

## Abstract

Downhill thunderstorms frequently occur in Beijing during the rainy seasons, leading to substantial precipitation. The accurate intensity prediction of these events remains a challenge, partly attributed to insufficient observational studies that unveil the thermodynamic and dynamic structures along the vertical direction. This study provides a comprehensive methodology for identifying both enhanced and dissipated downhill thunderstorms. In addition, a radar wind profiler (RWP) mesonet has been built in Beijing to characterize the pre-storm environment downstream to the thunderstorms at the mountain foot. This involves deriving vertical distributions of high-resolution horizontal divergence and vertical motion from the horizontal wind profiles measured by the RWP mesonet. A case study of enhanced downhill thunderstorm on 28 September 2018 is carried out for comparison with a dissipated downhill thunderstorm on 23 June 2018, supporting the notion that a deep convergence layer detected by the RWP mesonet, combined with the enhanced southerly flow, could favor the intensification of thunderstorms. Statistical analysis based on radar reflectivity from April to September 2018–2021 have shown that a total of 63 thunderstorm events tend to be enhanced when entering the plain, accounting for about 66% of the total number of downhill thunderstorm events. A critical region for intensified thunderstorms lies on the downslope side of the mountains west to Beijing. The evolution of the downhill storm is associated with the dynamic conditions over the plain compared to its initial morphology. The existence of strong westerly winds and divergence in the middle of troposphere exert a critical influence on the enhancement of convection, while low-level divergence more leads to the dissipation. The findings underscore the significant role of RWP network in elucidating the evolution of downhill storm.

## Short Summary

49

50

51 The prediction of downhill thunderstorm (DS) remains elusive. Here we propose an  
52 objective method to identify DS, based on which enhance and dissipated DS are  
53 discriminated. A radar wind profiler (RWP) mesonet is used to derive divergence and  
54 vertical velocity. The mid-troposphere divergence and prevailing westerlies enhance  
55 the intensity of DS, whereas the low-level divergence is observed when the DS  
56 dissipates. The findings highlight the key role that RWP mesonet plays in the evolution  
57 of DS.

60

## 61 **1. Introduction**

62 The complex evolution of convective systems crossing mountainous terrain  
63 represents a substantial forecasting challenge. It has been previously reported that  
64 downhill thunderstorms with intensive reflectivity and good organization are more  
65 likely to successfully maintain or strengthen compared to isolated and small-scale  
66 thunderstorms (Castro *et al.*, 1992). Various thermal factors that favor the development  
67 of downhill thunderstorm have been identified, including higher instability and lower  
68 convective inhibition (Letkewicz and Parker, 2010, 2011; Keighton *et al.*, 2007),  
69 adequate water vapor accompanied by low-level jets (Tompkins, 2001; McCaul and  
70 Cohen, 2004; Weckwerth *et al.*, 2014), and cool pool (Teng *et al.*, 2000; Jeevanjee and  
71 Romps, 2015; Li *et al.*, 2017; Xiao *et al.*, 2017). Furthermore, a few studies in the  
72 literature have demonstrated the importance of the dynamic environment over the plain,  
73 such as surface and low-tropospheric convergence for convection initiation (Frame and  
74 Markowski, 2006; Miglietta and Rotunno, 2009; Wilson *et al.*, 2010), and strong  
75 vertical wind shear (Parker *et al.*, 2007; Reeves and Lin, 2007; Xiao *et al.*, 2019).

76 The topography in Beijing is intricate, given its location at the foot of the Taihang  
77 Mountains to the west and the Yan Mountains to the north, both of which have ridges  
78 with elevations exceeding 1200 meters (Figure 1a). Wilson *et al.* (2007) found that  
79 downhill thunderstorms, particularly those originating from the west, constituted 79%  
80 of all thunderstorms in Beijing between 2003 and 2005, as determined through a  
81 statistical analysis of thunderstorm datasets. The distinctive topography and the  
82 frequent occurrence of downhill thunderstorm in Beijing afford us an excellent  
83 opportunity to observe the inherent dynamic structures of downhill thunderstorms and  
84 their pre-storm environments. This, in turn, allows for a more in-depth investigation  
85 into the potential physical mechanisms underlying the formation of this severe weather  
86 event. However, most of the previous studies are limited to the analysis of a single  
87 downhill thunderstorm case (Chen *et al.*, 2017; Sun and Cheng, 2017; Kang *et al.*, 2019).  
88 Besides, the investigation of pre-storm environment and evolution process of  
89 thunderstorm are either based on the model simulation (Chen *et al.*, 2005; Xiao *et al.*,

90 2015; Li *et al.*, 2017) or reanalysis data (Wang *et al.*, 2019), largely owing to the dearth  
91 of high-density continuous vertical profiling measurements of wind, temperature, and  
92 humidity.

93 Furthermore, there exist no objective method that can be used to identify and track  
94 the propagation of downhill thunderstorm in the literature. Therefore, more urgent  
95 efforts are warranted to investigate the difficult-to-forecast storm type from a statistical  
96 perspective of ground-based atmospheric profiling mesonet observations. A high-  
97 density mesonet, consisting of six radar wind profilers (RWP) has been established in  
98 the Beijing since 2018 (Figure 1b) to continuously observe three-dimensional wind  
99 fields with high temporal and vertical resolution. This provides us with a valuable tool  
100 to explore the atmospheric dynamic structures, such as areal averaged vorticity,  
101 divergence, and vertical velocity, of the pre-storm environment for the downhill  
102 thunderstorms by using the parameters derived from the RWP mesonet. The primary  
103 goals of this study are twofold: (1) to develop an objective method to identify the event  
104 of downhill thunderstorm and its evolution, mainly based on composite radar  
105 reflectivity from weather radar; and (2) to explore the statistical patterns of downhill  
106 thunderstorms and reveal the dynamical structures in the development of downhill  
107 thunderstorms, aiming to attain a deeper understanding of the evolution processes of  
108 these thunderstorms.

109 The next section describes the data and methodology, in which a novel objective  
110 method is proposed to characterize the evolution of downhill thunderstorm. Section 3  
111 presents a case study of an enhanced downhill thunderstorm. Statistical analyses of the  
112 relationship is conducted in section 4 between wind profile, convergence and the  
113 evolution of downhill thunderstorms. A summary and concluding remarks are given in  
114 section 5.

## 115 **2. Methodology and data**

### 116 *2.1. Identification of downhill thunderstorms*

117 To study the downhill thunderstorms in Beijing, areas in Figure 2a is selected as  
118 the region of interest (ROI). Then, ROI is divided into three subregions by terrain height:  
119 Area to the west and north of the ridge line is defined as the mountainous region ( $ROI_m$ ),  
120 marking as dark gray in Fig. 2a; and the area with surface elevation less than 100 m is  
121 defined as the plain region ( $ROI_p$ ), marked with white; the light-gray area between these  
122 two lines is defined as the downslope region ( $ROI_d$ ).

123 The flow chart for identifying downhill thunderstorms from composite radar  
124 reflectivity is illustrated in Figure 2b, which is mainly comprised of the following steps:  
125 Firstly, based on the well-established findings in literature from previous studies (e.g.,  
126 Kingsmill, 1995; Weckwerth, 2000; Qin and Chen, 2017; Bai *et al.*, 2019), echoes with  
127 radar reflectivity reaching over 35 dBZ triggered in  $ROI_m$  are identify as potential  
128 downhill thunderstorms. To eliminate false signals, those echoes with area less than 50  
129  $km^2$  are filtered out.

130 Secondly, these potential clusters are tracked using the area overlapping method  
131 (Machado *et al.*, 1998; Huang *et al.*, 2018; Chen *et al.*, 2019). Noted that during  
132 merging processes, only the largest cluster is tracked continuously, while others are  
133 subsequently terminated. Likewise, during the splitting processes, only the largest  
134 cluster is tracked continuously, while others are attributed to newly initiated storms.  
135 Suppose the  $i^{th}$  ( $i = 1, 2, \dots$ ) thunderstorm (i.e.,  $S_i$ ) is observed in  $ROI_m$  at time  $n$  (i.e.,  
136  $T^n$ ), the properties of  $S_i^n$  including the centroid ( $C_i^n$ ), area ( $A_i^n$ ) and maximum  
137 reflectivity ( $MR_i^n$ ) are obtained.

138 Thirdly, the downhill thunderstorms are defined by whether the potential clusters  
139 move into  $ROI_d$  and  $ROI_p$ . And if the centroid of  $S_i$  crosses the ridge line and moves  
140 from  $ROI_m$  to  $ROI_d$  at time  $j$ ,  $T^j$  is defined as the starting time when  $S_i$  begins to go  
141 down the hills. Similarly, if the centroid of  $S_i$  crossed the plain line and moves from

142 ROI<sub>d</sub> to ROI<sub>p</sub> at time  $k$ ,  $T^k$  is defined as the arrival time when  $S_i$  reaches the plain. Then,  
143  $T^k - T^j$  is defined as the downhill duration of  $S_i$ . An example of  $S_i$  is depicted in Fig. 2a.

144 Finally, the downhill thunderstorms are classified into two categories, the  
145 enhanced downhill storms (EDS) and dissipated downhill storms (DDS). These two  
146 subsets are classified by comparing the area and maximum reflectivity at the time  $T^k$   
147 to those at time  $T^j$ . If at least one of the criteria  $A_i^k \geq A_i^j$  and  $MR_i^k \geq MR_i^j$  fulfils,  $S_i$   
148 is considered as an EDS, otherwise it is defined as a DDS.

149 Most of previous research, either case studies or small sample statistics analysis,  
150 lack an objective criterion used to determine downhill thunderstorms. They typically  
151 focus on EDS in the presence of high-impact weather and less consider DDS. Compared  
152 to the existing approaches in the literature, our methodology can discriminate between  
153 these two types of downhill thunderstorms for its capability in defining the timing and  
154 location of storms and tracking their corresponding evolution. Therefore, this  
155 methodology can be readily applied to other regions with similar topography as long as  
156 weather radar measurements are available.

## 157 2.2. Meteorological data

158 As depicted in section 2.1, radar reflectivity derived from the Doppler radar  
159 network dataset with a grid resolution of  $0.01^\circ$  at 10-min intervals during the rainy  
160 seasons (i.e., April–September) in 2018-2022 is used to identify downhill  
161 thunderstorms over Beijing.

