use of ultra-low sulfur fuel ($< 0.1\%$ (m/m)) globally is an inevitable trend in the near
102 future. Fuel quality could affect the pollutants from ship exhausts significantly. For
103 example, a large amount of PM, SO₂ and NO_x have been reduced since the
104 implementation of ship emission control policies (Weng et al., 2022;Wang et al.,
105 2021b;Zhang et al., 2019;Viana et al., 2015;Repka et al., 2021). While it also reveals
106 that the switching of high-sulfur content fuels (sulfur content $\geq 0.5\%$) to low-sulfur
107 content fuels ($0.1\% < \text{sulfur content} < 0.5\%$) leads to significant uncertainties of VOCs
108 emissions from the results of previous studies. For example, Wu et al. (2019) show that
109 the reduction in EF of VOCs (EF_{VOCs}) is 67% when switching from high-sulfur content
110 heavy fuel oil (HFO) to low-sulfur content marine diesel oil for a container ship. While
111 another study finds that after limiting fuel sulfur content, the EF_{VOCs} are approximately
112 15 times that of before implementation of the fuel switch policy (IFSP) from ships at
113 berth in Guangzhou, China. This leads to nearly 29 times greater OFP and

114 approximately 2 times greater SOAFP than those before IFSP (Wu et al., 2020). Huang
115 et al. (2018) also presented similar results of larger SOAFP when switch fuel from high-
116 sulfur content HFO to diesel oil for a large cargo vessel. It seems the low-sulfur fuel
117 regulation has different effects on VOCs emission for different types of ships. Therefore,
118 it is essential to figure out the actual emission of VOCs as well as formation potentials
119 of SOA and O₃ under the condition of low-sulfur fuel regulations. This will greatly
120 reduce the uncertainties in VOCs inventory estimation and provide basic data for the
121 formulation of optimal emission control policies of ships after considering
122 comprehensive impacts on various pollutants.

123 By the end of 2022, China had 121,900 water transport vessels (Ministry of
124 Transport of the People's Republic of China, 2022), 15 ports in China were listed among
125 the top 20 ports in the world for cargo throughput, and 7 container ports were listed
126 among the largest 10 container ports in the world. The large amount of active ships in
127 China has resulted in serious impact on ambient air and human health, particularly in
128 coastal, inland and port areas (Huang et al., 2022;Zhang et al., 2017;Liu et al., 2016).
129 Research reveals that most of the pollutants are from cargo-transport ships compared
130 with other types of ships (Wan et al., 2020). Clarifying the EF of VOCs, profiles,
131 influence factors, and their contribution to O₃ and SOA formation potentials of the
132 typical cargo ships are the basis to estimate the VOCs inventory and to establish proper
133 control measures. Besides, it is also a very important breakthrough point to further
134 improve the ambient air quality in port and nearshore areas by controlling the VOCs
135 emission from ship exhaust.

136 Therefore, on-board test of exhaust pollutants from 9 typical cargo ships in China,
137 including 2 coastal cargo ships (CCSs), 3 ocean-going vessels (OGVs) and 4 inland
138 cargo ships (ICSs) were carried out in this study. VOCs samples from different types of
139 engines with different fuels under actual operating conditions were collected and 106
140 VOC species were analyzed. Based on the data, the following factors were evaluated
141 and discussed in this study: (1) fuel-based emission factor of VOCs (EF_{VOCs}) and their

142 components, (2) influence factors, (3) profiles of VOCs, (4) O₃ and SOA formation
143 potentials.

144 **2. Materials and methods**

145 **2.1 Test ships and fuels**

146 VOCs samples from 9 different ships were collected in this study, including 2
147 coastal cargo ships, 3 ocean-going vessels, and 4 inland cargo ships in Yangtze River.
148 The detailed technical parameters of the sampling ships are shown in Table 1. Different
149 types of cargo ships had different technical parameters in China. For example, the
150 engine powers of coastal cargo ships varied largely, with about 57% are equipped with
151 engines of more than 500 kW. Of the other left coastal cargo ships, 17% of which are
152 ranging from 150 kW to 250 kW. Therefore, one large coastal cargo ship with main
153 engine power of 1470 kW and another small coastal cargo ship with main engine power
154 of 178 kW were selected here. Coastal cargo ships typically transport cargos among
155 different coastal ports, with one to several days per voyage. The main operating modes
156 are cruise (~75% engine load), maneuvering (low and variable engine loads), and idling.

157 Ocean-going vessels usually have large tonnages with large power main engines.
158 Statistical AIS data show that engines with power of 4 kW to 10 kW account for the
159 largest proportion (~25%) of the total OGVs in China, followed by 2 kW to 4 kW (~23%)
160 and 10 kW to 20 kW (~20%). Besides, newly built OGVs have a tendency to have larger
161 and larger engine powers. Hence, three ocean-going vessels with different engine
162 powers ranging from 13.5 kW to 15.7 kW were tested in this study. They are designed
163 for transporting goods across borders, usually with several months per voyage. The
164 main operating mode is cruise in the open ocean. While during the processes of in and
165 out of the port, the engines of OGVs typically active in maneuvering mode with relative
166 lower and variable engine loads, which could have great influence on the nearshore
167 environment due to higher emission levels of pollutants.

168 Most inland cargo vessels are generally equipped with high-speed small main
169 engines of power within 1000 kW (~70%). Among them, the vast majority are below

170 500 kw. Therefore, four typical inland cargo ships of engine power between 138 kW
171 and 300 kW were chosen in this study. The inland cargo vessels typically active among
172 different inland ports or coastal ports near inland rivers, with several hours to several
173 days per voyage. Affected by the complicated water conditions of inland rivers, cruise
174 and maneuvering are the most important operating modes for inland cargo ships.

175 In brief, the measured ships in this study could represent the typical cargo ships in
176 China to a certain extent. It's worth noting that the ocean-going vessels were newly
177 constructed ships, while the inland cargo ships had older engines (6 to 14 years)
178 compared with other types of ships (less than 10 years).

179 Besides, most large cargo ships are equipped with both main engine and auxiliary
180 engine. The main engine provides navigation power, and the engine loads vary greatly
181 with the different operating modes. While the auxiliary engine mainly provides
182 domestic electricity or heating on board, and the engine load is relatively stable with
183 about 75% load. Small cargo ships are equipped only with main engines, such as the
184 tested inland cargo ships and small coastal cargo ships in this study.

