11 **Abstract.** The violent explosion of the Hunga Tonga-Hunga Ha'apai volcano on January 15, 2022, was the
12 origin of an atmospheric wave and a volcano-meteorological tsunami (VMT), both of which were recorded
13 worldwide. The Tonga tsunami event caused resonance effects, leading to wave amplification in some far-
14 field coastal areas like La Pampilla port in Callao, Peru, 10,000 km away from the volcano, where the
15 rupture of the Vessel mooring lines occurred 15 hours after the eruption, resulting the spill of over 11,000
16 barrels of crude oil. This study aims to better understand the coastal effects of the Tonga tsunami, focusing
17 on mooring loads in marine port environments. We examine how the VMT affected the safety of vessel
18 moorings, hypothesising that atmosphere-induced acoustic ocean waves exerted hydrodynamic loading that
19 endangered ships in port areas. A tsunami propagation obtained with a validated Boussinesq model at the
20 local scale in Callao Bay provides the input to the mooring system model applied to a vessel with similar
21 characteristics to the one docked at La Pampilla Port on the day of the Tonga event. This allows to study
22 the effect of the VMT on overstraining and the potential mooring breakage. The results suggest that the
23 Tonga tsunami event could be responsible for the movement and loss of positioning of the vessel.
24 Furthermore, atmospheric waves significantly increased mooring stresses, particularly on the starboard
25 quarter moorings. This event showed the need to prepare Tsunami Early Warning Systems and port
26 authorities for detecting and managing VMTs induced by atmospheric acoustic waves. The work provides
27 new insights into the far-field effects of the Tonga 2022 tsunami and discusses the lessons learned from
28 such an uncommon event.

29 **1. Introduction**

30 Volcanic activity can trigger tsunamis through underwater explosion, caldera collapse, pyroclastic flow,
31 flank collapse, or atmospheric gravity waves produced by large explosions (Paris, 2015). Throughout
32 history, tsunamis of volcanic origin have been poorly studied due to their scarcity, leading to a limited
33 understanding of their generation mechanisms and impacts at local, regional, and global scales (Hayward
34 et al., 2022). To better understand this type of tsunami geneses and, therefore, reduce the epistemic

35 uncertainties associated with it, several studies have been carried out (Antonopoulos, 1992; Pararas-
36 Carayannis, 1992, 2004), which also include aquatic environments other than oceans, such as great lakes
37 in Russia and The Philippines (Belousov et al., 2000; Falvard et al., 2018). In these studies, the 1883
38 eruption of the Krakatau volcano in the Sunda Strait (Indonesia), is commonly accepted as a main reference
39 and a unique example (Kienle et al., 1987), as it was the first event of its kind recorded by different
40 instruments worldwide (Paris et al., 2014; Yokoyama, 1981).

41 The Hunga Tonga-Hunga Ha'apai volcano (HTHH) is a submarine volcano near an island with the same
42 name, and located 65 km NNW of the island of Tongatapu capital of Tonga, Nuku'alofa (20.55°S,
43 175.39°W, see location in Figure 1). It is one of several active volcanoes in the Kingdom of Tonga, an
44 archipelago nation in the South Pacific. The latest eruptive phase of the HTHH volcano began in mid-
45 December 2021 with vigorous shallow-water explosive activity. On January 15, 2022, the volcano erupted
46 at 4:00 a.m. UTC (Tonga Volcanic Eruption & Tsunami, 2022). Tonga experienced a volcano-
47 meteorological tsunami (VMT) following a violent volcanic explosion that generated atmospheric gravity
48 waves that propagated several times across the globe (Omira et al., 2022; Wright et al., 2022). These waves
49 resulted from particle agitation in the atmosphere, travelling both vertically and horizontally at sonic and
50 supersonic speeds (Kubota et al., 2022; Matoza et al., 2022; Wright et al., 2022; Dogan et al., 2023). Reports
51 of ocean-free surface elevations greater than 1 m, causing damage to ports and infrastructure, emerged after
52 the volcano explosion, originating from coastal areas near Tonga to the northwest and southeast Pacific
53 (Ramírez-Herrera et al., 2022; Imamura et al., 2022). The affected locations include Australia, New
54 Zealand, the United States, Mexico, and Peru, resulting in economic losses of approximately \$102 million
55 due to damages to floating docks, vessels, and infrastructure (Terry et al., 2022; World Bank, 2024).

56 The Tonga VMT was exceptional as it travelled at faster speeds than common tsunamis, had a global reach,
57 affected the far-field coasts, and caused noticeable damages, human fatalities, and coastal hydrodynamic
58 effects (Terry et al., 2022; Omira et al., 2022; Lynett et al., 2022). In their study, Omira et al. (2022)
59 demonstrated that the primary source of the globally observed Tonga tsunami was the acoustic gravity
60 waves radiated from the volcanic explosion. Here, the sizeable tsunami at some distant coasts (i.e., South
61 America and Japan) was associated with the amplified ocean waves under Proudman resonance (Proudman,
62 1929) when the atmospheric wave propagated over very deep water (i.e., oceanic trenches). Other triggering
63 mechanisms, including the submarine volcanic explosion, likely contributed to the generation of the locally
64 observed tsunami in the far-field (Lynett et al., 2022; Omira et al., 2022).

65 The consequences of harbour-intruding long waves on moored vessels have been investigated by numerous
66 studies (Ayca and Lynett, 2016, 2018, 2021; Kirby et al., 2022; Wilson et al., 2017). Seismic tsunamis often
67 cause damage to port environments, such as broken moorings, collisions, or subsidence due to the large
68 amount of momentum flux travelling within the harbour (Lynett et al., 2022; Ohgaki et al., 2008; Inoue et
69 al., 2001). This also applies to tsunamis induced by atmospheric disturbances, which, like the previous ones,
70 have caused damage to ships, moored vessels, and small bays (Imamura et al., 2022; Thomson et al., 2009).
71 It has been observed in these studies that strong currents, often accompanying long-period waves, increase
72 the probability of generating large catastrophes in harbours (Shigeaki and Masayoshi, 2009; Sakakibara et

73 al., 2010; Zheng et al., 2022; Lynett et al., 2012). Likewise, based on DOFs (Degrees Of Freedom), some
74 authors such as López and Iglesias (2014) agree with the hypothesis that the motions in the vessel's
75 horizontal plane (named roll, heave, and yaw) are strongly correlated with the total tsunami wave energy,
76 with the currents being quite significant in ship sway response (Inoue et al., 2001). Furthermore, Ohgaki et
77 al. (2008) and Zheng et al. (2022) mention that tsunamis are usually closer to the natural period of a mooring
78 system (>80 sec), which makes these waves more prone to generate damage. Given the non-linearity of
79 physical processes, it is pertinent to perform specific studies focused on each situation, configuration, and
80 need (Zheng et al., 2022).