162 Upper-air sounding balloons launched at the Zhangjiakou (ZJK) and Beijing  
163 Weather Observatory (BWO) (see their locations in Fig. 1b) are used to provide the  
164 vertical thermodynamic features during the downhill thunderstorms. Generally, the  
165 balloons launches twice a day at 0800, and 2000 Local Standard Time (LST), providing  
166 the vertical profiles of temperature, pressure, relative humidity, and horizontal winds  
167 with a vertical resolution of 5–8 m (Guo *et al.*, 2020). For the sake of improving the  
168 prediction skill of summertime storm, an additional radiosonde launch is performed at  
169 1400 LST daily at the BWO for the period from June 1 to August 31.

170 Ground-based meteorological variables, including 2-m air temperature ( $T_{2m}$ ), dew  
171 point temperature, and pressure measured at 5-min intervals and precipitation measured  
172 at 1-min intervals from automated surface stations (AWSs) are also used in the analysis  
173 over the study area.

174 Geopotential height at 500 hPa and horizontal wind at 850 hPa from the fifth  
175 generation ECMWF reanalysis (ERA5) datasets derived by European Centre for  
176 Medium-range Weather Forecasts (ECMWF) are used for analysing the large-scale  
177 conditions in a case study of a heavy precipitation event in Beijing. The dataset has 37  
178 pressure levels, which is made publicly accessible on a grid spacing of  $0.25^\circ$  at hourly  
179 intervals (Hoffmann *et al.*, 2019).

### 180 *2.3. Radar wind profiler measurements*

181 The RWP mesonet in Beijing, as presented in Table 1 and Fig. 1b, consists of six  
182 RWPs positioned at Shangdianzi (SDZ), Huairou (HR), Yanqing (YQ), Haidian (HD),  
183 Pinggu (PG), and BWO. The RWPs used in this study are CFL-6 Tropospheric Wind  
184 Profilers, manufactured by the 23rd Institute of China Aerospace Science and Industry  
185 Corporation. These instruments provide sampling height, horizontal wind direction and  
186 speed, vertical wind speed, horizontal credibility, vertical credibility, and refractive  
187 index structure parameter. And the data are recorded at 6-min intervals at 34 levels with  
188 a vertical resolution of 120 m below 4 km above the ground level (AGL) in low-  
189 operating mode, and at 25 levels with a vertical resolution of 240 m from 4 to 10 km  
190 AGL in high-operating mode (Liu *et al.*, 2019). Considering that the six RWPs located  
191 at different terrain heights, the horizontal velocities measured by each RWP are  
192 interpolated to the same altitude, starting from 0.5 km above mean sea level (AMSL)  
193 with a vertical resolution of 120 m.

194 Dynamic parameters, such as the horizontal divergence profiles can readily be  
195 calculated by vertical wind profile measurements derived from soundings or RWPs  
196 distributed along the perimeter of a circle or a triangle over an area (Bellamy, 1949;  
197 Carlson and Forbes, 1989; Lee *et al.*, 1995; Bony *et al.*, 2019). The reliability of the  
198 measurements and triangle method is demonstrated in the previous work (Guo *et al.*,

199 2023). Thus, we also employ this methodology to calculate the regional mean  
200 divergence, vorticity and vertical velocity profiles within the triangular regions built by  
201 the RWP's mesonet.

### 202 **3. A case study of an EDS event**

203 EDSs present significant challenges for local weather forecasters in accurately  
204 predicting the intensity of precipitation during nowcasting. In this section, an  
205 observational case study of this type of downhill thunderstorm is selected to explore  
206 the role of thermodynamic and dynamic environment on the evolution of the downhill  
207 thunderstorms.

208 This storm originated from the ROI<sub>m</sub> and began to go down the hill at 1200 LST of  
209 28 September 2018, then hit Beijing after approximately 2–3 hours. Several AWSs in  
210 the Yanqing District recorded lightning activity and hails accompanied with an hourly  
211 rainfall amount of over 30 mm from 1430 to 1530 LST. It is noteworthy that the  
212 intensity of downhill thunderstorm became weakened before 1400 LST but intensified  
213 as it approached the plain area of Beijing.

#### 214 *3.1. Synoptic background*

215 Sounding taken at the ZJK (Figure 3a) at 0800 LST located in the westerly flow  
216 sector, showed a surface-based temperature inversion below 900 hPa and a deep dry  
217 layer aloft from 850 hPa up to about 400 hPa. At the same time, similar temperature  
218 and humidity stratification was seen at the BWO (Figure 3b) with little convective  
219 available potential energy (CAPE) of 170.8 J kg<sup>-1</sup> and convective inhibition (CIN) of  
220 61 J kg<sup>-1</sup>. The veering of a northwesterly wind to a westerly wind from 850 hPa to above  
221 600 hPa indicated the presence of cold advection at 0800 LST. Unfortunately, no  
222 sounding was available to elucidate the temporal evolution of atmospheric  
223 thermodynamic and dynamic environments during the passage of EDS from 1200 LST  
224 to 1500 LST. We can only speculate that the thermal stratification seems insufficient to  
225 facilitate the initiation and subsequent organization of deep convection, even though

226 considering the possible enhancement of unstable layer as the mixed layer grew after  
227 0800 LST.

228 Then, we resort to the synoptic pattern from ERA-5 reanalysis at hourly intervals.  
229 At 500 hPa (Figure 3c), the large-scale conditions at 1400 LST on 28 Sep 2018 was  
230 characterized with a deep cold vortex at the border of Mongolia and China, and Beijing  
231 was situated in the cold sector, with a cold center approximately 500 km to the south,  
232 and influenced by strong westerly flows. At 850 hPa (Figure 3d), a trough extended  
233 from northeast to southwest over ROI<sub>d</sub>, resulting in significant southwesterly flow prior  
234 to the trough over Beijing. The veering of a southwesterly wind at 850 hPa to a westerly  
235 wind 500 hPa indicated the presence of warm advection. The changeover from cold  
236 advection at 0800 LST to warm advection at 1400 LST in the lower troposphere could  
237 account for the subsequent deepening organization of convection after the thunderstorm  
238 entered the plain.

### 239 3.2. Radar reflectivity and surface observations

240 Radar reflectivity at 1200 LST (Figure 4a) showed that a convective line with  
241 several convective cores was detected across the ridge line and moved gradually  
242 southeastward into ROI<sub>d</sub> driven by the low-level northwesterly flows. Surface  
243 streamlines evidently showed dominant west-to-southwesterly surface winds in ROI<sub>m</sub>  
244 and south-to-southwesterly flows in ROI<sub>p</sub> (also see Figure 4a). In downslope regions,  
245 the local mountain-valley orientations appeared to account for up-valley flows in  
246 various directions. A surface analysis at 1200 LST, given in Figure 5a, shows a humid  
247 center in the northwest of the mountain region due to the previous precipitation,  
248 whereas the relative humidity of the downslope and plain was less than 60%. The  
249 thermal boundary near the ridge line which generated by the terrain could also be seen.  
250  $T_{2m}$  over the plain area was on average of greater than 20 °C, whereas the mean  $T_{2m}$   
251 over the mountainous region was less than 10°C. The large northwest-southeast-  
252 oriented temperature gradient appeared to account for the intensification and better  
253 organization of the at 1230 LST (Figure 5b). Surface convergence emerged ahead of

254 the convective line, indicated by the streamlines in Figure 4b, which were associated  
255 with a pre-squall mesotrough/mesolow.

256 At 1300 LST, convective line with reflectivity exceeding 35 dBZ had splitted into  
257 two segments (Figure 4c). The northern segment was completely separated from the  
258 main storm in the southwest and then expanded northeastward by the intersecting  
259 streamlines, with another convective cell initiated near the local converging center  
260 around 117°E, 41.5°N before 1330 LST (Figure 4d). The southern segment maintained  
261 with the total rainfall exceeding 10 mm from 1300 to 1400 LST. Meanwhile, the wet  
262 center gradually moved eastward to the northeast of the mountain region (Figure 5c-d).  
263 Until 1400 LST, the convective cells started to merge into a linear convective system,  
264 and the frontal edge of the convection line had arrived at triangle 1 with weaker  
265 intensity than before (Figure 4e).

266 Further, we attempt to examine the roles of cold pool and low-level wind shear in  
267 maintaining the intense squall line in accordance with the theory of Rotunno et al.  
268 (1988). However, it's difficult to perform a comprehensive and quantitative analysis  
269 due to the inhomogeneous environment and measurement. Here, we qualitatively use  
270 the horizontal winds over YQ (Figure 6a) to estimate vertical wind shear (VWS) on  
271 the downslope and  $T_{2m}$  to identify a cold pool (Figure 5). At 1300 LST, the wind speed  
272 below 1.5 km AMSL was weaker than  $5 \text{ m s}^{-1}$  while was stronger than  $15 \text{ m s}^{-1}$  above  
273 2.5 km AMSL. The maximum value of VWS occurred at the altitude of 1.8 km AMSL  
274 with the value exceeding  $20 \text{ m s}^{-1} \text{ km}^{-1}$ . In less than 10 minutes, cold downdrafts  
275 produced a sharp drop in  $T_{2m}$  by  $6^\circ\text{C}$  in the south of the convective cells (Figure 5c-d).  
276 The effects of the resulting low-level VWS might balance with those of the cool pool,  
277 which helped stimulate the development of more intense storms from 1300 to 1330 LST.  
278 Meanwhile, the accompanying evaporative cooling in the descending flows  
279 strengthened the cold pool. After 1330 LST, horizontal wind speeds in the lowest 2 km  
280 layer strengthened to shrink the low-level VWS to about  $10 \text{ m s}^{-1} \text{ km}^{-1}$ . The cold-pool-  
281 induced horizontal vorticity could overpower that of the low-level wind shear, partly  
282 facilitating the dissipated radar echo before 1400 LST (Figure 5e). Moreover, this might

283 be related to the relatively strong cold pool located in the south, which potentially cut  
284 off the warm southerly inflow from the plains to the mountains. Then, cool pool  
285 weakened with convection and the overpowering effect diminished.