185

Table 1 Technical parameters of the sampling ships

Ship ID	Type	Tonnage (kt)	Main engine	Auxiliary engine	Ship age (year)	Implementation standard of fuel
CCS1	Coastal cargo ship	9.17	4-stroke, 1470 kW, 850 rpm	4-stroke, 182 kW, 1500 rpm	3	S<0.5% (m/m)
CCS2	Coastal cargo ship	0.30	4-stroke, 178 kW, 1500 rpm	-	10	S<0.5% (m/m)
OGV1	Ocean-going vessel	180	2-stroke, 15748 kW, 75 rpm	4-stroke, 1280 kW, 900 rpm	0	S<0.5% (m/m)
OGV2	Ocean-going vessel	110	2-stroke, 13500 kW, 91.1 rpm	4-stroke, 900 kW, 900 rpm	0	S<0.5% (m/m)
OGV3	Ocean-going vessel	210	2-stroke, 15745 kW, 75rpm	4-stroke, 1180 kW, 900 rpm	0	S<0.5% (m/m)
ICS1	Inland cargo ship	0.90	4-stroke, 255 kW, 1000 rpm	-	14	S<0.1% (m/m)
ICS2	Inland cargo ship	0.98	4-stroke, 300 kW, 1000 rpm	-	12	S<0.1% (m/m)
ICS3	Inland cargo ship	0.80	4-stroke, 145 kW, 1000 rpm	-	6	S<0.1% (m/m)
ICS4	Inland cargo ship	0.39	4-stroke, 138 kW, 1500 rpm	-	10	S<0.1% (m/m)

188 Characteristics of HFO and diesel oil used for the test ships in this study are shown
189 in Table S1. In order to meet the requirements of diesel engines of non-road mobile
190 machinery of China, regular diesel (0#) was used for all inland cargo ships here. Results
191 showed that the sulfur contents of all the fuels were no more than 0.5% (m/m), which
192 were within both current ship emission control standards of China and IMO. As typical
193 tracers of high-sulfur content HFO, nickel and vanadium content levels and their ratios
194 were still higher but not distinguishable enough in low-sulfur content HFO compared
195 with diesel oil, which further evidence that it needed to be cautious when they were
196 used as tracers of ship emissions under current low-sulfur regulation. While it should
197 be noted that much higher levels of calcium and zinc were detected in lubricating oils
198 of OGVs.

199 **2.2 Sampling system and samples**

200 A portable dilution sampling system was used in this campaign, whose
201 components and principles were described elsewhere (Zhang et al., 2018). Briefly, two
202 separate sampling pipes were placed into the exhaust stacks (about 1.5 m deep of the
203 exhaust outlet) to route emissions from the main engine and auxiliary engine to
204 sampling system on the highest deck of ship, respectively. Then, the probe of a flue gas
205 analyzer (Testo 350, testo, Germany) was placed into the sampling pipe to test the
206 gaseous matters directly to get online data (CO₂, O₂, CO, NO, NO₂, SO₂). Another
207 probe was used to extract the flue gas for the diluted system. The dilution ratios ranged
208 between 1-10 in this study. VOCs samples were collected by summa canister from both
209 main engines and auxiliary engines of all the ships listed in Table 1. The sampling time
210 was 20-30 minutes for each sample according to actual operating condition.

211 A total of 48 VOCs samples were obtained for the test ships, involving different
212 engine types with different fuels under different operating modes (seen Table S2 for
213 detailed information). For the coastal/inland cargo ships, all samples were collected
214 based on actual operating modes (about one to several days from one trip). While for
215 ocean going vessels, samples from much more operating modes could be obtained

216 thanks to the testing of the newly constructed ships (about one week from one trip).

217 **2.3 Chemical and data analysis**

218 As shown in Table S3, a total of 106 volatile organic compounds were detected in
219 this study according to USEPA TO15-1999, including 11 oxygenated volatile organic
220 compounds (OVOCs), 17 aromatics, 29 alkanes, 11 alkenes, 35 halohydrocarbons and
221 4 other species. These measured VOCs species were typical concerned VOCs and could
222 be considered as main VOC components referring to relative studies (Huang et al.
223 2018;Wu et al. 2020;Araizaga, Mancilla and Mendoza 2013), and could reflect the
224 emission conditions of ship exhaust. As shown in formulas (1) and (2), carbon balance
225 method was used to calculate the EF_{VOCs} , which was also introduced in our previous
226 study (Zhang et al., 2016a).

$$227 \quad EF_X = \frac{\Delta X}{\Delta CO_2} \cdot \frac{M_X}{M_{CO_2}} \cdot EF_{CO_2} \quad (1)$$

228 where EF_X is the EF for VOC species X (g/kg fuel), ΔX and ΔCO_2 represent
229 the concentrations of X and CO_2 with the background concentrations subtracted (mol
230 m^{-3}), M_X represents the molecular weight of species X ($g \text{ mol}^{-1}$), M_{CO_2} is the
231 molecular weight of CO_2 (44 g mol^{-1}), and EF_{CO_2} is the EF for CO_2 ($g \text{ (kg fuel)}^{-1}$).

$$232 \quad EF_{CO_2} = \frac{C_F}{c(C_{CO})+c(C_{CO_2})+c(C_{PM})+c(C_{HC})} \cdot c^*(CO_2) \cdot M_{CO_2} \quad (2)$$

233 where C_F represents the mass of carbon in 1 kg diesel fuel ($g \text{ C (kg fuel)}^{-1}$), $c(C_{CO})$,
234 $c(C_{CO_2})$, $c(C_{PM})$, and $c(C_{HC})$ represent the mass concentrations of carbon as CO,
235 CO_2 , PM, and HC ($g \text{ C m}^{-3}$), respectively, in the flue gas, and $c^*(CO_2)$ is the molar
236 concentration of CO_2 ($mol \text{ m}^{-3}$).

237 Detailed calculation processes of normalized ozone reactivity (R_{O_3} , $g \text{ O}_3 \text{ g}^{-1}$
238 VOCs), OFP ($g \text{ O}_3 \text{ kg}^{-1}$ fuel), normalized secondary organic aerosols reactivity (R_{SOA} ,
239 $mg \text{ SOA g}^{-1}$ VOCs) and SOA formation potential (SOAFP, $mg \text{ SOA kg}^{-1}$ fuel) are given
240 as follows:

241 Normalized ozone reactivity (R_{O_3} , $g \text{ O}_3 \text{ g}^{-1}$ VOCs) and OFP ($g \text{ O}_3 \text{ kg}^{-1}$ fuel) were
242 calculated using the maximum incremental reactivity (MIR) coefficient method (Carter,
243 2010a), which represents the maximum contribution of VOC species to the near-surface

244 O₃ concentration under optimal conditions. The equations are as follows:

$$245 \quad R_{O_3} = \sum_i(\omega_i \times \text{MIR}_i) \quad (3)$$

246 where ω_i is the mass percentage of the total VOC emissions for species i , MIR_i
247 is the MIR coefficient for VOC species i , which was referenced from Carter (2010b),
248 seen in Table S3 for details.

$$249 \quad \text{OFP} = \sum_i(\text{MIR}_i \times [\text{VOC}]_i) \quad (4)$$

250 where OFP is the ozone formation potential (g kg⁻¹ fuel), $[\text{VOC}]_i$ is the emission
251 factor for VOC species i (g kg⁻¹ fuel).