81 In La Pampilla Port in Peru, 10,000 km away from the Tonga volcano, the Italian-flagged oil tanker Mare
82 Doricum reported the breakage of their mooring lines, 15 hours after the explosion of the HTHH volcano.
83 The ship captain associated the breaking of the vessel's moorings with the abnormal waves in the sea, for
84 which no warning was issued (SPDA Actualidad Ambiental, 2024). The Peruvian National Tsunami
85 Warning System (CNAT) stated that the Tonga tsunami did not generate a tsunami on the Peruvian coast
86 (CNAT, 2022). However, the tide gauge located in Callao Bay recorded a sudden change in sea level
87 coincident with the time of the accident (Sea level station monitoring facility, 2022). This article addresses
88 the impact of the Tonga 2022 tsunami on vessels moored on the Peruvian coast. It uses both sea-level data
89 analysis and numerical modelling to improve the understanding of the damage caused by far-field Tonga
90 VMT, studying its influence on the safety of moored vessels.

91 **2. Data and Methods**

92 Considering the complexity of the Tonga tsunami event, which likely involved multiple triggering volcanic
93 mechanisms, analysing waves measured by both oceanic and atmospheric instruments is highly important
94 (Wright et al., 2022). Firstly, we used the wavelet analysis to examine the composition of the signals
95 recorded by both tidal gauges and DART buoys. Secondly, we studied the hydrodynamic effects of the
96 Tonga tsunami in the far field, using tsunami numerical simulations (Boussinesq-type model) over high-
97 resolution bathymetric models. Thirdly, we developed an analytical model to assess the stresses due to
98 hydrodynamic loads on moored vessels.

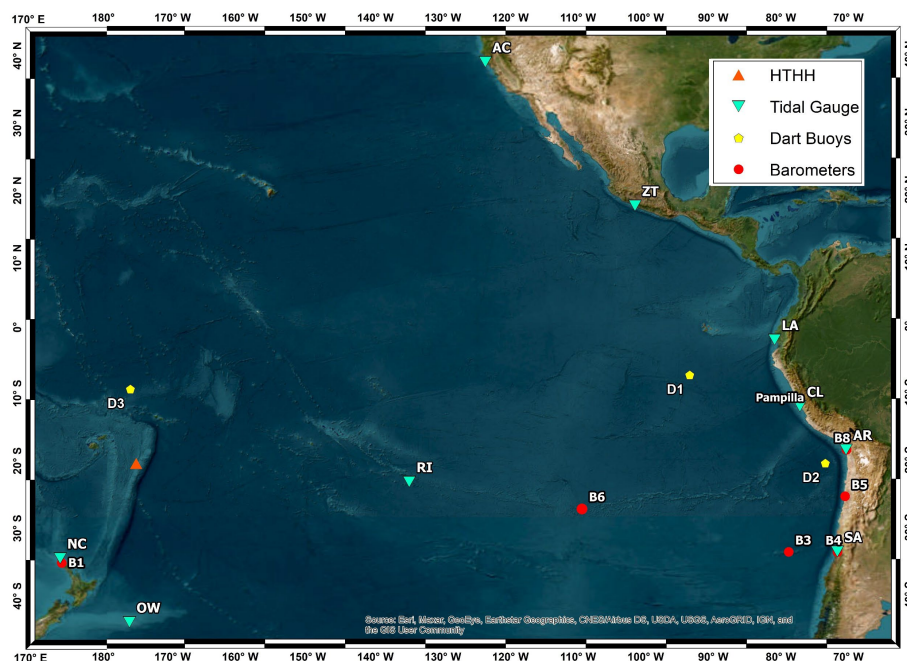

99 **2.1. Air pressure and sea level data**

100 The data used in this study includes records from DART buoys, tide gauges, and weather stations in the
101 Pacific Ocean. Figure 1 shows the location of the instruments considered in this study, with red circles
102 representing the atmospheric pressure sensors, light blue triangles for the tide gauges, and yellow dots for
103 the DART buoys.

104 The deep-water sea level time series (**D1**, **D2**, and **D3**) were obtained from the DART buoys, which in turn
105 managed by the Center for Operational Oceanographic Products and Services of the National Oceanic and
106 Atmospheric Administration (NOAA, <https://www.ndbc.noaa.gov/>). Coastal sea level data used in this
107 study come from tidal stations connected in real-time to the Sea Level Station Monitoring Facility of
108 UNESCO's Intergovernmental Oceanographic Commission (IOC, <http://www.ioc->

109 sealevelmonitoring.org/). The **B1** air pressure data have been obtained from local agents in New Zealand
 110 (NIWA, <https://niwa.co.nz/>) and those from stations **B3**, **B4**, **B5**, and **B8** came from the Dirección General
 111 De Aeronáutica Civil de Chile (DGAC, <https://climatologia.meteochile.gob.cl/>) through the Chilean
 112 Meteorological Office.

113
 114 **Figure 1. Locations of the measuring instruments. Red circles show the atmospheric pressure sensors, the light**
 115 **blue triangles show the tide gauges, and the yellow circles refer to the Dart Buoys. The location of the Tonga**
 116 **volcano (HTTH) is the orange triangle.**

117 The sea level time series were de-tided using bandpass filters of 1.5 min-2.5 hours and 2 min - 3 hours for
 118 DART and tide gauge data, respectively, following Lynett et al. (2022). For atmospheric pressure data, a
 119 bandpass filter of 1.5 min - 2.5 hours was used (Table 1). Figure 2 shows the filtered time-series. The air-
 120 pressure time-series shows a notable peak of approximately 2 hPa with the "N-wave" pulse shape associated
 121 with the leading Lamb wave (Lynett et al., 2022; Omira et al., 2022).