286 As the storm approached ROI<sub>p</sub> from 1400 LST, composite radar reflectivity shows  
287 that it was significantly strengthened to an intense and well-organized squall line  
288 (Figure 4e-4g). AWSs within triangle 1 captured its associated rainfall. Abrupt increase  
289 in surface pressure by +3 hPa was seen across the gust front in the triangle 1 when the  
290 maximum rainfall rate exceeded 3mm (6min)<sup>-1</sup> (not shown). Except for the above-  
291 mentioned balanced state between cool pool and low-level vertical wind shear, this  
292 enhancement could potentially be associated with the dynamic lifting over plain area .  
293 Due to the disadvantage of surface observations in monitoring the vertical dynamic  
294 features, we have to resort to the examination of the evolution of high-resolution  
295 divergence and vertical velocity derived from the fine-scale RWP mesonet in the  
296 following subsection.

### 297 *3.3. Divergence and vertical velocity*

298 Before the convective system reached the plain area, sustained southwesterly wind  
299 above 2 km AMSL was observed after 1200 LST at YQ (Figure 6a), which was likely  
300 driven by the synoptic pattern, accompanied with upper-layer divergence and  
301 downdraft in triangle 1 (Figure 6b). The much weaker near-surface southerly wind and  
302 unnoticeable divergence could to a certain extent be influenced by the valley flows at  
303 the foot of the mountains. Meanwhile, a peak of positive vorticity exceeding  $10^{-4} \text{ s}^{-1}$   
304 and a deep layer of negative vorticity up to 5 km AMSL in triangle 1 were maintained  
305 during this time period (Figure 6c). Then, pronounced southerly wind occurred after  
306 1300 LST that corresponded to the rapidly intensification in convergence below 2 km,  
307 providing an uplifting background, albeit less than  $0.1 \text{ m s}^{-1}$ . This updraft assisted the  
308 upward transport of moist air in the planetary boundary layer (PBL), which facilitated  
309 the subsequent formation of clouds and convective rainfall. Additionally, a vorticity  
310 maximum near  $3 \times 10^{-4} \text{ s}^{-1}$  at 1348 LST in the PBL might also be favorable for  
311 organized convective development.

312 The low-level wind speeds over YQ started to increase to  $10 \text{ m s}^{-1}$  as a result of  
313 the downward momentum transport. The subsequent enhancement in convergence  
314 coincided well with the intensification of southwesterly winds ( $>10 \text{ m s}^{-1}$ ) up to 3 km  
315 ASML after 1418 LST. Such intensification in convergence and updraft were also well  
316 captured by triangles 2 (not shown), even with more than one hour in advance of the  
317 convective rainfall arrival. Upward motion in triangle 1 increased in amplitude and  
318 deepened rapidly in depth as the squall line propagated southeastward, and triggered  
319 rainfall over triangle 1. The most intense convergence occurred at 1430 LST and  
320 extended from 1 km to above 2.5 km AMSL afterwards as a result of latent heat release  
321 during cloud formation. The maximum vertical velocity reached  $0.35 \text{ m s}^{-1}$  around 3.5  
322 km AMSL, which were about 6 min prior to the peak area-averaged rainfall rate at 1448  
323 LST. The significant convergence diminished after 1454 LST, when deep convection  
324 moved out of triangle 1 (Figure 4h). Downdrafts are found with moderate upward and  
325 downward motions in the stratiform area.

326 Interestingly, as the squall line propagated eastward and approached the urban  
327 center after 1500 LST, it rapidly dissipated as the area of convective echo was reduced  
328 by a scale factor of 4/5 until 1600 LST (not shown). This appeared to result from the  
329 blocking of water supply by the high risings over the Beijing's built-up area, the so-  
330 called "urban bifurcation" effects on moving thunderstorms (Changnon, 1981; Zhang,  
331 2020). In this case, deep convection in the urban center and northern suburban area  
332 were suppressed due to the urban blocking effects. It was consistent with the persistent  
333 low-level divergence over triangle 3 and 4 with the maximum value of  $3 \times 10^{-4} \text{ s}^{-1}$   
334 occurring near surface (not shown). Clearly, this result can help understand the urban  
335 building-barrier induced divergence and the dissipation of thunderstorm.

#### 336 **4. Comparison with a DDS event**

337 In the preceding section, low-level convergence is an effective signal for the  
338 maintenance of an EDS event. In this section, we present a DDS event that occurred on  
339 23 June 2018 in attempt to investigate the difference of pre-storm environment for two  
340 types of downhill thunderstorms. Similar to the trajectory of the EDS, the DDS began

341 to go downhill at 1600 LST (Figure 7a) and then propagated southeastward with the  
342 area larger than 1000 km<sup>2</sup>. It had dissipated rapidly upon reaching the plain of Beijing  
343 after 1900 LST and diminished until 2100 LST.

344 Figure 8a shows the SkewT/Log P diagram derived from the sounding taken at the  
345 BWO at 1400 BJT, 23 June 2018. It can be seen that a dry troposphere was presented  
346 in the early afternoon. As the time lapsed, the humidity above 700 hPa increased at  
347 2000 BJT (Figure 8b), even though the surface was characterized by a dry layer near  
348 the surface. The surface relative humidity was less than 40% with T<sub>2m</sub> exceeding 30°C  
349 and the dew point temperature less than 20°C. The CIN slightly decreased from 280.2  
350 J kg<sup>-1</sup> at 1400 LST to 264.0 J kg<sup>-1</sup> at 2000 LST. By comparison, The CAPE increased  
351 from 35.5 J kg<sup>-1</sup> at 1400 LST to 483.0 J kg<sup>-1</sup> at 2000 BJT. As shown in Figure 8c, the  
352 study area was situated to the west of the high-pressure ridge at 500 hPa and influenced  
353 by northerly flows in front of the ridge, whereas the lower levels were dominated by  
354 weak southwesterly winds below 850 hPa.

355 In the next, we examine the dissipation stage of downhill storm when it reached  
356 triangle 1 with a focus on the evolution of atmospheric dynamic variables. A sustained  
357 near-surface southeasterly winds was found over YQ before 1900 LST from the surface  
358 streamlines and vertical wind profile that are shown in Figures 7b, c and 9a. The low-  
359 level troposphere over triangle 1 was dominated by distinct deep divergence (Figure 9a)  
360 and positive vorticity (Figure 9b) below 2 km AMSL. The deep divergence of regional  
361 flows and larger CIN more tended to suppress the vertical motion breaking through the  
362 resistance of a stable atmosphere (Xiao et al., 2019).

363 As the downhill thunderstorm reached YQ at 1900 LST (Figure 7d), the near-  
364 surface wind turned into weak northwesterly winds accompanied by the rapid  
365 intensification of convergence over triangle 1 under the force of the convective system  
366 itself. The strongest convergence of this event with a value of  $-3.8 \times 10^{-4} \text{ s}^{-1}$  below 1  
367 km AMSL at 1906 LST. It is worth noting that the divergence layer above 1.5 km AMSL  
368 persisted during the occurrence of precipitation after 1924 LST. Even though there were  
369 the cyclone motion and weak updrafts with the maximum vertical velocity reaching 0.1

370  $\text{m s}^{-1}$ , it was not enough to penetrate the divergence layer and lift the vapor to the lifting  
371 condensation level (LCL) at around 800 hPa as shown in Figure 8b. The maximum  
372 composite radar reflectivity of the echo sharply decreased from 64.5 dBZ at 1900 LST  
373 to 53.5 dBZ at 2000 LST with the area shrinking by half (Figure 7e). The rainfall was  
374 terminated which was consistent with the dominated low-level divergence until 2100  
375 LST (Figure 7f).

376 The above comparison indicates that a linear system was intensified in to the squall  
377 line with fast speed in front of a shortwave troughs in the EDS event. In the DDS event,  
378 some scattered convective cells were organized into clusters as they propagated to the  
379 plain under a weak ridge and then dissipated. For these two cases for EDS and DDS  
380 event, the thermal stratification indicated the presence of unfavorable pre-storm  
381 environmental settings with insufficient unstable energy and inadequate moisture. The  
382 dynamic condition played a pivotal role for convective development during the passage  
383 of the downhill thunderstorm. Compared with the DDS event, the enhanced southerly  
384 winds and corresponding convergence in the lower level were distinct features of the  
385 EDS. The above results indicate that the RWP mesonet could capture well the vertical  
386 profiles of horizontal divergence and vertical motion, favorably supporting the  
387 detection of convection.

388 Notably, small-scale variations of airflow in the narrow valley at the intersection  
389 of Mt. Taihang and Mt. Yan undoubtedly impacts the dynamics of the EDS and DDS  
390 event (Xiao et al., 2017). In other words, the storms from northwest need to pass by the  
391 downslope, valley, and then upslope to reach the plain. The complex local terrain should  
392 be taken into account the factors for the evolution of thunderstorms during the  
393 southeastward propagation. However, the current resolution of observations is not  
394 capable of resolving the dynamic processes associated with the convective development  
395 in that region. We hope further explore this factor with the help of the numerical  
396 simulation in the future.

397 **5. Statistical results**

398 *5.1. General features of downhill thunderstorm events*

399 To obtain a more robust understanding of the climatology for downhill  
400 thunderstorm evolution in Beijing, an in-depth statistical analysis is carried out in this  
401 study. According to the methodology mentioned in Section 2.1, we firstly identify a  
402 total number of 95 downhill thunderstorms triggered in ROI<sub>m</sub> and moved into ROI<sub>d</sub> and  
403 ROI<sub>p</sub> in the study area (Figure 1b) based on the radar reflectivity datasets during the  
404 rainy seasons (i.e., April- September) in 2018-2022. We perform a statistical analysis of  
405 the occurrence number of radar reflectivity that is equal to or greater than 35 dBZ on a  
406 grid spacing of 0.01° at 10-min intervals during these downhill thunderstorm events.

407 As shown in Figure 10a, downhill thunderstorms tend to initiate in ROI<sub>d</sub> with  
408 strong steep slopes near the ridges of the Yan Mountains associated with solar heating  
409 in the afternoon. The highest-frequency center is found mainly over the western  
410 downhill area extending to the plain with the occurrence number exceeding 400, due  
411 possibly to the large amount of eastward propagation of thunderstorms driven by the  
412 westerly or southwesterly flows during the warm seasons in Beijing (Chen *et al.*, 2012,  
413 2014).