252 The same as O₃, normalized secondary organic aerosols reactivity (R_{SOA} , mg SOA
253 g⁻¹ VOCs) and SOA formation potential (SOAFP, mg SOA kg⁻¹ fuel) were also
254 calculated, whose equations are as follows:

$$255 \quad R_{\text{SOA}} = \sum_i(\omega_i \times Y_i) \quad (5)$$

$$256 \quad \text{SOAFP} = \sum_i(\text{EF}_i \times Y_i) \quad (6)$$

257 where Y_i is the SOA yield for VOC species i (seen in Table S4 for details). Both
258 SOAFP of VOCs under high-NO_x and low-NO_x conditions were calculated.

259 **2.4 Quality assurance and quality control**

260 Rigorous quality assurance and quality controls were conducted during the whole
261 experiment. Ambient air blanks were analyzed in the same way as mentioned above to
262 determine background concentration. The VOCs concentrations of each sample were
263 obtained by subtracted ambient air blank results. Duplicate samples as well as standard
264 gas were examined after analyzing a batch of 10 samples to ensure that the error was
265 within 5%.

266 **3. Results and discussion**

267 **3.1 Emission factors and components of VOCs**

268 EF_{VOCs} for the test ships are shown in Fig.1 and Table S5. In order to calculate the
269 EF_{VOCs} and investigate their influence factors, EFs of other gaseous pollutants such as
270 CO₂, CO, NO, NO₂ were also given and discussed briefly. For CO₂, the emission factors
271 ranged from 2622 to 3185 g kg⁻¹ fuel that influenced by both fuel type and operating

272 mode. CO showed opposite trend with CO₂, varying from 0.62 to 180 g kg⁻¹ fuel,
 273 reflecting the condition of combustion efficiency. The EF_{NO_x} ranged from 6.26 to 92.8
 274 g kg⁻¹ fuel, with 60% to 99% of whom were NO, which inferred the condition of
 275 combustion temperature in cylinder.

276 Results showed that the EF_{VOCs} for all the test ships presented wide differences,
 277 which were ranging from 0.09 to 3.01 g kg⁻¹ fuel. Ship type, engine type, operating
 278 mode and fuel type could influence the EF_{VOCs} that would be discussed in more detail
 279 in Section 3.2. Briefly, higher VOCs had been observed both in low-load and high-load
 280 operating modes such as maneuvering and idling, while in medium-load operating
 281 modes, the EF_{VOCs} presented lower levels (detailed result was also shown in Fig. 3 (a)).
 282 Main engines presented obviously higher EF_s levels than auxiliary engines (Fig. 3 (c)
 283 for details). And CCSs and ICSs had relatively higher EF_s compared with OGVs (Fig.
 284 3 (d) for details). It was worth noting that when the fuels were switched from HFO to
 285 marine diesel oil for OGVs, increasing trends were presented for EF_{VOCs} in this study.
 286 While the CCSs showed the opposite trend with a slight decrease for EF_{VOCs}.

287

288 Figure 1 Emission factors of gaseous pollutants under all operating conditions for the

289 test ships

290 Average EF_{VOCs} emitted from ships in this study were also compared with those
291 reported in other studies (Table 2). Altogether, the measured EF_{VOCs} varied largely from
292 0.02 to 23.7 g kg⁻¹ fuel for all the test ships. Complex factors could lead to the large
293 uncertainty, such as the different detected VOC species in different studies, different
294 engine types and fuel qualities. This also indicated that the uncertainty should be
295 noticed when EF_{VOCs} were used as basic data to calculate emission inventory or estimate
296 other environmental influence. The test ships in this study presented comparable EF_{VOCs}
297 level with other studies. It seemed that OGVs with large engines typically showed lower
298 EF_{VOCs} levels no matter what types of fuels were used compared with river ships and
299 costal ships. Moreover, compared with on-road vehicles with diesel fuel (Zhou et al.,
300 2019a), VOCs emitted from non-road engines, such as ship, agricultural machinery and
301 construction machinery, had much higher levels (Huang et al., 2018a; Hua et al.,
302 2019; Zhou et al., 2022), which should be paid more attention, especially in the case of
303 more and more strict limitations of VOCs have been applied to on-road vehicles.

Table 2 EFs of VOCs from ships in this study and previous studies

Ship type	Sulfur content (%)	Operating mode	EF of VOCs (g kg ⁻¹ fuel)	Number of detected VOCs species	Data sources
Coastal cargo ship / Ocean going vessel					
CCS (main-HFO)	0.39	Cruise	2.24	106	This study

305 a, the EFs values were estimated based on Fig.2. b, the EFs were calculated by assuming that the fuel consumption rate for the test ships was 200 g fuel kWh⁻¹

306

307 Components and mass fractions of VOCs from the test ships are shown in Fig. 2
308 and Fig. S1. OVOCs and aromatics were the main components of the detected VOC
309 species, accounting for 9.38% - 88.0% and 5.38% - 74.0% of total VOCs, respectively.
310 Alkanes also accounted for non-ignorable fractions, which were ranging from 0.2% to
311 57.2%. While alkenes, halohydrocarbons and other quantified species only contributed
312 small fractions of the total VOCs. The results in this study were consistent with that of
313 Huang et al. (2018) about a large ocean-going bulk carrier, but showed different VOCs
314 components with that of Wu et al. (2019) for a coastal container ship and Wu et al.
315 (2020) for auxiliary engines at berth. The different detected VOCs species in different
316 studies played an important role for the differences, while the fuel type and its chemical
317 composition might also have considerable impacts.

318 The main VOCs components of OVOCs, aromatics, alkanes and alkenes presented
319 different variation patterns under different operating modes, fuel types, and engine
320 types due to their different formation mechanisms (Fig. 2). For example, OVOCs from
321 diesel engines are typically from the oxidation of small molecular weight yet
322 uncomplete combustion hydrocarbons (Hao et al., 2014;Pan, 2008), therefore,
323 operating mode and engine type could influence the EF levels obviously, but not fuel
324 type. The direct emission of unburned fuel components and pyrosynthesis (formation
325 of aromatics by regeneration of fragmented radical species) are the two main formation
326 processes of PAHs (Radischat et al., 2015). EFs of aromatics showed relatively higher
327 levels in medium operating modes compared with other modes in this study. One main
328 reason was that the higher temperature in medium operating modes promoted the
329 polymerization, resulting in the processes of dehydrogenation and PAH formation
330 (Zhang et al., 2021), which exceeded the direct emission of unburned fuel components
331 (Radischat et al., 2015). Alkanes are mainly from the incomplete combustion of fuels,
332 therefore, alkanes from diesel fuel presented higher EFs than HFO because of the higher
333 aliphatic compounds in diesel fuel (Liu et al., 2022;Sippula et al., 2014). While alkenes
334 emitted from diesel engine are always related to the pyrolysis process of the fuel

335 combustion in the cylinder (Alotaibi et al., 2018;Zhang et al., 2022a). As a result, in
 336 high operating modes of more than 90% engine loads, it had higher EF_{alkenes} levels in
 337 this study due to the pyrolysis process under higher temperature and incomplete
 338 combustion because of the less air to fuel ratios in the cylinder.