124

125 Figure 2. De-tided time series. Air pressure data (right panel), tide gauge, and Dart data (left panel). Vertical
126 red lines used to scale the magnitude of the variations in each instrument.

127 **2.2. Spectral analysis**

128 Spectral analysis is a practical tool for identifying the characteristic frequencies and energy levels in a time-
129 series, particularly when it is composed of the superposition of signals with different frequencies. This
130 method has found extensive application in the study of tsunamis (Abe, 2011; Rabinovich, 1997;
131 Shevchenko et al., 2011; Satake et al., 2013; Baptista et al., 2016; Xu et al., 2022). In the time domain, we
132 use wavelets to perform spectral analysis, allowing the estimation of the evolution of the spectral energy
133 and, consequently, the first instants of energy increase for a given specific period.

134 **2.3. Tsunami propagation model**

135 Although air-ocean interaction has been recognized as a primary mechanism for the global fast-travelling
136 Tonga 2022 tsunami (Omira et al., 2022), volcano-ocean interaction provided valid explanations for the
137 near-field observation (Lynett et al., 2022; Pakoksung et al., 2022). As our primary target is Callao Bay,
138 located approximately 10,000 km away from the HTHH volcano (Figure 3), we only focused on the tsunami
139 induced by the atmospheric disturbances that followed the volcano explosion. The hypothesis of a point-
140 source tsunami reaching the South American coast was ruled out considering the modelling results of a
141 tsunami generated by the underwater explosion of the HTHH volcano (Omira et al., 2022).

142

143 **Figure 3. Callao Bay and location of the vessel (Orange vessel) in the offshore port of La Pampilla, Peru.**

144 To simulate the VMT triggered by the explosion of the HTHH volcano, we used the finite volume GeoClaw
145 code equipped with atmospheric pressure forcing terms that are handled using the flux-splitting method in
146 momentum balance (Mandli and Dawson, 2014). This numerical code was validated in various

147 meteotsunami studies (Kim and Omira, 2021; Kim et al., 2022; Omira et al., 2022). The determination of
148 atmospheric source terms is based on barometric records from three distinct-selected observations in **B1**,
149 **B6**, and **B8** (see Table 1 for details). We assumed the symmetrical propagation of atmospheric pressure
150 from the source (HTHH volcano) at a constant speed of 310 m/s. Since a point source simulation on a
151 sphere has two singularities (at the origin and antipode), we used a relaxation method as described in Omira
152 et al. (2022).

153 Initially, our computational domain is between 40°S to 40°N and 170°E to 65°W, with a coarse bathymetry
154 resolution of 1 degree, as obtained from GEBCO (<https://www.gebco.net/>). To achieve a finer spatial
155 representation of the study area (i.e., Callao Bay), we employed four levels of refinement with resolutions
156 of 1°, 1°/5, 1°/30, and 1°/2, using an adaptive mesh refinement (AMR), with a maximum refinement level
157 of 3 across the entire domain. The full resolution of approximately 800 meters was reinforced near Callao
158 Bay with local higher-resolution bathymetry data (GEOGPS PERÚ, <https://www.geogpsperu.com/>). To
159 account for the bottom friction, GeoClaw software uses Manning's formulation, and the Manning
160 coefficient of 0.02 was considered in this work. Our simulations were conducted using the Madsen's
161 Boussinesq-type equations, with a constant value of $B = 1/15$ (Kim et al., 2017; Madsen and Sørensen,
162 1992).

163 The computation was performed on Intel Core i7-8700 CPU 3.2GHz using 10 cores corresponding to 1161
164 hours of propagation time, and 119 hours of wall time.

165 **2.4. Stresses in moored ships model**

166 Here, we use an analytical model to estimate the loads on a vessel's mooring system under the
167 hydrodynamic effects of a tsunami (Tahar and Kim, 2004; OCIMF, 2010). The vessel is modelled as a rigid
168 body with six degrees of freedom (DOFs). The first three DOFs are the surge, sway, and heave (x , y , and z)
169 of the vessel's centre of gravity (C_{OG}), given in the global frame (Figure 4). The other three are the Euler
170 angles, roll, pitch, and yaw (α , β , and γ), which describe the local frame rotation status with respect to the
171 global frame.

172 We considered two reference frames, the first of which is a global orthogonal inertial frame (fixed) with its
173 origin located somewhere at the mean water level, where the X-axis points eastward and the Z-axis points
174 upward for the global frame. The second is an orthogonal non-inertial frame, moving with the vessel, with
175 its origin located at the C_{OG} . The X-axis points toward the bow while the Z-axis points upward for the local
176 frame. The roll and pitch initial equilibrium positions are considered at zero degrees.

177

178

179 **Figure 4. Definition of Ship Motions in Six Degrees of Freedom, the yellow ones describe translation and the red**
 180 **ones rotation.**

181 The model contemplates the vessel's hydromechanics and physics characteristics such as hydrostatic
 182 stiffness (which considers both buoyancy and gravity forces), vessel mass (m), metacentric heights ($GM_{t,l}$),
 183 and inertial forces defined by the vessel's moments of inertia around the principal axes ($I_{x,y,z}$) as well as
 184 describing the vessel's stability (Journée and Massie, 2001). The vessel's dynamics are described with the
 185 equations of a forced and damped mass-spring system which allows the following initial value problem
 186 (Eq. 1):

$$187 \begin{cases} \dot{Y} = f(Y, t) = \begin{bmatrix} \dot{\xi} \\ \ddot{\xi} \end{bmatrix} = \begin{bmatrix} \dot{\xi} \\ M^{-1} \cdot [B \cdot \dot{\xi} + G \cdot (\xi - \xi_0(t)) + F_m(\xi) + F_d(\xi, t)] \end{bmatrix} \\ Y(t = 0) = Y_0 \end{cases} \quad (1)$$

188 where Y_0 is the initial vessel state vector, containing the initial position and the speed of the vessel, B is the
 189 damping matrix, G is the stiffness matrix, ξ is defined as the stacking of all the DOFs, ξ_0 is the initial
 190 equilibrium position, and F_m and F_d are the mooring system forces and the current drag forces (Figure 5).