414 For all downhill thunderstorms, the relationship between the initial area and  
415 length-width ratio of thunderstorms at the beginning and the relative variation of area  
416 to the time it arrives at ROI<sub>p</sub> is analyzed. Here, we record the maximum (minimum) axis  
417 length of the radar echo with reflectivity  $\geq 35$  dBZ as the length (width) of the downhill  
418 thunderstorm, respectively. The area and length-width ratio tends to reflect the  
419 horizontal scale and organization of convective storms. Generally, linear convective  
420 storms show a length-width ratio greater than or equal to 3.0 (Chen and Chou, 1993;  
421 Meng *et al.*, 2013; Yang *et al.*, 2017). The results show that several mature  
422 thunderstorms with the area larger than 5000 km<sup>2</sup> tend to dissipate during the downhill  
423 process with weaker intensity and area, which are likely due to the splitting processes  
424 (Figure 10b). Convective lines commonly intensify to the squall lines, but several  
425 isolated and loose thunderstorms expand rapidly during the downhill process with

426 increasing area when entering the plain, which may be associated with the favorable  
427 regional-scale lower tropospheric environment.

428 It is found that 63 thunderstorms events tend to be enhanced after it moved into  
429 the downhill and urban areas, accounting for about 66 % of the total number of downhill  
430 thunderstorms events, whereas 32 thunderstorm events tend to be dissipated. Most of  
431 the DDSs arrive at the plain area in mornings and late afternoons (Figure 10c).  
432 Specifically, 11 and 18 DDSs arrive at the plain area during the period of 0600–1200  
433 and 1600–0000 LST which account for 34% and 56% of all DDSs, respectively. In  
434 contrast, the EDSs tend to occur in early mornings and afternoons. 18 and 43 EDSs  
435 arrive at the plain area before 0800 LST and after 1400 LST, respectively,  
436 corresponding to the percentage of 26% and 68%. Meso-scale circulations driven by  
437 the urban heat island (UHI) effect and topography may contribute to the difference of  
438 downhill storms' duration. As presented by Dou et al. (2015), the magnitude of UHI of  
439 Beijing at the nighttime are stronger than in daytime. In the early morning, low-level  
440 westerly and northwesterly winds converged into the Beijing's plain area because of a  
441 combination of downslope mountain breezes and strong-UHI-induced convergence,  
442 which accelerate the speed of thunderstorms towards the plain. The weaker  
443 southeasterly upslope valley breezes in the late afternoon and evening make downhill  
444 storms slow down and contribute to the prolonged duration. One caveat is that the  
445 conclusions may vary by the number of available sample cases.

## 446 5.2. *Dynamic conditions*

447 We present the trajectories and their moving directions of two types of downhill  
448 storms (Figure 11) to confirm that the western part of ROI<sub>d</sub> is a key area for the  
449 development of downhill thunderstorms. To better understand the similarities and  
450 differences between EDS and DDS from the perspective of ambient atmospheric  
451 environment, three-dimensional dynamic structures derived from RWP mesonet are  
452 analyzed. Variables including wind speed, vertical wind shear, u-component and v-  
453 component of wind, divergence and vorticity profiles are used to provide information  
454 of dynamic structures before the downhill thunderstorms arrive. Thus, we select 68

455 downhill thunderstorms, including 50 EDSs and 18 DDSs, which pass through triangle  
456 1 to the plain among all 95 samples and focus on these meso-scale parameters from YQ  
457 station and triangle 1 in the following discussions.

458 The mean vertical wind profiles two hours prior to the arrival of the thunderstorms  
459 are investigated. Horizontal wind speed, vertical wind shear, u-component and v-  
460 component from the RWP in YQ, and divergence and vorticity over triangle 1 are  
461 calculated (Figure 12). Results indicate that wind speed preceding EDSs and DDSs is  
462 about  $5 \text{ m s}^{-1}$  below 1.5 km (Figure 12a). Much stronger horizontal winds with the  
463 maximum wind speed exceeding  $15 \text{ m s}^{-1}$  are observed in the 1.5-5 km layer in advance  
464 of the EDS events, The VWS below 5 km AMSL have no significant differences  
465 between EDSs and DDSs before their arrival (Figure 12b). But the VWS preceding  
466 EDS events is little bit stronger than that preceding DDS events, which could be likely  
467 associated the critical influence that high vertical wind shear exerts on convection.  
468 EDSs and DDSs mainly appears under the near-surface southeasterly and prevalent  
469 southwesterly low-level flow near the foothills. The persistent supply of water vapor is  
470 key for the successful propagation to the plains of downhill storms but doesn't  
471 determine the enhancement or dissipation of convection. Notably, the average v-  
472 component of wind decreases to near-zero above 3 km AMSL. The existence of stronger  
473 westerly flow above 3 km AMSL is a favorable condition for the intensification of  
474 downhill storms (Figure 12c), which well corroborates the results from case study.

475 The mean vertical structure of divergence and vorticity are given in Figure 12e and  
476 f. Before the arrival of downhill storms, one can see the presence of weak divergence  
477 near the surface due to the weak wind. Compared with EDSs, the divergence around  
478 1.5-3 km AMSL is more evident near the arrival of DDSs with the maximum value of  
479  $10^{-4} \text{ s}^{-1}$ . When thunderstorms pass by, the strong divergence in the low level is not  
480 conducive to the extension of upward movement within the boundary layer which  
481 attributes to the dissipation of storms, especially when instability and moisture supply  
482 are unfavorable. In contrast, the high-level divergence at around 4-5 km altitudes  
483 promotes the compensation of the moist air and the upward transport heat, which

484 ultimately reinforce the storm. The vorticity field in Figure 8f is characterized by  
485 cyclonic flows at lower-levels and anticyclonic flows at midlevel, which is possibly  
486 dependent on the synoptic forcing. The vorticity prior to EDSs seems to be stronger  
487 than that of DDSs, the cooperation between lower-level cyclones and less divergence  
488 of convective system tends to promote the maintenance of updrafts, leading to heavy  
489 rainfall.

490 In the previous work, it has been confirmed that these dynamical variables derived  
491 from the RWP mesonet in Beijing provide strong supports for machine-learning-based  
492 prediction of severe convection (Wu *et al.*, 2023). The results therein show that the  
493 usage of RWP observational data as the random forest model input tends to result in  
494 better performance in the rainfall/non-rainfall forecast 30 min in advance of rainfall  
495 onset than using the ERA5 reanalysis data as inputs. In the future, these dynamic  
496 observations and methodologies need to be further incorporated into machine learning  
497 model for improving the prediction skill of downhill thunderstorms.

## 498 **6. Summary and concluding remarks**

499 Given the large uncertainty in prediction and huge impact, here we revisit the  
500 evolution of downhill thunderstorms and concurrent ambient atmospheric dynamic  
501 structures as derived from a high-density radar wind profiler (RWP) mesonet in Beijing.  
502 This RWP mesonet in Beijing is shown to be capable of continuously observing the  
503 horizontal wind fields in the lower troposphere with ultra-high vertical and temporal  
504 resolutions. It follows that the profiles of vertical wind shear, divergence and vorticity  
505 are derived from the triangle algorithm, which are used to analyze the pre-storm  
506 dynamic environment for the downhill storms.

507 First of all, a novel objective methodology has been developed to identify and  
508 track the downhill thunderstorms. Combined with the changes in area or intensity of  
509 radar echoes, enhanced downhill thunderstorms (EDSs) and dissipated downhill  
510 thunderstorms (DDSs) are discriminated. A case study of an EDS during the period of  
511 1200-1500 LST of 28 September 2018 is performed. Of interest is that the intensity of

512 downhill thunderstorm became weaker before 1400 LST but intensified as it  
513 approached the plain area of Beijing. Meanwhile, we present a DDS event that occurred  
514 on 23 June 2018 in attempt to investigate the difference of pre-storm environment for  
515 two types of downhill thunderstorms. For these two cases of EDS and DDS, the thermal  
516 stratification indicated the presence of unfavorable pre-storm environmental settings  
517 with insufficient unstable energy and inadequate moisture. The dynamic condition  
518 played a pivotal role for convective development during the passage of the downhill  
519 thunderstorm. Compared with the DDS event, the enhanced southerly winds and the  
520 corresponding convergence in the lower level were distinct features of the EDS. The  
521 above results indicate that the RWP mesonet could capture well the vertical profiles of  
522 horizontal divergence and vertical motion, favorably supporting the detection of  
523 convection.

524 To obtain a robust result concerning the evolution characteristics of the downhill  
525 thunderstorms in Beijing, an in-depth statistical analysis is merited. The beginning and  
526 arrival time of a downhill thunderstorm event are defined as the moment when the  
527 centroid crosses the ridge line and plain, respectively. A total of 95 downhill  
528 thunderstorms events occurring in the study area are identified based on the datasets of  
529 radar reflectivity at 10-min intervals during the rainy season (i.e., April- September) of  
530 2018–2022. The high occurrence frequency center of convection is found mainly  
531 resides west to Beijing' plain area. And the area variation of convection is not sensitive  
532 to the initial morphology itself. It is found that 63 thunderstorms tend to be enhanced  
533 with larger area or radar reflectivity after it moved into the downhill and urban areas,  
534 accounting for about 66 %. The statistical analysis indicates that most of the downhill  
535 thunderstorms affect the plains in the morning and late afternoon. Most downhill  
536 processes last about two hours while thunderstorms from the northwest and the north  
537 may take a longer time possibly due to the further distance.

538 Thus, we illustrate the statistical analysis of dynamic quantities, such as horizontal  
539 winds, vertical wind shears derived from the RWP at the mountain foot, and divergence  
540 and vorticity derived from the west-most triangular region in the RWP mesonet, in

541 relation to the enhanced and dissipated downhill storms. Results indicate that much  
542 stronger westerly winds are observed in 1.5-5 km layer in advance of the EDS events  
543 and exert a critical influence on the development of storms. Furthermore, divergence at  
544 around 4-5 km altitudes promotes the compensation of the moist air and the upward  
545 transport heat, which ultimately reinforce the storm. Weaker lower-level divergence and  
546 cyclonic flows over the plain contribute to the development of robust updrafts and  
547 closer coupling between boundary layer and clouds, which favor the intensification of  
548 downhill thunderstorms.

549 Continuous measurements of the accurate dynamic quantities will make it  
550 possible to enable a more critical and quantitative evaluation for the development of  
551 downhill thunderstorms in the future. Nevertheless, the above-mentioned dynamic  
552 features, which are necessary to diagnose the evolution of thunderstorms, are not  
553 adequate to fully characterize the environment in which downhill storms are embedded.  
554 In particular, more explicit analysis of thermodynamic parameters, such as CAPE, K  
555 index, precipitable water, will be performed to characterize the pre-storm environments  
556 in detail.