339

340 Figure 2 EFs of VOC components and their mass fractions

341

342 3.2 Influence factor analysis

343

344 It was mentioned above that influence factors such as operating condition, engine
 345 type, ship type and fuel type could affect the emission level and component of VOCs
 346 from ship exhaust. Box-whisker plots of VOC emission factors under these different
 347 drivers are presented in Fig. 3. As shown in Fig. 3 (a), engine load could affect the
 348 VOCs emission significantly. EF_{VOCs} had the lowest level when the engines were
 349 operating in medium loads, and the highest in low loads. This was consistent with the
 350 results of VOCs emission reported by previous studies such as Huang et al. (2018), Wu
 351 et al. (2019) and Radischat et al. (2015), which were also shown in Fig. S2. The
 combustion condition in the cylinder could be responsible for the variation of VOCs
 emission, which meant incomplete combustion was one principal reason for the high

352 VOCs emission.

353 Engine type is also one significant influence factor of VOCs emission. The engines
354 were classified into three types in this study according to their engine speed, including
355 low-speed engines (LSE, rated speed < 100 rpm), medium-speed engines (MSE, 100
356 rpm \leq rated speed < 1000 rpm) and high-speed engines (HSE, rated speed \geq 1000 rpm).
357 It could be seen from Fig. 3 (b) that with the increase of engine speed, the EF_{VOCs}
358 showed an increasing trend. This could be explained by that compared with HSEs, LSEs
359 with high engine power usually had higher combustion efficiencies that led to lower
360 levels of VOCs emission (Zhang et al., 2018).

361 The EF_{VOCs} between main engines and auxiliary engines also varied obviously.
362 The average EF_{VOCs} from the main engines was 2.3 times that of auxiliary engines in
363 this study (seen in Fig. 3 (c)). Similar result was also reported by Liu et al. (2022) about
364 the intermediate volatile organic compounds (IVOCs) emission for the same test OGVs.
365 Even though the auxiliary engines were mainly high-speed or medium-speed engines
366 that had higher VOCs emissions mentioned above. Owing to the much lower VOCs
367 emission in medium loads that the auxiliary engines have been using, it could be
368 inferred that the impact of operating condition exceeded that of the engine type to VOCs
369 emission.

370 As seen in Fig. 3 (d), the EF_{VOCs} varied obviously under different types of ships,
371 with CCSs having the highest levels and OGVs the lowest. This could be explained by
372 the combined influence of operating condition and engine type as mentioned above.
373 Firstly, as shown in Fig. 3 (b), high-speed and medium-speed engines were equipped
374 for the CCSs, they could lead to higher EF_{VOCs} compared with low-speed engines that
375 equipped for OGVs. Besides, the unstable operating conditions of SSCs and ICSs, such
376 as maneuvering and low-load, also promoted the emission of VOCs (Radischat et al.,
377 2015). Therefore, it could be indicated that coastal areas with high population density
378 need get more attention due to the higher VOCs emissions from CCSs and ICSs.

379 As mentioned before, fuel type could influence the EF_{VOCs} significantly (Wu et al.,

2019;Wu et al., 2020), which also would be one of the most important influence factors in the future under the background of increasingly strict ship oil policy. Under the condition of low-sulfur content fuels in China, the average EF_{VOCs} were 592 mg kg⁻¹ fuel and 878 mg kg⁻¹ fuel for diesel and HFO in this study, respectively (seen in Fig. 3 (e)). In addition to the direct emission of unburned fuel components, VOCs also could be emitted from the pyrosynthesis process of the fuel in the cylinder (Radischat et al., 2015). In order to explore the relationship between chemical composition of low-sulfur content fuel and VOCs emission, n-alkanes, b-alkanes and aromatics in the fuels from OGVs were tested (Liu et al., 2022) (seen in Table S6 for details). Obviously, diesel had higher content of n-alkanes and b-alkanes than HFO, and aromatics were the opposite. It could be seen from Fig. S3 that both the $EF_{Alkanes}$, $EF_{Alkenes}$ and $EF_{halohydrocarbons}$ from ships with diesel presented higher levels compared with that of HFO. $EF_{Aromatics}$ and other components showed the opposite trends. While no obvious difference of EF_{VOCs} was observed between diesel and HFO. Emission characteristics of VOC main components were basically consistent with fuel composition in this study. It could be provided that the composition of fuel did have significant impact on VOC emissions.

To further explore the impact of sulfur content of fuel on VOCs emissions, EF_{VOCs} of low-sulfur content fuel (<0.5% m/m) and high-sulfur content fuel ($\geq 0.5\%$ m/m) in this study and previous studies were summarized in Fig. 3 (f). The average EF_{VOCs} from low-sulfur content fuel was significantly higher than that of high-sulfur content fuel, with almost 3.4 times. This indicated that when the fuels were switched from high sulfur to low sulfur, there was dramatic increase in VOCs emissions. Low-sulfur content fuels are usually produced in three ways, including blending technique that use light low-sulfur oils mixed with heavy high-sulfur oils, heavy oil hydrogenation technology that remove sulfur through hydrogenation of high-sulfur residual oil, and biological desulfurization technology that use microbial enzymes catalyze and oxidate the organic sulfur in oil, convert it into water-soluble sulfide and then remove (Kuimov et al., 2016). Among these, blended low-sulfur oils are the most widely used oils (Zhang, 2019;Han

408 et al., 2022). Except for light low-sulfur oils mixed during the production of low-sulfur
 409 oils, other non-petroleum refined oils, such as coal tar and chemical waste are also
 410 added. Consequently, emission factors as well as the composition of VOCs have
 411 changed significantly. Since low-sulfur content fuels (<0.5% m/m) have been using
 412 worldwide since 2020, and 0.1% (m/m) in ECAs since 2015, it would imply that the
 413 impact of fuel type on VOCs emissions needed to be given sufficient attention.