191

192

193 **Figure 5. Schematic layout of Ship Mooring system forces F_m and Drag Forces F_d . The dynamics of the moored**
 194 **vessel are defined with a second-order ordinary differential equation (ODE)**

195 The mooring system F_m is exclusively considered when the movement of the vessel results in a greater
196 increase in the length of the line L_i compared to the previous position, as shown in the following Eq. (2):

$$197 F_{m,i} = \begin{cases} K_i \cdot (L_i - L_{0,i}) \cdot \frac{r_{A,i} - r_{F,i}}{L_i}, & L_i > L_{0,i} \\ 0, & L_i \leq L_{0,i} \end{cases} \quad (2)$$

198 Where K_i includes Elastic properties for the i -th line, L_i is the line length, r_A and r_F are the pile and fairlead
199 positions (where the line is tied to the hull). The Morison drag force model (Oh et al., 2020) is utilized to
200 calculate the drag force F_d . The tsunami current at time t is defined by its speed. The current drag force
201 changes depending on the angle of incidence, the $F_{d,x,y}$, calculated as Eq (3):

$$202 F_{d,x,y}(\xi, t) = \frac{1}{2} \rho \cdot V(t) \cdot L_{BP} \cdot T \cdot \begin{pmatrix} \cos(\gamma) & -\sin(\gamma) \\ \sin(\gamma) & \cos(\gamma) \end{pmatrix} \cdot \begin{pmatrix} C_x(|\theta(t)|) \\ C_y(|\theta(t)|) \cdot \text{sgn}(\theta(t)) \end{pmatrix} \quad (3)$$

203 Where C_x and C_y are the drag forces in the x and y axes, ρ is the water density, $V(t)$ is the tsunami current
204 velocity, L_{BP} is the length between the perpendicular, T is the vessel's draft, and γ is the Yaw DOF. We
205 considers the tsunami current angle θ to be parallel to the vessel's centerline at zero degrees. Finally, this
206 first-order ODE is integrated with a Runge-Kutta-4-5 method implemented in the SciPy Python library
207 (Dormand and Prince, 1980; Shampine, 1986).

208 The model inputs consist of the vessel's dimensions, hydromechanical and mass properties, the ship's
209 berthing scheme (including piles and fairleads coordinates), the line properties (such as young modulus and
210 length), and the temporal tsunami dynamics (including waves and currents time-series) at the vessel's
211 location. The model outputs the movements in each DOF and the resulting stress, measured in tons, for
212 each line throughout the time series.

213 3. Results

214 3.1. Atmospheric and oceanic data analysis

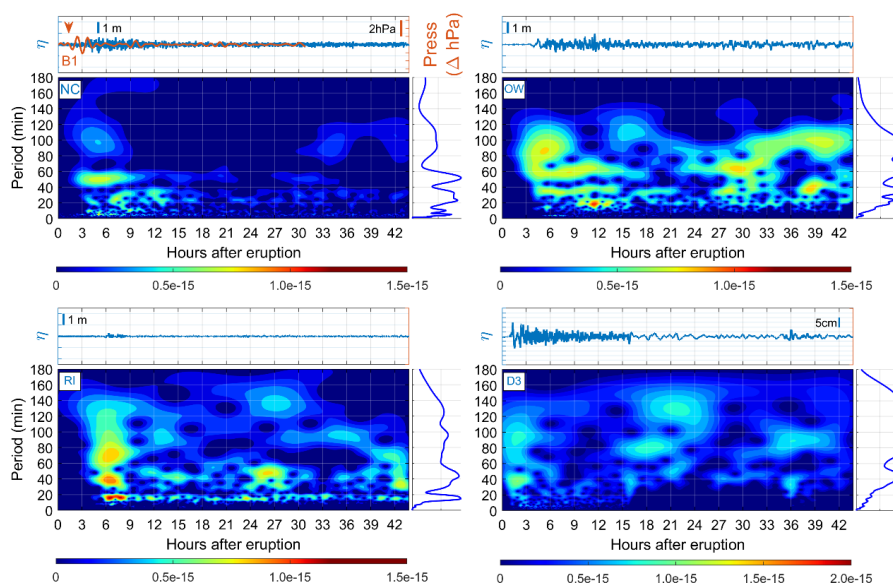

215 The analysis using wavelets is based on the hypothesis that the atmospheric waves' integral characteristics,
216 such as the periods and propagation velocities, remain reciprocal when resonance is generated between
217 atmospheric and oceanic waves. This allows the current knowledge extrapolation about atmospheric waves,
218 which have been extensively studied in the literature, and their effect on oceanic tsunami waves.

219 The results in Figure 6, Figure 7, and Figure 8 show the analysis of the recorded atmospheric and sea-level
220 signals, which are composed of three panels for each sensor. The top panel shows the filtered time-series
221 of both sea level and atmospheric pressure (blue and orange respectively). The orange arrow indicates the
222 leading Lamb wave arrival time respectively. The lower panel shows the spectral results (wavelets) of the
223 de-tided series of the ocean surface, the red-blue color scale marks the highest and lowest energy
224 concentrations respectively; to the right is the Fourier spectrum obtained from integrating the wavelet over
225 time.

226 Results in Figure 6 correspond to the tide gauges **NC**, **OW**, and **RI**, DART buoy **D3**, and pressure sensor
 227 **B1** (see Figure 1 for location). Wavelets consistently show four energy groups for sensors tide gauges **NC**,
 228 **OW**, **RI**, and DART buoy **D3**. These results allows for the identification of the initial characteristics of
 229 tsunami waves forced by atmospheric waves, i.e., the arrival times and wave periods.

230

231

232 **Figure 6.** Analysis of air-pressure and sea-level records at tide gauges **NC** (North Cape, New Zealand), **OW**
 233 (**Owenga**, New Zealand) and **RI** (**Rikitea**, France), DART buoy **D3** (51425, NDBC), and air-pressure sensor **B1**
 234 (North Cape, New Zealand). For each sensor, the time series of the air-pressure sensor (orange line) and tide
 235 gauge (blue line) are shown in the upper panel. The orange arrow refers to the arrival time of the leading
 236 pressure pulse. The panel to the right of the wavelet is the resulting frequency spectrum (FFT) of the time
 237 integration of the wavelet.