### 557 **Data Availability**

558 We are grateful to ECMWF for providing ERA5 hourly data  
559 (<https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5/>). The radar  
560 wind profiler data are obtained from the National Meteorological Information Center  
561 of China Meteorological Administration (<https://data.cma.cn>), which can be only  
562 accessed via registration.

### 563 **Acknowledgments**

564 This work was supported by the National Natural Science Foundation of China under  
565 Grants of 42325501, U2142209 and 42105090. Last but not least, we appreciated  
566 tremendously the constructive comments and suggestions made by the anonymous  
567 reviewers that significantly improved the quality of our manuscript.

568 **Author Contributions**

569 The study was completed with close cooperation between all authors. JG designed the  
570 research framework; XG and JG performed the analysis and drafted the original  
571 manuscript; JG, TC, NL, FZ and YS helped revise the manuscript.

572 **Completing interests**

573 The authors declare that they have no conflict of interest.

**Table 1.** Summary of six radar wind profilers in Beijing.

| Station Name                   | Acronym | Lat. (°N) | Lon. (°E) | Alt. (m, AMSL) |
|--------------------------------|---------|-----------|-----------|----------------|
| Shangdianzi                    | SDZ     | 40.66     | 117.11    | 286.5          |
| Huairou                        | HR      | 40.36     | 116.63    | 75.6           |
| Yanqing                        | YQ      | 40.45     | 115.97    | 489.4          |
| Haidian                        | HD      | 39.98     | 116.28    | 46.9           |
| Pinggu                         | PG      | 40.17     | 117.12    | 32.1           |
| Beijing Weather<br>Observatory | BWO     | 39.79     | 116.47    | 32.5           |

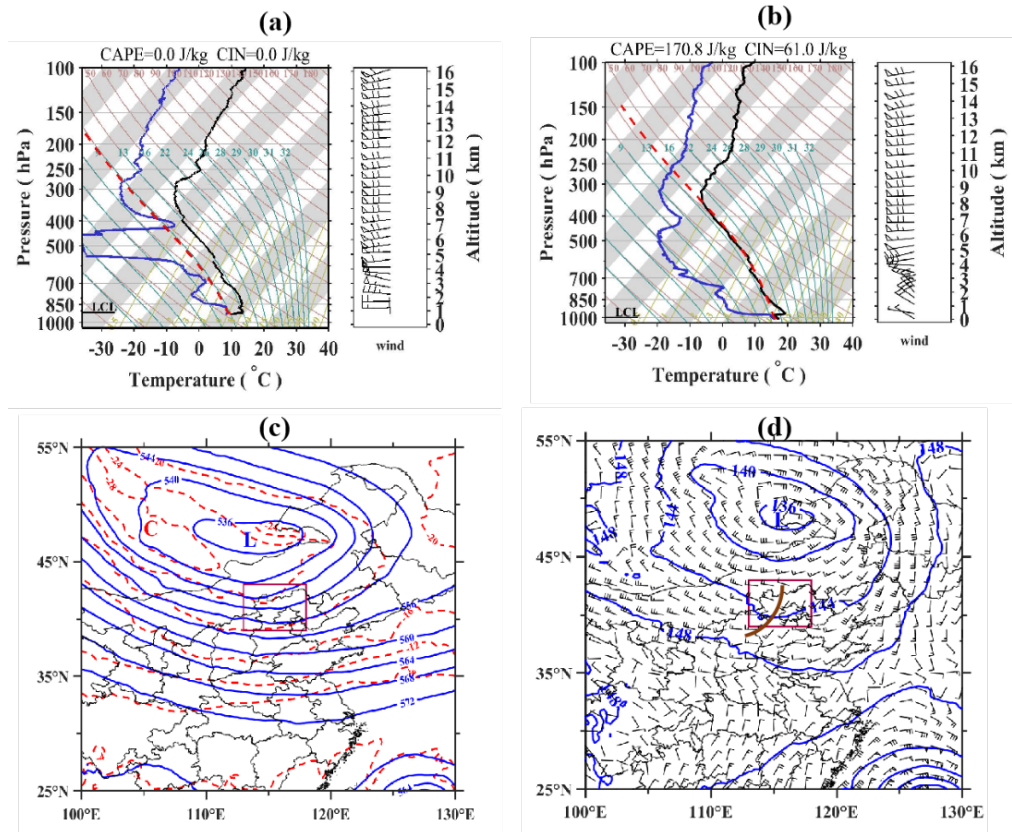

753

754 **Figure 1.** (a) Spatial distribution of the topography over northern China with the blue  
 755 line denoting the Province boundaries. The locations of Taihang Mountains (Mt.  
 756 Taihang), Yan Mountains (Mt. Yan) and Bohai Sea are written in black text. (b) Map of  
 757 Beijing with six RWPs (red dots) deployed at Shangdianzi (SDZ), Huairou (HR),  
 758 Yanqing (YQ), Haidian (HD), Pinggu (PG), and the Beijing Weather Observatory  
 759 (BWO) and surrounding areas. The BWO and Zhangjiakou (ZJK) are deployed with an  
 760 L-band radiosonde (red pentagrams). The four red triangles denote the areas used to  
 761 calculate the horizontal divergence with the triangle method. The left black line mark  
 762 the ridge line, and the right black line mark the plain line that denotes the 200-m terrain  
 763 elevation.

766 **Figure 2.** (a) Definition of the ROIs and the schematic diagram showing the track of a  
 767 downhill thunderstorm  $S_i$  (red circle). The red arrow denotes the trajectory of  $S_i$ . (b)  
 768 Flow chart showing the primary processes to identify downhill thunderstorms in this  
 769 study.