414
 415 Figure 3 Box-whisker plots of VOC emission factors under different influence factors

416 3.3 Profiles and diagnostic characteristics of VOCs

417 3.3.1 Profiles of VOCs

418 Fig. 4 presents the mass fractions of VOCs (except halohydrocarbons,
 419 tetrahydrofuran, carbon disulfide, and 1,4-dioxane and due to their very small mass
 420 fractions (0.55%-3.06% of total VOCs)) from the three types of test ships (CCS, OGV
 421 and ICS) under different engine types (main engine and auxiliary engine) and fuels
 422 (HFO and diesel). Detailed mass fractions of all the test VOC species in this study were
 423 also given in Table S7. As shown in Fig. 4, the profiles of VOCs showed obvious
 424 differences. To be specific, the most abundant VOC species were acetone and acrolein

425 in OVOCs, propene and butene in alkenes, n-Nonane, n-Decane, n-Undecane, n-
426 Dodecane in alkanes for almost all the test ships. As for aromatics, the OGVs showed
427 big differences compared with other types of ships that had large amounts of
428 naphthalene, while benzene, toluene and m/p-xylene were the highest content aromatic
429 substances for other ships. Previous studies about OGVs showed the similar high
430 naphthalene and acetone contents in the exhaust when use low-sulfur fuels (Agrawal et
431 al., 2010;Huang et al., 2018b). Besides, high levels of formaldehyde and acetaldehyde
432 were also found in exhausts from OGVs (Agrawal et al., 2010). Unfortunately, because
433 of the limitation of testing methods, they were not measured in this study. Due to the
434 high reactivity and the important role in formation of secondary organic aerosols,
435 formaldehyde and acetaldehyde needs to get more attention from ship exhausts,
436 especially for OGVs. In addition, a small scientific research ship (499 t, 5 years, high-
437 speed engine, 0# diesel) was also tested in this study, whose VOCs profile was given in
438 Fig. S4 for comparison. Obviously, the VOCs profile pattern was very similar with that
439 of inland cargo ships with the same small high-speed engines and 0# diesel as fuel,
440 indicating the significant impact of engine type and fuel type.

441

442 Figure 4 Mass fractions of individual VOCs from test ships under different engine types
 443 and fuels (except halohydrocarbons, tetrahydrofuran, carbon disulfide, and 1,4-
 444 dioxane and due to their very small mass fractions)

445 The top 25 VOC species from the test cargo ships are presented in Table S8. It
 446 could be seen that most of the top 25 VOC species emitted from exhausts were the same
 447 but with different rankings for different engine types under different fuels. For example,
 448 OVOCs, alkenes and aromatics were the most abundant VOC species for the main
 449 engines of CCS and ICS, while alkanes were ranked as the highest content VOC species

450 for auxiliary engine. As mentioned above, naphthalene and acetone were the absolute
451 highest two VOC species for OGVs. While other VOC species were different from
452 different fuels for OGVs, such as high alkenes, OVOCs and aromatics from exhausts
453 of HFO fuel, but high alkenes, OVOCs and alkanes from exhausts of diesel fuels. This
454 high naphthalene emission has also been shown in other studies (Radischat et al.,
455 2015;Huang et al., 2018c;Yeh et al., 2023). The unusually high naphthalene from OGVs
456 needed to be noted. Naphthalene was mainly formed during the pyrolyzation from
457 incomplete combustion and direct emission of unburned fuel components (Radischat et
458 al., 2015). A recent study reported that the addition of additives of naphthalene-based
459 lubricants to low-sulfur fuel during the blended fuel manufacturing process to improve
460 stability could lead to an increase in PAHs emission in exhaust, with naphthalene being
461 the main pollutant (Yeh et al., 2023). To further explore the extent to which the content
462 of naphthalene in fuel affects EFs of naphthalene in ship exhaust, several chemical
463 compositions such as alkanes and aromatic contents in fuels of the test OGVs were
464 measured and shown by Liu et al. (2022) (Seen in Table S6). Results showed that the
465 average naphthalene content in HFO was almost 30 times higher than that in diesel.
466 When the engine was operated in the same operating condition, higher $EF_{\text{naphthalene}}$ was
467 observed from HFO than diesel. Therefore, we infer that chemical component in fuel
468 does influence the emission of PAHs including naphthalene in the exhaust. Besides,
469 VOCs with lower molecular weights such as acetone and acrolein were the dominant
470 OVOCs compounds in this study. The main reason is probably as follows: OVOCs
471 compounds are typically derived from the oxidation of VOCs with incomplete
472 combustion (Hao et al., 2014), while VOCs with lower molecular weights have a higher
473 chance to be oxidized to form oxides than those with higher molecular weights which
474 are often broken up to VOCs with less carbon number during the oxidation process
475 (Wang et al., 2020).

476 Furthermore, characteristics of VOCs based on carbon number are also given and
477 discussed in this study. The detected VOC species were classified into 12 groupings,

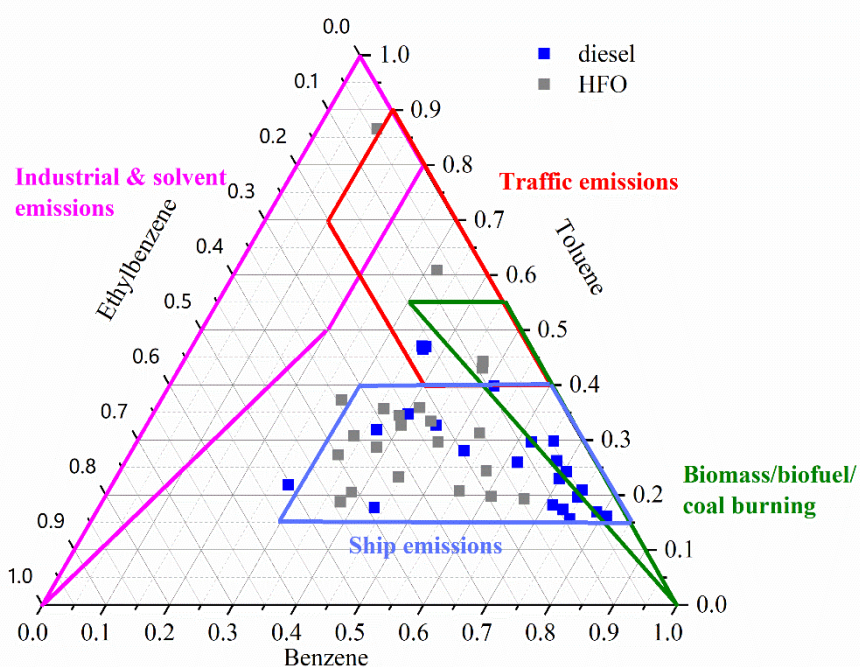

478 from C1 to C12 (Fig. S5). Different types of ships with different fuels showed obvious
479 differences in components. For example, C3 VOCs were found to be the most important
480 species for all test ships, while C10 showed much higher mass fractions from OGVs
481 than other ships, which was caused by the high naphthalene content. The same as VOCs
482 profiles, ICSs and scientific research ships presented very similar VOCs mass fraction
483 distributions of the 12 groupings. Besides, except for the auxiliary engine of CCS with
484 diesel oil, the OGVs emitted comparatively higher high-carbon number (C7-C12)
485 components than low-carbon number (C1-C6) components.