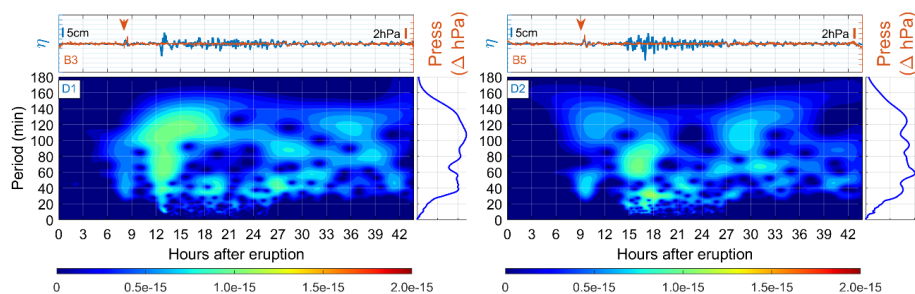

238 The energy clusters fall within the 5-10 min, 20 to 40 min, 40 to 60 min, and 80-120 min periods, do the
 239 energy clusters suggest that there were multiple mechanisms that generated the Tonga tsunami waves.
 240 These results are consistent with the findings of previous studies (Hu et al., 2023; Kubota et al., 2022;
 241 Omira et al., 2022). The manometer station **B1** and tide gauge **NC** allow the estimation of the propagation
 242 velocities of the atmospheric disturbances as approximately 324 m/s.

243 Figure 7 shows far-field results (deep waters near the Peruvian coast) in sensors **D1-B3** and **D2-B5**. Air-
 244 pressure time-series shows the 2 hPa pulse associated with the leading Lamb wave arrived first, followed
 245 by second disturbances travelling at more than 200 m/s (Hu et al., 2022; Omira et al., 2022). DART buoy
 246 wavelets provide more spectral information related to the physical properties of these atmospheric waves
 247 coupled in the ocean. For example, DART Buoy **D2** shows that the first pulse coincides with the leading
 248 Lamb wave between 30- and 60- minute periods arriving 9 hours after the main eruption. Then, there is a
 249 group of energy contained in four ranges of periods: (i) about 10 min, (ii) between 20 and 40 min, (iii)
 250 between 60 and 90, and (iv) between 100 and 140 min. The latter is possibly associated with the air-ocean

251 Proudman resonance that occurred on the Tonga Trench and propagated as common tsunami gravity waves
 252 towards the Southern American coast (Omira et al., 2022).

253

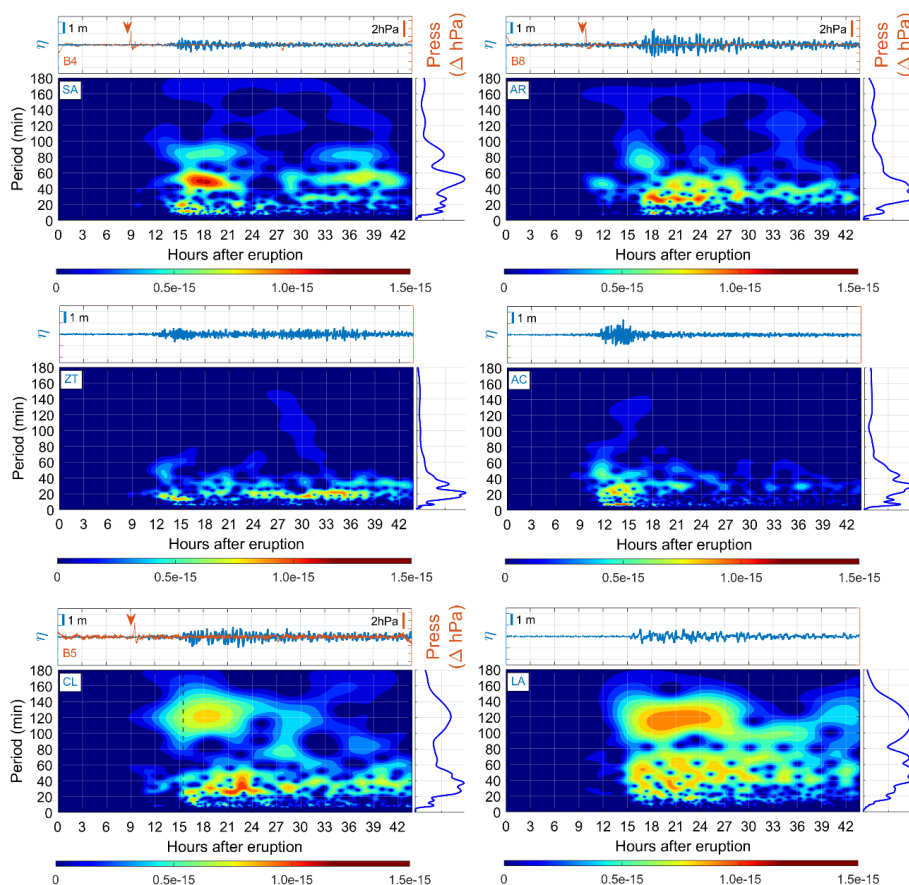

254

255 **Figure 7.** Analysis of air-pressure and sea-level records at DART buoys D1 (32413, NDBC) and D2 (32401, NDBC) and atmospheric pressure sensors B3 (330031, Chile) and B5 (250005, Chile). For each sensor, the filtered time series of the atmospheric pressure sensor (orange line) and tide gauge (blue line) are shown in the upper panel. The orange arrow refers to the arrival of the leading pressure pulse. The right panel of the wavelet is the frequency spectrum resulting from the time integration of the wavelet.

260 Figure 9 shows the spectral results for other locations along the Pacific American coasts. The South Pacific American instruments are SA-B4 (Chile), AR-B8 (Chile), CL-B5 (Peru) and AL (Ecuador). The sensors in Central and North America are ZT (Mexico) and AC (USA). The wavelets' results in Chile, Mexico, and the USA show several energy groups: one in 40 - 60 min periods, another group between 20 - 40 min, and finally, energy in periods less than 10 min. Those wavelets exhibit a pattern similar to that observed in deep water sensors, with a notable difference regarding the absence of periods close to 120 min.