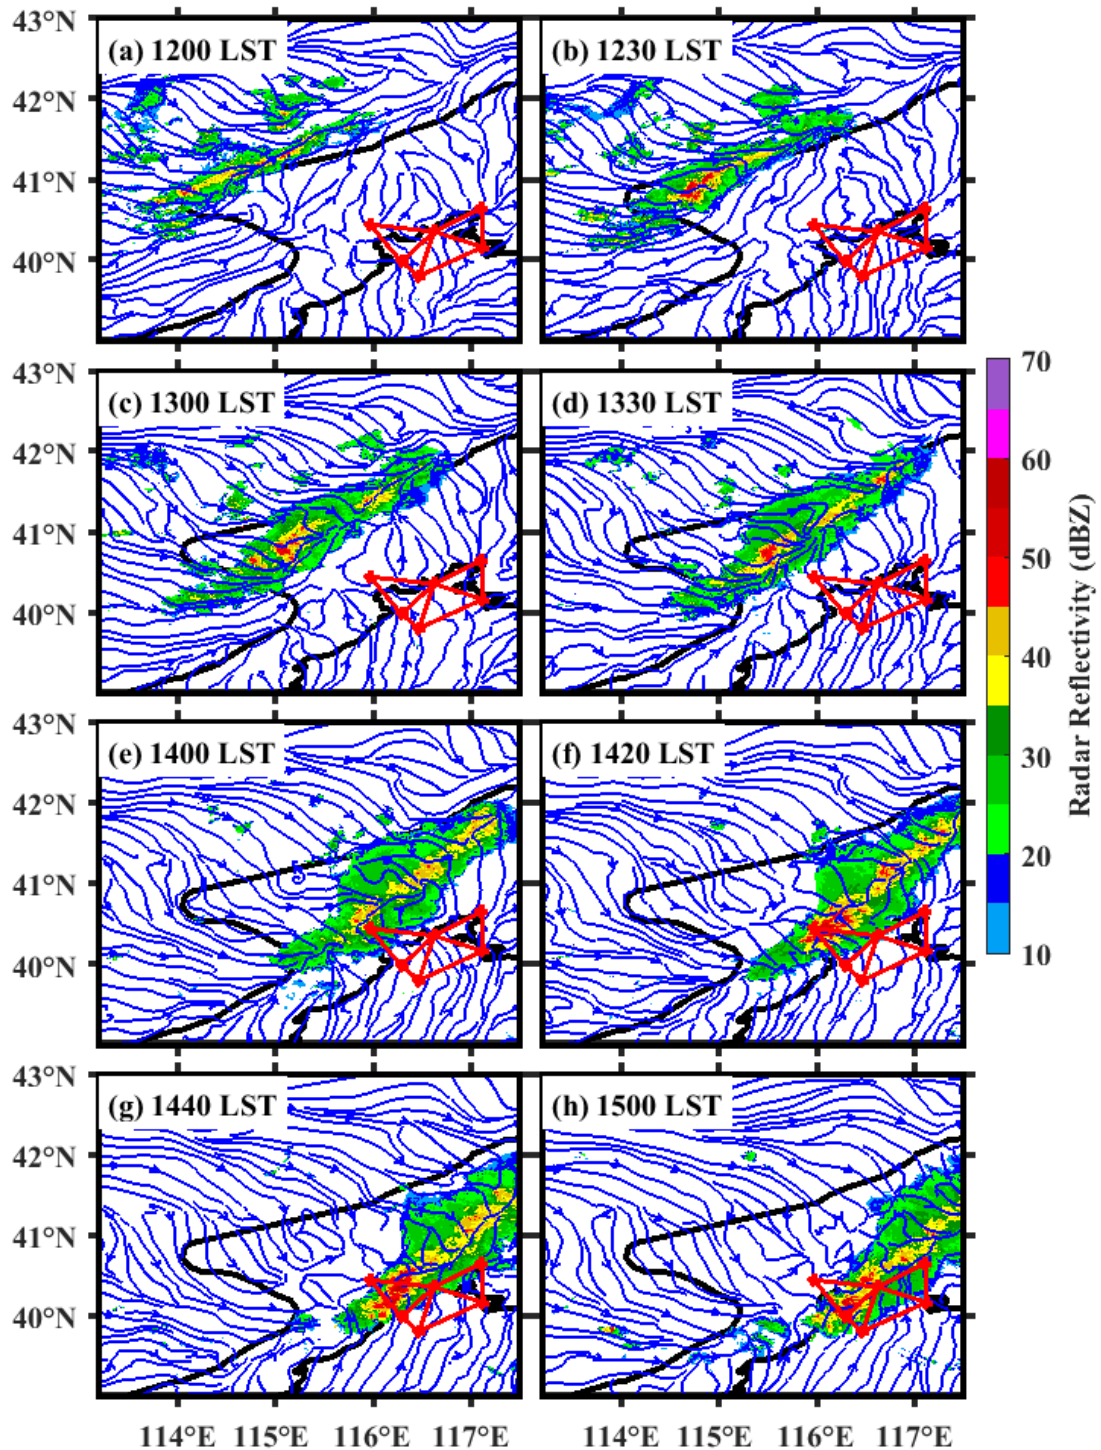

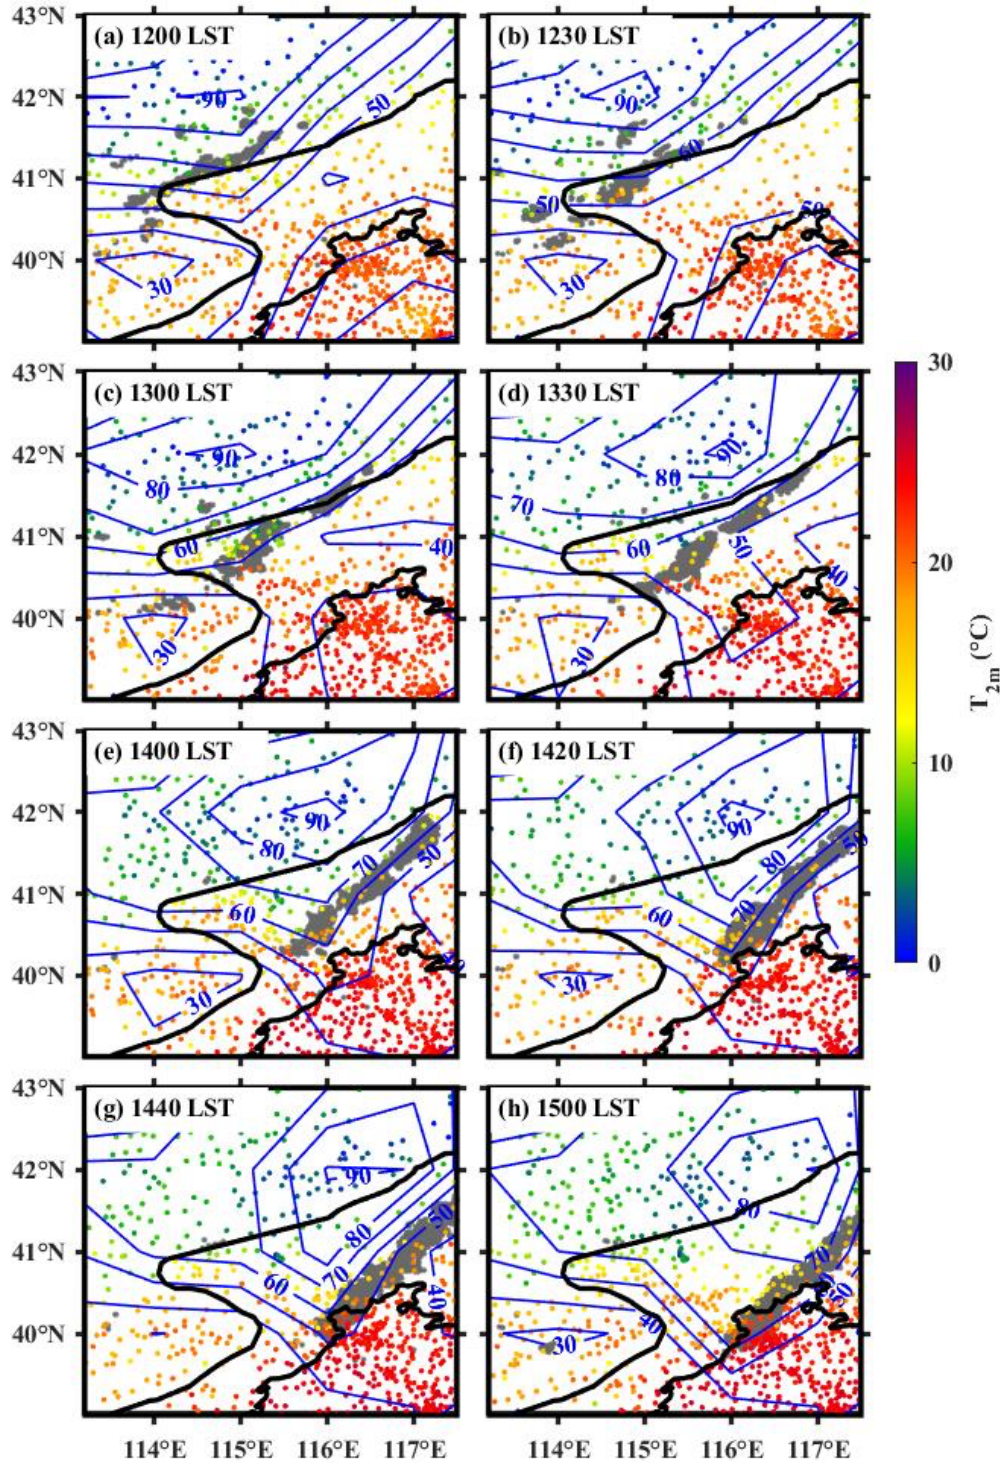

770

771 **Figure 3.** (a) SkewT/Log P diagram derived from the upper-air sounding at the ZJK at  
 772 0800 LST of 28 Sep 2018. (b) Same as (a) but for the upper-air sounding at the BWO.  
 773 (c) Horizontal distribution of geopotential height at 500 hPa (solid blue lines at 40 gpm  
 774 intervals) and temperature at 500 hPa (dashed red lines at intervals of 4 °C) at 1400  
 775 LST of 28 Sep 2018, both of which are obtained from the ERA5 hourly reanalysis data.  
 776 The purple rectangle indicates the location of the study area shown in Figure 1b. Letters  
 777 “L” and “C” denote the centers of a low-pressure system, and cold air, respectively. (d)  
 778 Same as (c), but for the fields of geopotential height at 850 hPa (solid blue lines at 40  
 779 gpm intervals) and horizontal wind at 850 hPa. Note the distribution of a trough along  
 780 the thick brown line.

781

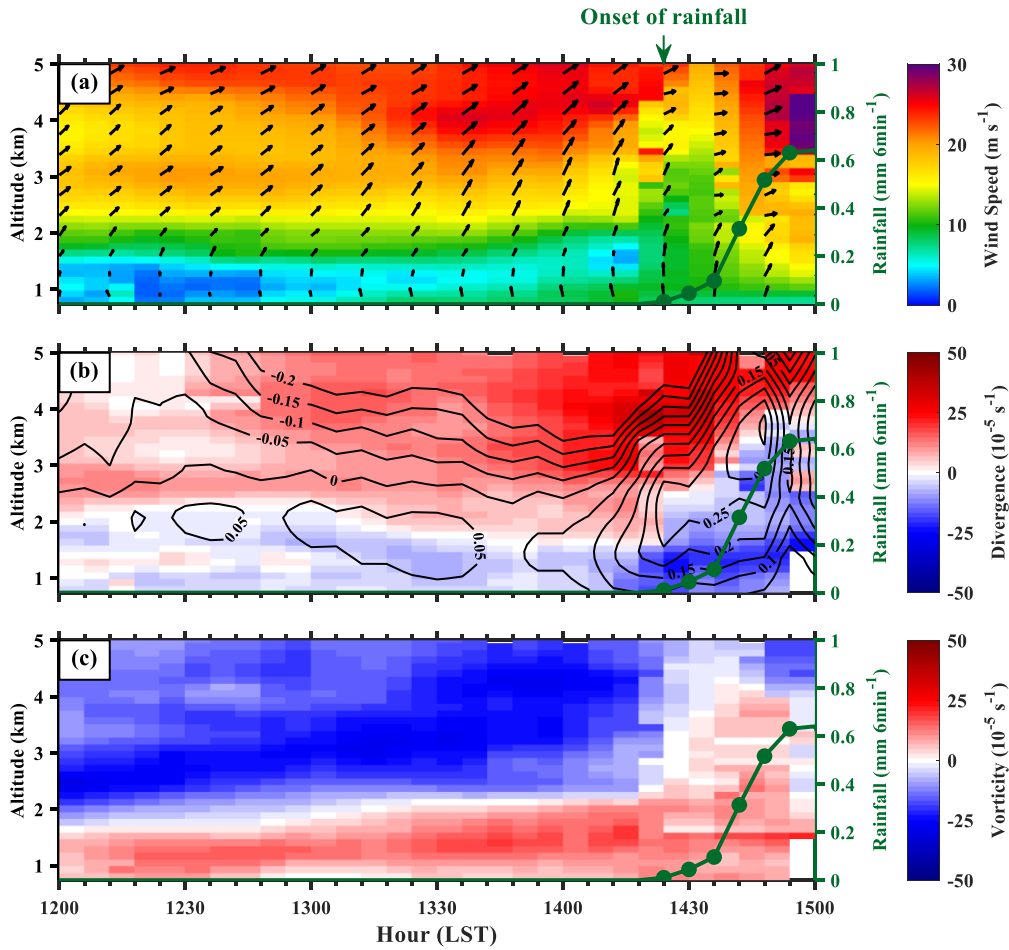

782  
 783 **Figure 4.** Evolution of the composite radar reflectivity (color-shaded, dBZ) and surface  
 784 streamlines derived from AWSs for the case of an EDS event occurring during the  
 785 period from (a) 1200 to (h) 1500 LST on 28 September 2018. The four red triangles  
 786 denote the regions used to calculate the horizontal divergence and vertical motion with  
 787 the triangle method. The two black lines mark the boundaries of the  $ROI_m$ ,  $ROI_d$  and  
 788  $ROI_p$ .