486 3.3.2 Diagnostic characteristics of VOCs

487 Diagnostic ratios of pair species, such as toluene to benzene (T/B), ethylbenzene
488 to m,p-zylene (E/X), n-butane to isopentane (n-Bu/i-Bu) and isopentane to n-pentane
489 (i-P/n-P), are always used to identify potential emission sources (Zhang et al., 2016b;Li
490 et al., 2021;Song et al., 2018;Song et al., 2020). These ratios from ship exhausts in this
491 study are shown in Table S9. T/B was further analyzed here as it is the most widely used
492 diagnostic ratio among them. It was reported in previous study that the T/B ratios were
493 <1 for biomass/biofuel/coal burning, 1 to 10 for vehicle emissions, and >1 for solvent
494 applications or industrial processes (Zhang et al., 2016b). In this study, the T/B ratios
495 varied between 0.29 and 1.28 from ship exhausts, which were overlapped with
496 biomass/biofuel/coal burning sources to some extent. However, it could be considered
497 to distinguish on-road diesel vehicles with a T/B ratio of 1.5 ± 0.8 (Wang et al.,
498 2013;Yao et al., 2015) and non-road diesel construction vessels with a T/B ratio of 1.4
499 ± 1.3 . The results were similar with that of 0.45 - 0.57 from Wu et al. (2020) and 1.07
500 from Xiao et al. (2018), but significantly differed from that of 4.81 - 42.8 from Huang
501 et al.(2018c).

502 In order to overcome the overlapping effects of the T/B ratio among different
503 emission sources and better distinguish ship emissions from other emission sources, a
504 ternary diagram of the relative compositions of Benzene, Toluene, and Ethylbenzene
505 from ship exhausts in this study was presented in Fig. 5. The B:T:E ratios were

506 0.50:0.30:0.20 on average from the test ships, differed from that of 0.69:0.27:0.04 for
 507 biomass /biofuel/coal burning, 0.06:0.59:0.35 for industrial emissions, and especially
 508 0.31:0.59:0.10 for traffic emissions, respectively (Zhang et al., 2016b). Besides, most
 509 of the relative compositions of B, T, and E from ship exhausts in this study were
 510 relatively stable and mainly concentrated within certain area that was seldom
 511 overlapped with other emission sources in the ternary diagram. This indicated that the
 512 B: T: E ratios could be considered as a diagnostic characteristic to distinguish ship
 513 emission from other emission sources, especially the traffic emissions.

514
 515 Figure 5 Relative proportions of benzene, toluene and ethylbenzene from the ship
 516 exhausts. B:T:E ratios from other sources were cited from Zhang et al. (2016b) that
 517 summarized 28 examples from biomass burning, 35 examples from biofuel burning, 17
 518 examples from coal burning, 11 examples from diesel vehicle exhaust, 31 examples
 519 from gasoline vehicle exhaust, 24 examples from gasoline evaporation, 25 examples
 520 from roadside or tunnel tests, and 66 examples from industrial processes and solvent
 521 applications.

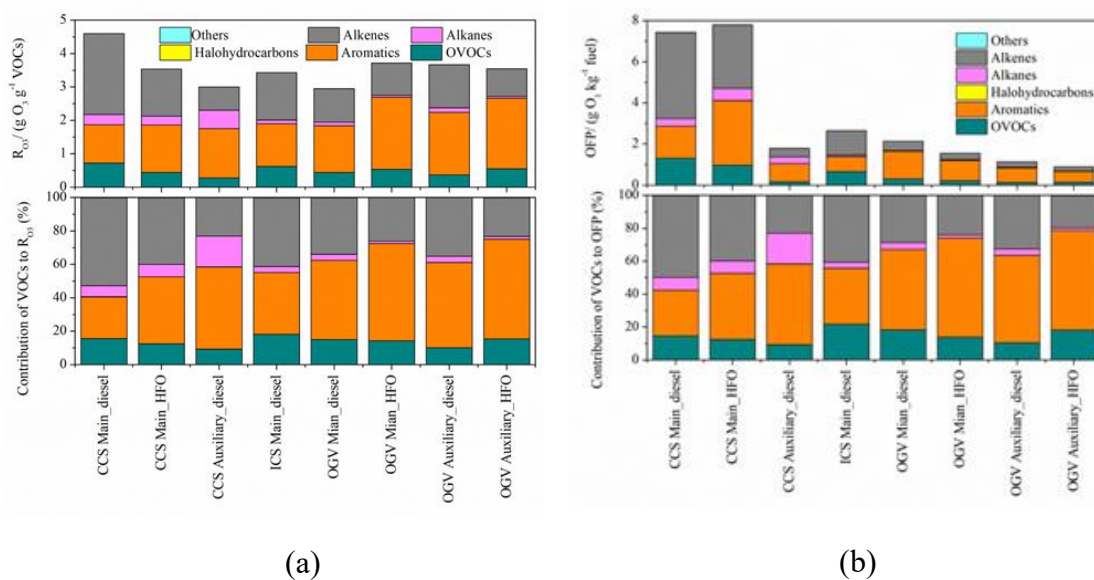

3.4 Ozone and SOA formation potential

3.4.1 Ozone formation potential

The normalized ozone reactivities (R_{O_3}) ranged between 2.95 and 4.60 g O₃ g⁻¹ VOCs for the test ships (presented in Fig. 6 and Table S10) in this study, meaning there was diversity of ozone reactivities in VOCs from different ships, which was due to the different shares of VOC species emitted from different ships with different fuels. The R_{O_3} values were within the range of previous reported results estimated by Wu et al. (2020) (2.62 to 5.41 g O₃ g⁻¹ VOCs) and Wu et al. (2019) (approximately 4.5 to 6.0 g O₃ g⁻¹ VOCs), but showed different fragments of VOC species to R_{O_3} . The different detected VOC species was also one inferred reason for the variation of R_{O_3} in different studies. Aromatics and alkenes were the most significant contributors to R_{O_3} in this study due to their high reactivities. Aromatics had relatively higher contributions for the OGVs, and the CCSs and ICSs were more affected by alkenes, excepted for the auxiliary engine with diesel oil of CCSs. Besides, it also can be seen from Fig. 6 (a) that when the fuels were switched from diesel to HFO, more aromatics were contributed to R_{O_3} because of the higher aromatic but lower aliphatic compounds in HFO (Sippula et al., 2014). On the contrary, alkenes showed reverse trends with aromatics, which were attributed to engine combustion and operation conditions of the test ships, as well as the high content of alkenes in diesel fuel in China (Mo et al., 2016).