266 Subsequently, Figure 8 shows the analysis for sensors LA (Ecuador), CL-B5 (Peru), 15 km from the vessel accident. The black dotted vertical line on the CL wavelet refers to the moment when the ship's moorings break and the oil spill occurs, according to the captain of the ship Mare Doricum. It can be observed in the CL wavelet that: (i) the Lamb wave coupled in the ocean (spectral energy between 30 - 60 min periods), (ii) the mooring break moment coincides with the high period spectral energy (max between 110-130 min period). Additionally, the energy within the 100 to 140 min period is present in deep water, (e.g., at DART buoy D1 in Figure 4) and amplified exclusively in front of the Ecuador and Peru coasts (LA and CL tide gauges).

274

275

276 **Figure 8.** Analysis of air-pressure and sea level records at the tide gauges of SA (San Antonio, Chile), AR (Arica,
 277 Chile), ZT (Zihuatanejo, Mexico), AC (California, USA), CL (Callao, Peru), and LA (La Libertad, Ecuador).
 278 The upper panel shows the time series of the atmospheric pressure sensor (orange line) and tide gauge (blue
 279 line). The orange arrow refers to the arrival of the leading Lamb wave. For the lower panel, we have the Wavelet.
 280 The vertical black dashed line in the CL wavelet refers to the instant when the vessel's moorings broke at La
 281 Pampilla port, Peru. The panel to the right of the wavelet is the frequency spectrum.

282 3.2. Numerical modelling of atmospheric pressure-induced tsunami waves

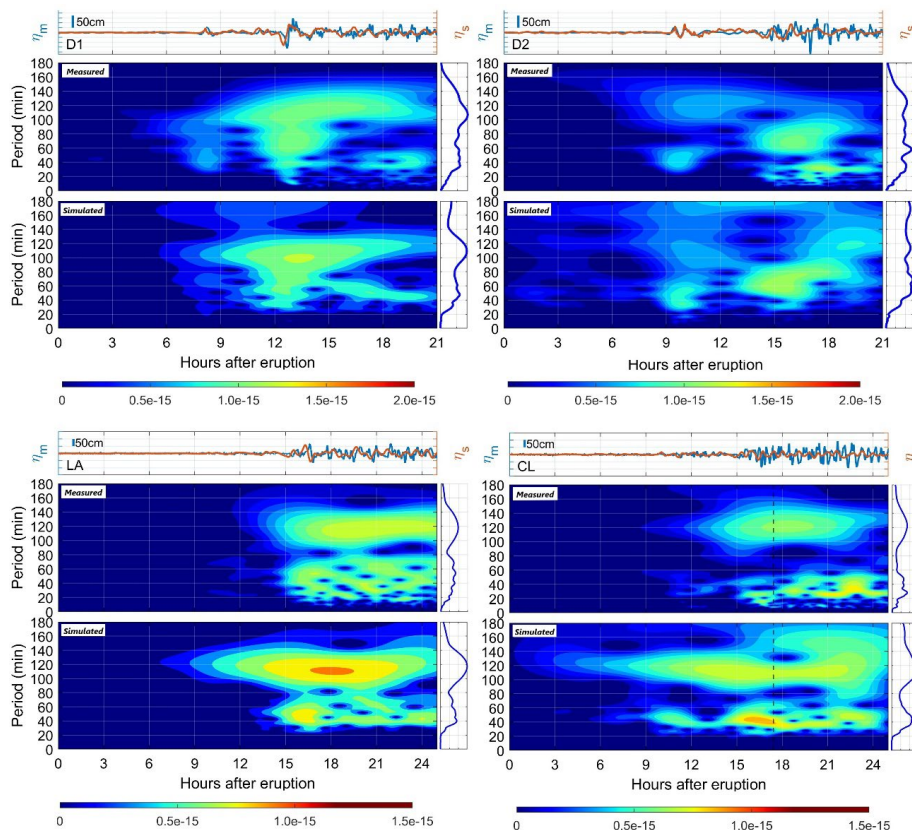

283 The numerical simulations have been calibrated/validated using both far- and near-field instrumental data.
 284 After validation, the significance of tsunami-like waves induced by atmospheric acoustic-gravity waves
 285 and tsunami-induced waves resulting from the submarine explosion were analyzed. We present the results
 286 in Figure 9, which shows the observed and simulated tsunami waveforms near the coast of Peru.

287 A comparison of observed and simulated tsunami waveforms at DART buoys (D1 and D2) shows that the
 288 Boussinesq numerical model correctly reproduces the first tsunami wave. It also fairly reproduces the
 289 second train of tsunami waves, likely associated with air-ocean resonance in deep ocean (near Tonga
 290 trench), and travelling at common tsunami speeds (Omira et al., 2022; Hu et al., 2023; Kubota et al., 2022).
 291 In shallow waters, the model correctly reproduces the tide gauges LA and CL (closest to the port of La

292 Pampilla in Peru.), like in deep waters. It is interesting to note that the model succeeded in correctly
 293 reproducing the 120-minute long-period wave (also observed in deep water).

294

295

296 **Figure 9. Validation of numerical results at DART D1 and D2 buoys and tide gauges CL (Callao, Peru), and LA**
 297 **(La Libertad, Ecuador). For each buoy, the measured (blue line) and simulated (orange line) time series are**
 298 **shown in the upper panel. The lower panel shows the measured free sea surface wavelets (upper wavelet) and**
 299 **numerical simulation (lower wavelet). The vertical black dashed line in CL refers to the instant of the vessel**
 300 **mooring break in La Pampilla harbor, Peru. The panel to the right of each wavelet is the frequency spectrum.**

301 In general, an adequate VMT simulation is achieved, then the wavelets and Fourier transform show a correct
 302 trend of the wave characteristics measured in each sensor, as shown in Figure 9. Wavelets corresponding
 303 to both deep and shallow waters present several groups of waves forced by acoustic waves between 20-40
 304 minutes, periods 40-60 min, and long-period waves about 120 min (Hu et al., 2023; Kubota et al., 2022;
 305 Omira et al., 2022). Likewise, the Fourier spectra also show two distinguished groups of 40-60 min and
 306 100-120 min in shallow water.