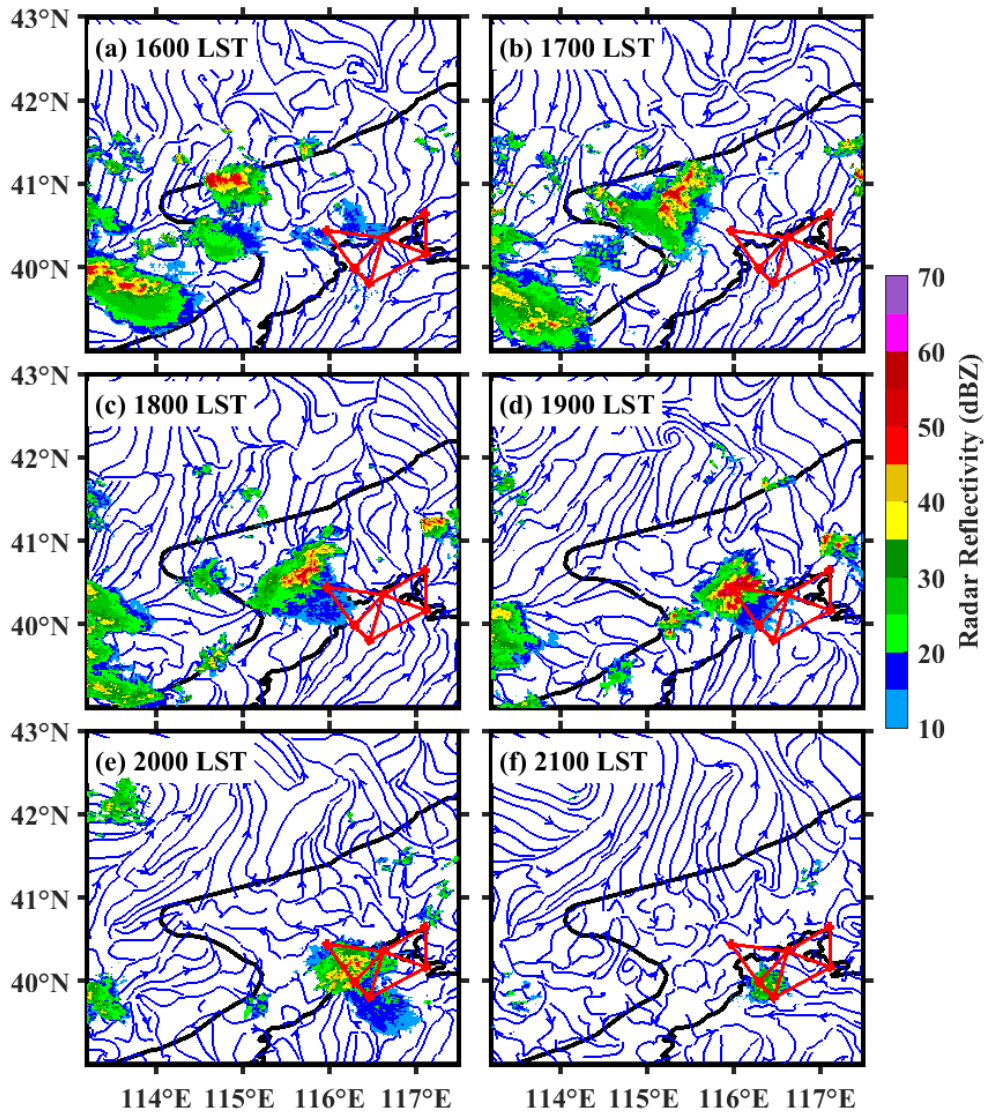

789

790 **Figure 5.** Evolution of the  $T_{2m}$  (color-shaded, °C) and relative humidity (contour, %)
 791 derived from AWSs from (a) 1200 to (h) 1500 LST 28 Sep 2018. The left black line is
 792 the ridge line, the right black line is the plain line which denotes the 200-m terrain
 793 elevation. The gray region denotes the position of echo with radar reflectivity exceeding
 794 35 dBZ.

795

796 **Figure 6.** (a) Time series of horizontal wind vectors ( $\text{m s}^{-1}$ ) with wind speeds shaded  
 797 in the 0.5–5-km AMSL layer during the period of 1200–1500 LST 28 Sep 2018 at YQ  
 798 station. Green-dotted lines represent the triangle-area-averaged rainfall amount ( $\text{mm}$   
 799  $6\text{min}^{-1}$ ) of triangle 1. (b) same as (a), but for the vertical profiles of the triangle-averaged  
 800 divergence (shaded,  $10^{-5} \text{ s}^{-1}$ ) and vertical velocity (contour,  $\text{m s}^{-1}$ ) for triangle 1. (c)  
 801 same as (b), but for the vertical profiles of the vorticity (shaded,  $10^{-5} \text{ s}^{-1}$ ) for triangle 1.

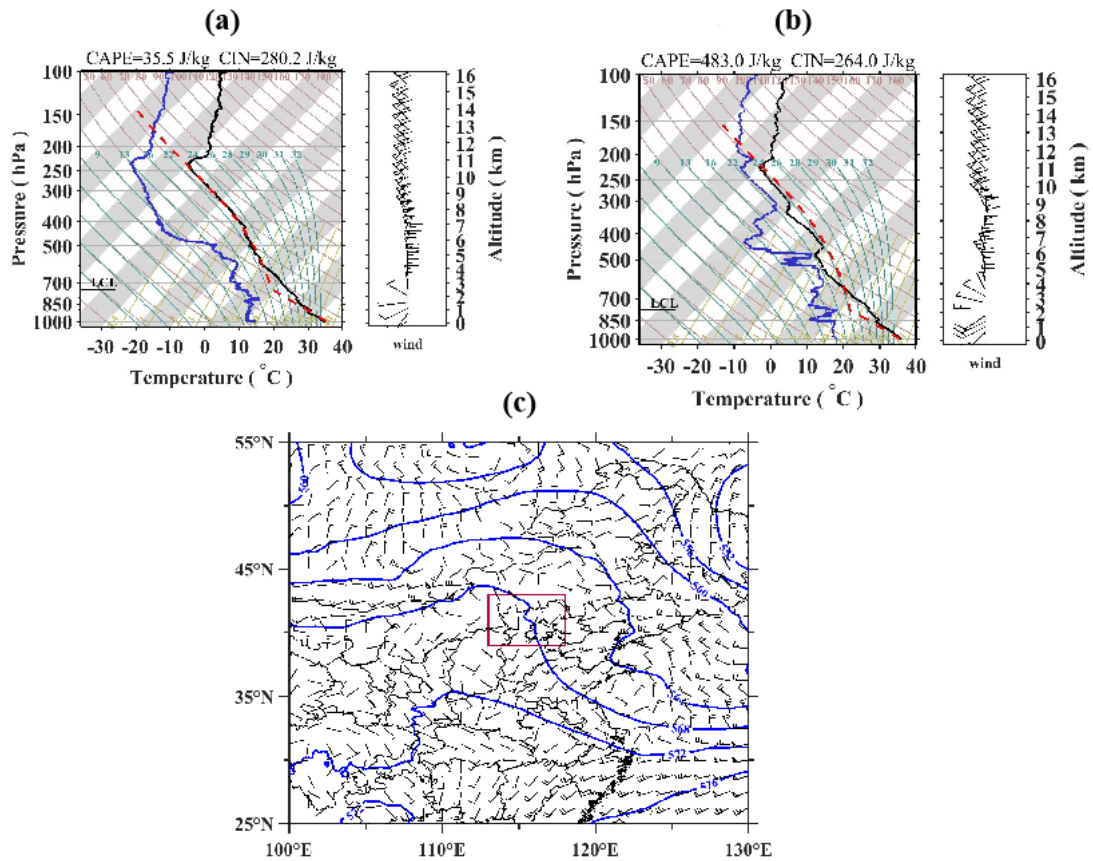

802

803 **Figure 7.** Same as Figure 4, but for the case of a DDS event occurring during the period  
 804 from (a) 1600 to (f) 2100 LST 23 June 2018.