As described in Fig. 6 (b), the OFP varied significantly from 0.91 to 7.81 g O₃ kg⁻¹ fuel, with the main engines of CCSs presented the highest levels, but auxiliary engines of OGVs the lowest, even though the R_{O_3} showed no such big differences among all the test ships. The main reason was the huge variation of EF_{VOCs}, as well as the difference in component of VOC species emitted from different ships with different fuels. However, due to the missing of OVOC species such as formaldehyde, acetaldehyde, and benzaldehyde in this study, the presented OFPs were underestimated. The same as R_{O_3} , aromatics and alkenes were the most significant contributors to OFP, accounting for 28-61% and 20-50% of the total OFP, respectively. It's worth noting that

550 when the fuels were switched from HFO to diesel for the OGVs, there were obvious
 551 increasing OFP trends. This was similar with result of Huang et al. (2018b) that HFO
 552 had lower OFP compared with diesel fuel about an ocean-going vessel and Wu et al.
 553 (2020) that after implementation of the fuel switch policy for ships at berth, OFP
 554 increased from 0.35 to 10.37 g O₃ kg⁻¹ fuel. However, the CCS had slightly higher OFP
 555 value with HFO than diesel in this study. A previous study also reported that OFP from
 556 HFO was ~3.3-fold higher than from burning diesel for a coastal container ship (Wu et
 557 al., 2019). It seemed that when the fuels were switched from high sulfur to low sulfur,
 558 there was obvious increase in OFP, especially for OGVs. While when the fuels were
 559 switched from low sulfur HFO to ultra-low sulfur diesel (sulfur content <0.1%), the
 560 OFP would be also influenced by other factors, such as engine type, which needs to be
 561 further explored by more on-board measurements. Besides, river ships and costal ships
 562 had higher OFP than OGVs, and main engines had higher OFP than auxiliary engines,
 563 which were consistent with previous study (Wu et al., 2020).

564
 565 Figure 6 (a) The normalized ozone reactivity (R_{O_3} , g O₃ g⁻¹ VOCs) and contribution of
 566 VOC species to R_{O_3} , (b) ozone formation potential (OFP, g O₃ kg⁻¹ fuel) and
 567 contribution of VOC species to OFP

568 3.4.2 SOA formation potential

569 The same as R_{O_3} , normalized SOA reactivities (R_{SOA}) under high-NO_x and low-

570 NO_x conditions were also estimated and presented in Fig. 7 (a), (b), and Table S10. The
571 R_{SOA} ranged from 63.2 to 134 mg SOA g⁻¹ VOCs under high-NO_x condition and 137 to
572 312 mg SOA g⁻¹ VOCs under low-NO_x condition in this study, which were within the
573 range of previous reported results (Wu et al., 2020;Huang et al., 2018b;Xiao et al.,
574 2018;Wu et al., 2019), but at relatively higher levels compared with these studies.
575 Unlike R_{O₃}, the R_{SOA} showed relatively higher values for OGVs compared with CCSs
576 and ICSs. The main reason for this was the content difference of heavy organic
577 compounds in VOCs, such as higher proportion of naphthalene that has high SOA yield,
578 which is also presented above in Table S4 and Fig. 4. Huang et al. (2018c) also showed
579 the similar R_{SOA} levels about a test OGV. Almost all the R_{SOA} were contributed from
580 aromatics and alkanes in this study. There were different variation trends of the total
581 R_{SOA} between different fuels for different types of ships, but obvious higher proportions
582 of aromatics for ships with HFO than diesel fuel due to the higher aromatic contents in
583 fuels, while alkanes were the opposite. Besides, the R_{SOA} of ship exhausts in this study
584 showed much higher levels compared with other traffic sources presented in previous
585 study (Xiao et al., 2018), including diesel trucks and gasoline vehicles, which suggested
586 that VOCs from ship exhaust deserved special attention.

587 The SOAFP in this study were ranging from 26.5 to 140 mg SOA kg⁻¹ fuel and
588 71.5 to 303 mg SOA kg⁻¹ fuel under high-NO_x and low-NO_x conditions, respectively
589 (Fig. 7 (c) and (d)). The SOAFP values in this study were within the range of previous
590 studies but showed relatively higher levels, which might be mainly caused by both the
591 different detected VOCs species and the variation of VOCs EFs. Even though OGVs
592 had relatively higher R_{SOA} levels, due to the variation of EFs among the test ships,
593 SOAFP showed different patterns with R_{SOA}. Main engines in this study had higher
594 SOAFP values than auxiliary engines, no matter what type of fuel was used, indicating
595 the important effect of engine type. The same as OFP, the switch of fuel from HFO to
596 diesel could increase SOAFP for OGVs. Similar results were also found from Wu et al.
597 (2020) that after IFSP, the SOAFP increased 1.6 times and 2.5 times under high-NO_x

598 and low-NO_x conditions, and Huang et al. (2018b) that higher SOAFP was presented
599 from diesel than from HFO. The CCSs showed opposite SOAFP variation trend with
600 OGVs, also similar with Wu et al. (2019) that SOAFP from HFO was 2.1-fold higher
601 than that of diesel. Moreover, the same as R_{SOA}, aromatics and alkanes were the most
602 significant contributors to SOAFP, and there were also obvious higher proportions of
603 aromatics to SOAFP for ships with HFO than diesel fuel. The main reason for this was
604 that EFs of aromatics from engines with HFO were higher than that of diesel fuel due
605 to the higher content of aromatics of HFO than diesel. It has been indicated that
606 intermediate VOCs (IVOCs) were significant SOA precursors with high yields
607 (Robinson et al., 2007; Tkacik et al., 2012). In another of our study, IVOCs from the test
608 OGVs were also detected, and the SOAFP of IVOCs from several selected conditions
609 (main engine and auxiliary engine of cruising loads, using MGO and HFO, respectively)
610 were calculated (Liu et al., 2022). Results showed that the SOAFP from IVOCs of the
611 main engine by using diesel and HFO were 540.5 and 482.1 mg SOA kg⁻¹ fuel,
612 respectively, 542.2 and 451.3 mg SOA kg⁻¹ fuel for auxiliary engine, respectively.
613 Obviously, the switch from low-sulfur fuel of HFO to ultra-low-sulfur fuel of diesel
614 could also increase the SOAFP from IVOCs. Even though SOAFP from VOCs were
615 lower than that of IVOCs, they were still not negligible, especially under low-sulfur
616 fuel policies.

617

618 Figure 7 The normalized SOA reactivity (R_{SOA} , mg SOA g⁻¹ VOCs) and contribution of
 619 VOC species to R_{SOA} under (a) high NO_x, (b) low NO_x; and the SOAFP (mg SOA kg⁻¹
 620 fuel) and contribution of VOC species to SOAFP under (c) high NO_x, (d) low NO_x

621 3.4.3 Top 20 contributing VOC species to OFP and SOAFP

622 Due to the significant contribution of VOCs to O₃ and SOA, it is essential to
 623 distinguish the most contributing VOC species for the formulation of emission
 624 reduction policies. Therefore, the top 20 contributing VOC species to OFP and SOAFP
 625 are presented in Table S11 and Table S12. Most of the listed VOC species to OFP and
 626 SOAFP among different engine types and fuels were the same but with different
 627 rankings. For example, propene was the most contributing VOC species to O₃ for the
 628 main engines of CCSs and ICSs, followed by acrolein, trimethyl benzene, butene etc.