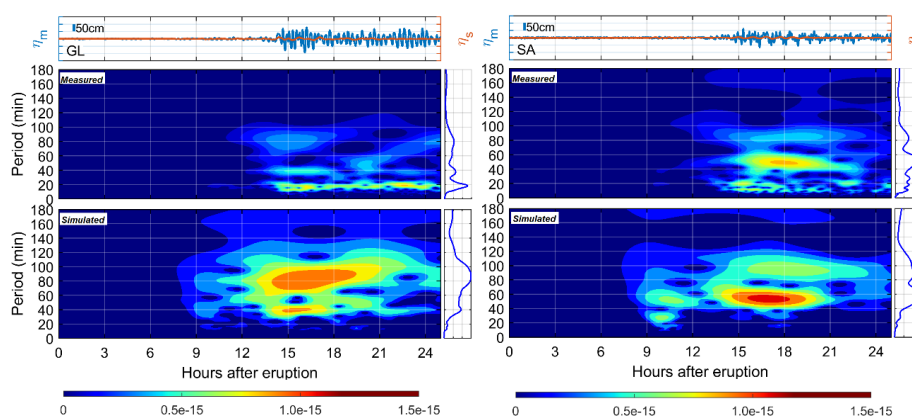

307 Compared to the DART buoys, the simulations exhibit similar behaviours because they are located at great
 308 depths, where the influence of the bathymetry and the land boundaries is negligible. The simulations
 309 demonstrate that tide gauges reveal variations such as earlier arrival times or more energy, possibly

310 associated with local effects and limitations in resolution. However, the model’s results are similar to the
 311 measured data.

312 Figure 10 displays simulation results for shallow water tide gauges **GL** and **SA** (located north and south of
 313 Peru, respectively), demonstrating that the 120-minute period wave is exclusive of the coast of Peru and is
 314 likely intensified by local effects. The wavelet analysis indicates that neither the simulated nor the measured
 315 waves show a significant amplification of high-period energy, as seen in the sensors situated off the coast
 316 of Peru.

317

318

319 **Figure 10.** Comparisons of the numerical results at the GL (Galapagos, Ecuador) and SA (San Antonio, Chile)
 320 tide gauges are shown. For each tide gauge, the measured (blue line) and simulated (orange line) time series are
 321 shown in the upper panel. The lower panel has measured (upper wavelet) and simulated (lower wavelet) ocean
 322 results. The panel to the right of each wavelet is the frequency spectrum.

323 3.3. Vessel response due to acoustic and tsunami waves

324 The model described in Section 2.4 was implemented to estimate the mooring stresses due to tsunami
 325 hydrodynamic effects produced during the Tonga event. The purpose is to demonstrate the variability in
 326 stress levels when exposed to tsunami waves of varying periods and, therefore, different hydrodynamic
 327 conditions.

328 The current velocity and water elevation time-series were extracted from the Boussinesq tsunami model,
 329 presented in Section 2.3 and validated in Section 3.2 at coordinates 11°56' S, 77°11' W, the location of
 330 Terminal 2 of La Pampilla port (as shown in Figure 3). Figure 11 describes the mooring scheme. Each pile
 331 is defined as immovable to focus stresses on every line. The scheme is similar to the one found in Terminal
 332 2 of the Port of La Pampilla in Peru during the mooring-break accident.

333

334 **Figure 11. La Pampilla port location (square in left map) and berthing scheme implemented in the mooring lines**
 335 **stress model (right panel).**

336 In Tables 2 and 3 presents the vessel's description and its hydromechanical characteristics. The entire
 337 mooring system schematic and the data used in the model are provided. The vessel used in this study is not
 338 the oil tanker Mare Doricum, but rather one with comparable physical characteristics. The vessel is moored
 339 to five buoys with eight moorings, one forward and four at the stern (in addition to two stern anchors
 340 anchored at a depth of 18 meters). The ship is considered fully loaded throughout the simulation. (Figure
 341 12).

344 **Table 3. Description of the mooring system used in the stress simulation**

345

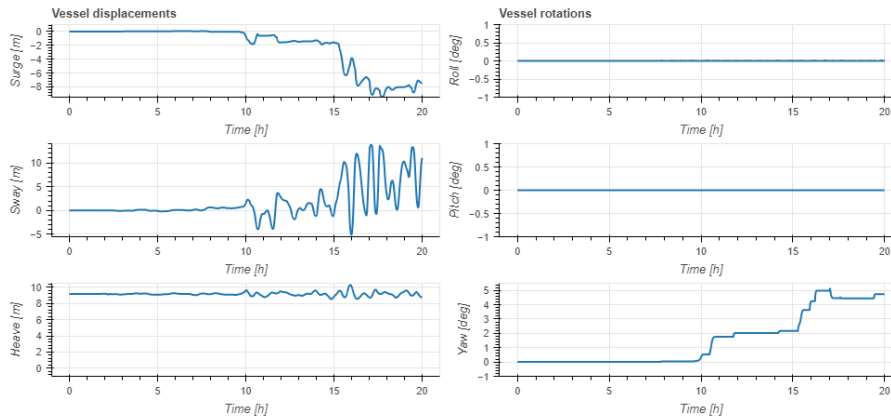

346

347 **Figure 12. On the left is the initial layout with the origin at the ship's CoG and on the right is the layout at the**
 348 **moment of mooring breakage, where the yellow and purple colors mark the maximum and minimum stress**
 349 **values, respectively.**

350 The results of the DOFs along the simulation are presented in Figure 13. The first instances of ship
 351 movement occur about 9 to 10 hours after the volcano erupts, coinciding with the arrival of atmospheric
 352 waves (VMT), with variations in the order of 2 m, 8 m, and 2 degrees for the DOFs Surge, Sway, and Yaw,
 353 respectively, in the movements directly associated with tsunami hydrodynamic loads (López and Iglesias,
 354 2014). Then, 15 hours after the eruption, when the 120-minute period wave is present and the mooring
 355 breaks, further ship motion is generated, drastically increasing the vessel mentioned above DOFs values.
 356 The model results indicate that the movement was caused by the VMT. The anchored ship aligns with the
 357 surge, sway, and yaw; with a maximum deviation of 9 meters, 14 meters, and 5 degrees, respectively, which
 358 is more than enough to produce the breakage of the mooring system according to the port authority of La
 359 Pampilla (CPAAAAE, 2023).