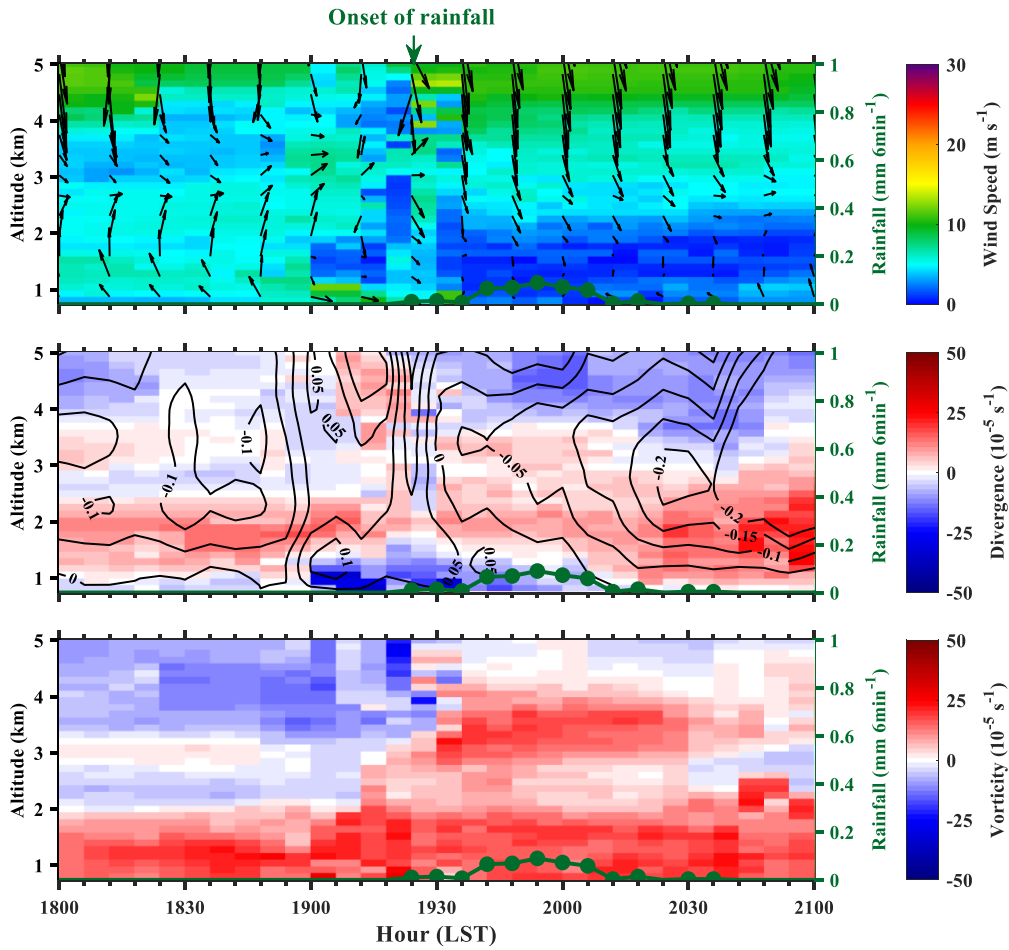

805

806

807

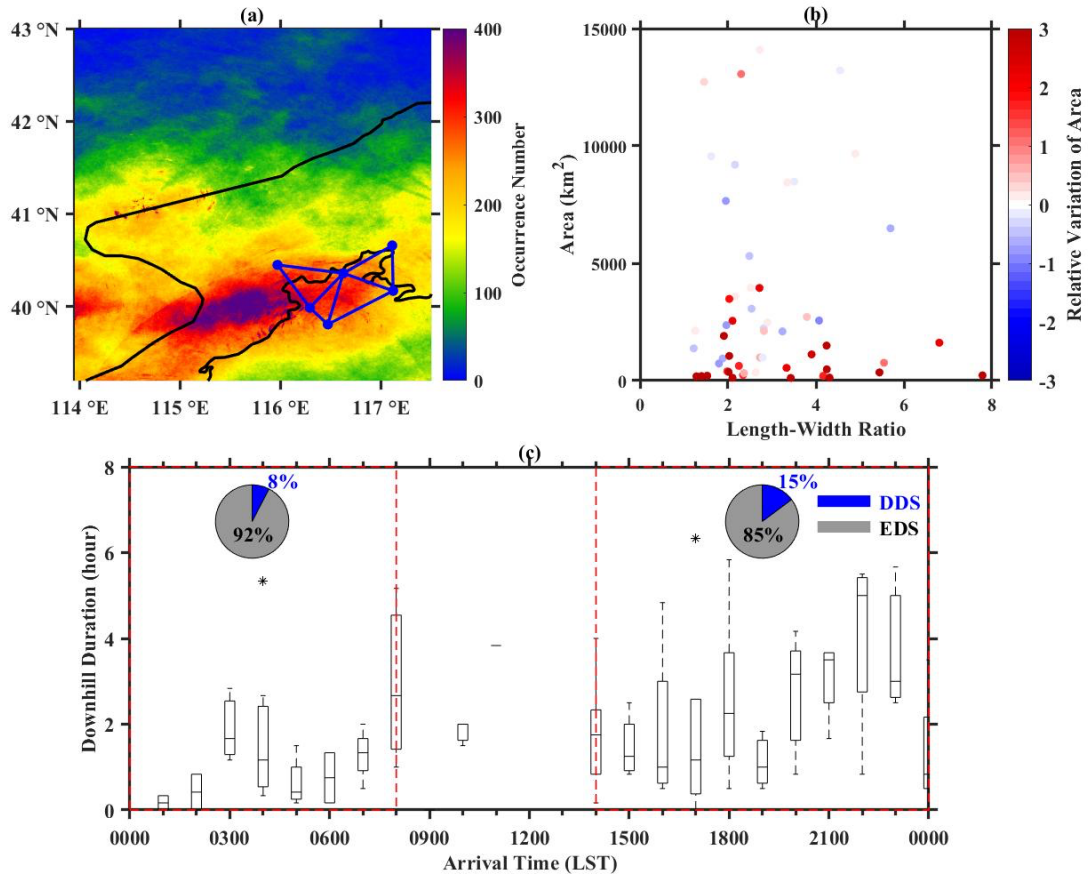

808 **Figure 8.** SkewT/Log P diagram derived from the upper-air sounding at the BWO at (a)  
 809 1400 LST and (b) 2000 LST of 23 June 2018. (c) Horizontal distribution of geopotential  
 810 height at 500 hPa (solid blue lines at 40 gpm intervals) and horizontal winds at 850 hPa  
 811 (wind barbs) at 2000 LST of 23 June 2018, which are both obtained from the ERA5  
 812 hourly reanalysis data. The purple rectangle indicates the location of the study area  
 813 shown in Figure 1b.

814

815 **Figure 9.** (a) Time series of horizontal wind vectors ( $\text{m} \cdot \text{s}^{-1}$ ) with wind speeds shaded  
 816 in the 0.5–5-km AMSL layer during the period of 1800–2100 LST 23 June 2018 at YQ  
 817 station. Green-dotted lines represent the triangle-area-averaged rainfall amount ( $\text{mm}$   
 818  $6\text{min}^{-1}$ ) of triangle 1. (b) same as (a), but for the vertical profiles of the triangle-averaged  
 819 divergence (shaded,  $10^{-5} \text{ s}^{-1}$ ) and vertical velocity (contour,  $\text{m s}^{-1}$ ) for triangle 1. (c)  
 820 same as (b), but for the vertical profiles of the vorticity (shaded,  $10^{-5} \text{ s}^{-1}$ ) for triangle 1.

821

822

823 **Figure 10.** (a) The occurrence number (shaded) of reflectivity greater than 35 dBZ  
 824 during downhill thunderstorm events. (b) Scatterplots showing the distribution of the  
 825 initial length-width ratio and area of downhill thunderstorms, with the corresponding  
 826 relative variation of area (shaded, km<sup>2</sup>). (c) Boxplots showing the distribution of the  
 827 arrival time and downhill duration of EDSs (red) and DDSs (blue). The central box  
 828 represents the values from lower to upper quartile (25th–75th percentile), the vertical  
 829 line extends from the 10th to 90th percentile, the solid line denotes the median.

830

831

832 **Figure 11.** The trajectories (color shaded curves) of (a) 63 Enhanced Downhill Storms  
 833 (EDSs) and (b) 32 Dissipated Downhill Storms (DDSs). The bold black curve in the  
 834 middle marks the ridge line, and the bold black line in the lower right corner marks the  
 835 plain line that denotes the 200-m terrain elevation.

836

837

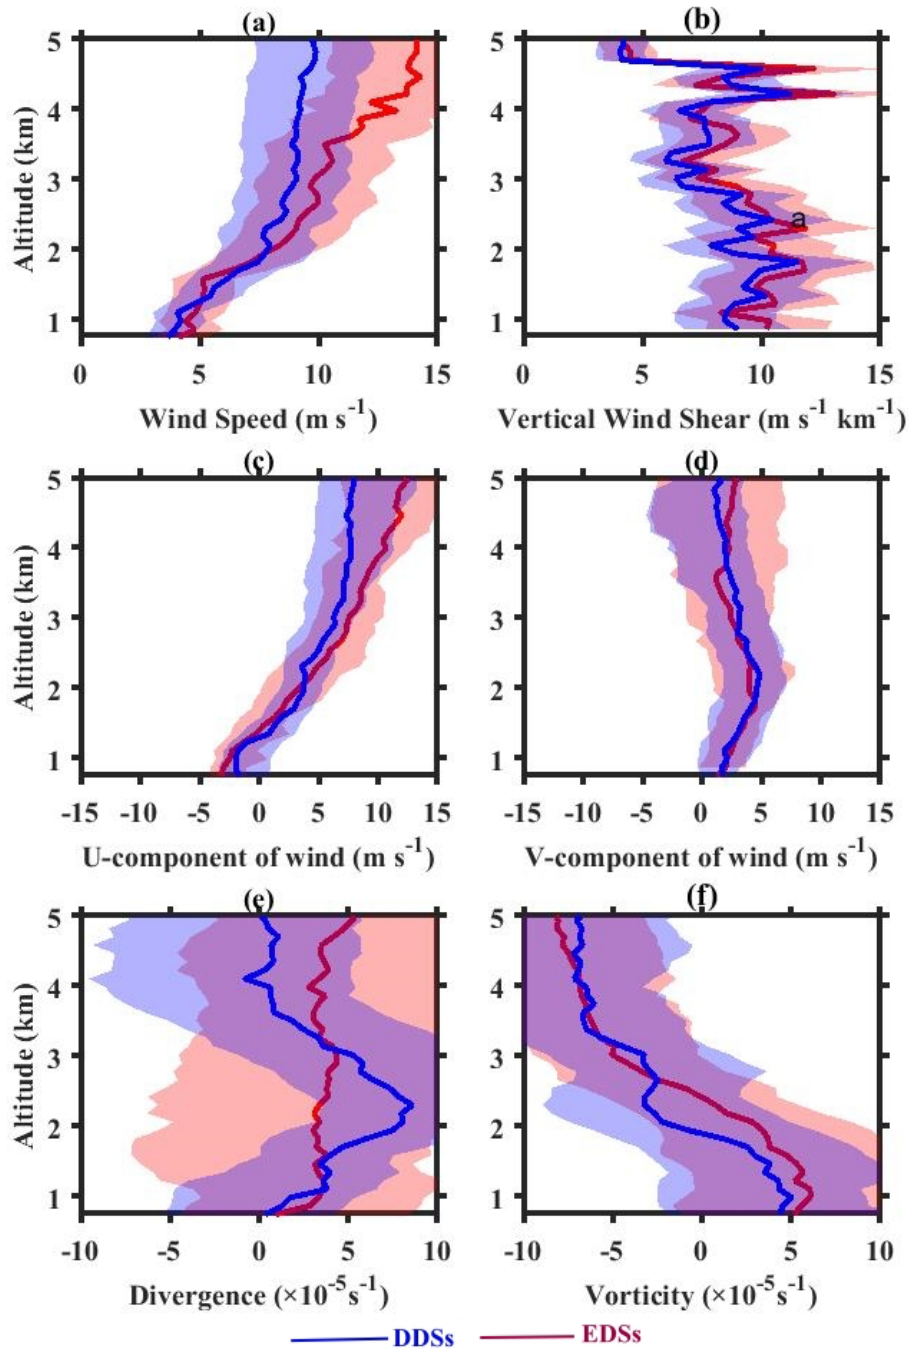

838

839

840

841

842

843

844 **Figure 12.** Vertical profiles of (a) wind speed, (b) vertical wind shear, (c) u-component  
 845 of wind, (d) v-component of wind over YQ station in two hours prior to the arrival of  
 846 EDSs (red) and DDSs (blue). (e) and (f) same as the above, except for the divergence  
 847 and vorticity over triangle 1 as shown in Figure 1b derived from the RWP mesonet,  
 848 respectively.