629 While trimethyl benzene, propene and acrolein were ranking as the top VOCs species
630 to OFP for the auxiliary engine of CCSs. As for OGVs, naphthalene was the most
631 contributing VOC species to O₃, followed by propene, acrolein, 1,3-butadiene and
632 xylene etc. As shown in Table S12, the top VOCs species contributed to SOAFP were
633 benzene, naphthalene, n-dodecane, n-undecane and xylene etc. for all the test ships.
634 Naphthalene was undoubtedly the most contributing VOC species to SOAFP for OGVs.
635 In conclusion, it was obvious that as the important common contributors to both O₃ and
636 SOA, aromatics should be prioritized in control. Besides, VOCs species with high O₃
637 reactivities also need to be paid enough attention, such as alkenes, even though with
638 low emission factor levels.

639 **4. Conclusions and atmospheric implications**

640 Shipping emission is a non-ignorable anthropogenic emission source of air
641 pollutants, especially in coastal areas. Therefore, more and more strict emission control
642 regulations have been implemented globally. For example, the maximum fuel sulfur
643 content has been set to be 0.5% (m/m) worldwide by 2020, and 0.1% (m/m) in ECAs.
644 The Chinese government also has set the coastal ECAs that require the sulfur content
645 of 0.5% (m/m) since 2019, and 0.1% (m/m) in inland ECAs since 2020. The mandatory
646 use of low-sulfur fuels has reduced the emissions of SO₂ and PM significantly on ships,
647 while it also leads to very large uncertainty on VOCs emission. In view of this, on-
648 board test of VOCs from 9 typical cargo ships with low-sulfur fuels in China were
649 carried out in this study.

650 Results showed that EF_{VOCs} varied largely from 0.09 to 3.01 g kg⁻¹ fuel, with
651 domestic coastal cargo ships (CCSs) had the highest levels and ocean-going vessels
652 (OGVs) the lowest. The test ships in this study presented comparable EF_{VOCs} level with
653 other studies. However, the measured EF_{VOCs} varied largely among different studies
654 due to complex reasons such as different detected VOC species, different engine types
655 and fuel qualities. OVOCs and aromatics were the main components of the detected
656 VOC species, followed by alkanes, while alkenes, halohydrocarbons and other

657 quantified species only contributed small fractions.

658 The emission level and component of VOCs from ship exhaust could be affected
659 by complex influence factors such as operating condition, engine type, ship type and
660 fuel type. For example, EF_{VOCs} had the lowest level when the engines were operating
661 in medium loads, and the highest in low loads. Besides, with the increase of engine
662 speed, the EF_{VOCs} showed an increasing trend. The average EF_{VOCs} from the main
663 engines was 2.3 times that of auxiliary engines in this study. Moreover, the EF_{VOCs}
664 varied obviously under different types of ships, with CCSs having the highest levels
665 and OGVs the lowest. It needs to be noted that fuel type could influence the emission
666 of EF_{VOCs} significantly. The switch of fuels from heavy fuel oil to diesel increased
667 EF_{VOCs} by 48% on average in this study. A bigger cause for concern is that from the
668 summarized results in this study and previous studies, the average EF_{VOCs} from low-
669 sulfur content fuel was significantly higher than that of high-sulfur content fuel, with
670 almost 3.4 times.

671 The most abundant VOC species were acetone and acrolein in OVOCs, propene
672 and butene in alkenes, n-Nonane, n-Decane, n-Undecane, n-Dodecane in alkanes for
673 almost all the test ships. As for aromatics, the OGVs showed big differences compared
674 with other types of ships that had large amounts of naphthalene due to the use of low-
675 sulfur fuels, while benzene, toluene and m/p-xylene were the highest content aromatic
676 substances for other ships. We also found that benzene, toluene, and ethylbenzene ratio
677 of 0.5:0.3:0.2 on average could be considered as a diagnostic characteristic to
678 distinguish ship emission from other emission sources.

679 The OFP in this study varied significantly from 0.91 to 7.81 g O₃ kg⁻¹ fuel, with
680 the main engines of CCSs presented the highest levels, but auxiliary engines of OGVs
681 the lowest. The SOAFP in this study were ranging from 71.5 to 303 mg SOA kg⁻¹ fuel
682 under low-NO_x conditions. Main engines in this study had higher SOAFP values than
683 auxiliary engines, no matter what type of fuel was used, indicating the important effect
684 of engine type. It's also worth noting that when the fuels were switched from high sulfur

685 to low sulfur, there was obvious increase in OFP and SOAFP, especially for OGVs.
686 Moreover, aromatics were the most important common contributors to O₃ and SOA in
687 ship exhausts, which need to be controlled with priority.

688 It could be concluded from this study and previous studies that either the switch
689 of high-sulfur HFO to low-sulfur HFO, or low-sulfur HFO to ultra-low-sulfur diesel,
690 VOCs emissions from OGVs increased significantly, which further promoted the
691 formation potential of O₃ and SOA, especially in coastal areas. Therefore, the
692 implementation of the ultra-low-sulfur oil policy in the near future is likely to further
693 increase the emission of VOCs, which needs to be optimized. Besides, the results herein
694 indicated that aromatics are absolutely the most important common contributors to OFP
695 and SOAFP, which need to be controlled with priority in ship exhausts. Since aromatics
696 are typically from the polymerization, improving engine combustion conditions of ship
697 engine is an effective way to reduce O₃ and SOA from ship exhausts, especially in
698 coastal and inland areas. Moreover, organic matters such as naphthalene from ship
699 exhausts with low-sulfur HFO should be explored and considered to be potential tracers
700 to identify ocean going ships from coastal and inland ships. Lastly, the EFs and profiles
701 of VOCs emitted from ship exhausts varied significantly, one important reason was that
702 the sample size of on-board measured VOCs was too small, in addition, the detection
703 methods and detected VOCs species differed greatly among different studies. Therefore,
704 much more on-board tests need to be implemented and standard VOCs detection
705 method as well as essential VOCs species should be clarified, especially under current
706 low-sulfur regulation.

707 **Author contributions**

708 FZ, YZ, CH, HW, YC and GW conceptualized and designed the study; BX, ZL,
709 CT, XW, YH, MC, and YC performed the measurements; FZ, RL, CW, YL, SZ, and
710 GW analyzed the data. FZ wrote the manuscript draft; All the authors reviewed, edited,
711 and contributed to the scientific discussion in the manuscript.