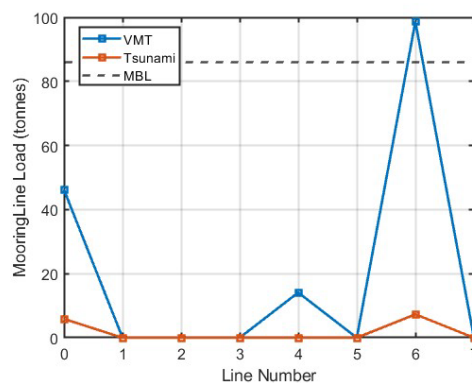

360

361

362 **Figure 13. Time series of ship 6 degrees of freedom obtained from numerical simulation. Measured in hours**
 363 **after the eruption.**

364 To support the hypothesis that the 120-minute long-period wave along the Peruvian coast caused the
 365 mooring to break, a comparison was made between the stresses obtained by forcing with the VMT time-
 366 series and the tsunami caused only by the submarine explosion. The stress results for each line in both cases
 367 are shown in Figure 14. This illustration shows two things. Firstly, with the VMT, the lines that are primarily
 368 under stress are the starboard moorings lines number 0, 4, and 6, the latter having the maximum load (96
 369 tons), which exceeds the Minimum Breaking Load (MBL) by more than 10 tons. The increase in stresses
 370 was due to the configuration of the mooring layout, tsunami wave direction, and hydrodynamic effects,
 371 which could cause the mooring line to break. Secondly, the findings suggest that the VMT results in a
 372 significant increase in mooring stresses, exceeding 10-times the levels observed during the tsunami-only
 373 event (where the VMT is not included in the simulation). These results confirm that the atmospheric waves
 374 generated during the volcanic eruption have transmitted energy to the ocean, generating tsunami-like waves
 375 that have affected the far field.

376

377 **Figure 14. Maximum stresses obtained from the simulation at each mooring. Blue and orange lines represent**
 378 **the results of the simulations with and without atmospheric waves, respectively.**

379 **4. Conclusions**

380 The propagation of atmospheric waves and their coupling with the ocean were extensively studied
381 following the Tonga event. Although epistemic uncertainties associated with the event are important, it was
382 possible to understand the main forcings and effects of the volcano-meteorological tsunami (VMT) in the
383 far-field, where the atmospheric waves were the dominant generation mechanism. The air-ocean Proudman
384 resonance in deep water was the driving mechanism that caused sizeable gravity waves, which had very
385 similar characteristics to those of a tectonic-source tsunami.

386 The potential of the explosion-induced atmospheric waves to magnify tsunamis once they pass over oceanic
387 regions of great depth has become apparent. This happened near the Tonga trench in the propagation
388 direction of South America (Figure 3-c in Omira et al., 2022), helping to understand the origin of long-
389 period tsunami waves propagated toward Peru. The spectral analysis results establish the influence of the
390 atmospheric waves generated by the HTHH volcano.

391 The presence of the high period waves exclusively in the tide gauges of Peru and Ecuador (**CL** and **LA**,
392 respectively) could be explained by several processes associated with shoaling. These processes could
393 include the width and slope of the continental shelf (which is wider on the Peruvian coast than on the
394 Chilean coast, for example) and the effects associated with topographic boundaries and their geometry,
395 such as the natural bay oscillation modes.

396 Considering that, the 120-minute long-period waves were associated with the air-ocean-resonance of the
397 Tonga event and that numerical simulations additionally show the mooring line stress using the VMT time-
398 series, it is possible to conclude that the Tonga tsunami caused the overstressing and subsequent accident
399 in the port of La Pampilla, Peru.

400 Various processes, including hydrodynamic loads on the ship's hull, can threaten the stability of moored
401 vessels. These loads primarily affect the horizontal plane, which influences the sway, surge, and yaw
402 degrees of freedom. The VMT produced during the Tonga 2022 event was accompanied by long-period
403 waves and currents, which could affect the stability of the mooring system in the port of La Pampilla, Peru.

404 The hydrodynamic effects that these very long-period waves can cause in port environments can generate
405 damages similar to those of tectonic-source tsunamis, affecting infrastructure, vessels, and merchandise.
406 One unique characteristic of VMT events is that their waves do not dissipate energy with a ratio of $r^{-1/2}$
407 (where r is the distance from the generation origin). Instead, they can be amplified thousands of kilometers
408 away from their origin, presenting an increased threat to the stability of port environments in the far field.

409 **4.1. Final Considerations**

410 Coastal and port infrastructure are not prepared to respond preventively to these Tonga-type tsunamis,
411 leaving them "unprotected", as tsunami warnings are not issued once a volcano eruption is known.
412 Furthermore, in the analyzed event, the initial ocean disturbance arrived earlier than anticipated because

413 the atmospheric waves produced a VMT that travelled at sonic velocity. This statement holds relevance as
414 state and international authorities are responsible for maritime safety and the creation of cautions-warnings
415 and suggestions to aid distinct users in coastal and offshore locations.

416 This event showed the need for Tsunami Early Warning Systems (TWS) to be prepared to include
417 atmospheric waves and detect them from existing monitoring sensors. In addition, Standard Operational
418 Procedures need to include protocols for these events to avoid damage to port facilities and ships, such as
419 the breaking of moorings and ship collisions. These events can also generate local flooding increasingly far
420 away from the origin and affect the population and coastal infrastructures (cities, nuclear reactors,
421 petrochemical industry, etc.). Therefore, efforts towards the incorporation of tsunamis caused by volcanic
422 acoustic waves in tsunami warning systems are needed.

423 **5. Author contribution**

424 Supervision and methodology (G.M and A-Q.I); Waves simulations (K.J and O.R); revision (B.M and O.R).
425 All authors have read and agreed to the published version of the manuscript.

426 **6. Competing interests**

427 At least one of the co-authors is a member of the editorial board of Natural Hazards and Earth System
428 Sciences.

429 **7. Acknowledgement**

430 This research was supported by an FPU (Formación de Profesorado Universitario) grant from the Spanish
431 Ministry of Science and Innovation (MCINN) to the first author. We have gratitude to The Ocean Energy
432 and Offshore Engineering Group of IHCANTABRIA for the model of mooring stresses. In addition, the
433 authors of this work would like to thank the various state institutions that have provided measured
434 atmospheric data mentioned in Chapter 2: IDEAM (Colombia), SENAMHI (Perú), DGAC (Chile), NIWA
435 (New Zealand), NOAA (USA) and IOC.
