37 **Abstract**

38 Tropospheric ozone results from in-situ chemical formation and stratosphere-troposphere
39 exchange (STE), with the latter being more important in the middle and upper troposphere than in
40 the lower troposphere. Ozone photochemical formation is nonlinear, and results from the
41 ~~photochemical~~ oxidation of methane and non-methane hydrocarbons (NMHCs) in the presence of
42 nitrogen oxide ($\text{NO}_x = \text{NO} + \text{NO}_2$). Previous studies showed that O_3 short- and long-term trends are
43 nonlinearly controlled by near-surface anthropogenic emissions of carbon monoxide (CO), volatile
44 organic compounds (VOCs), and nitrogen oxides. In addition, several studies have demonstrated
45 the important role of STE in enhancing ozone levels, especially in the midlatitudes. In this article,
46 we investigate tropospheric ozone spatial variability and trends from 2005 to 2019 and relate those
47 to ozone precursors on global and regional scales. We also investigate the spatiotemporal
48 characteristics of the ozone formation regime in relation to ozone chemical sources and sinks. Our
49 analysis is based on remote sensing products of the Tropospheric Column of Ozone (TrC- O_3) and
50 its precursors, nitrogen dioxide (TrC- NO_2), formaldehyde (TrC-HCHO), and total column of CO
51 (TC-CO) as well as ozonesonde data and model simulations. Our results indicate a complex
52 relationship between tropospheric ozone column levels, surface ozone levels, and ozone
53 precursors. While the increasing trends of near-surface ozone concentrations can largely be
54 explained by variations in VOC and NO_x concentration under different regimes, TrC- O_3 may also
55 be affected by other variables such as tropopause height and STE. Decreasing or increasing trends
56 in TrC- NO_2 have varying effects on the TrC- O_3 , which is related to the different local chemistry
57 in each region. ~~The concomitant increase or decrease in TrC- O_3 and TrC- NO_2 over the eastern US,~~
58 ~~and central Europe is due to dominant NO-sensitive conditions resulting from the strict measures~~
59 ~~to control NO_x emissions over the last two decades. The decreasing trends of TrC- NO_2 but~~
60 ~~increasing trends of TrC- O_3 in some regions in the central US and parts of eastern Asia are due to~~
61 ~~high NO_x conditions leading to VOC sensitivity in these regions.~~ We also shed light on the
62 contribution of NO_x lightning and soil NO and nitrous acid (HONO) emissions to trends of
63 tropospheric ozone on regional and global scales.

64

65 1. Introduction

66 Tropospheric ozone (O_3) is an important air pollutant due to its diverse effects on air quality,
67 ecosystem (Mills et al., 2018), health (Lefohn et al., 2018; Fleming et al., 2018), and climate
68 (Boucher et al., 2013; Myhre et al., 2013; Zanis et al., 2022). O_3 is a photochemical product
69 that results from the oxidation of methane (CH_4) and non-methane hydrocarbons (NMHCs) in
70 the presence of nitrogen oxides (NO_x). Tropospheric ozone burdens can also be affected by
71 stratosphere-troposphere exchange (STE) (Stohl et al., 2003; Zeng et al., 2010; Trickl et al.,
72 2011; Li et al., 2024). O_3 is considered a short-lived climate forcer (SLCF) and is the third-
73 most important greenhouse gas with a global average effective radiative forcing of
74 $(0.3447^{+0.0923}_{-0.0623})$ $W\ m^{-2}$; Forster et al., 2021; IPCC, 2023). Since the mid-1990s, free
75 tropospheric ozone trends based on in situ measurement and satellite retrievals have increased
76 with high confidence by 1-4 $nmol\ mol^{-1}\ decade^{-1}$ across the northern mid-latitudes and 1-5
77 $nmol\ mol^{-1}\ decade^{-1}$ within the tropics (Gulev et al., 2021). In the Southern Hemisphere, with
78 more limited observation coverage compared with the Northern Hemisphere, the tropospheric
79 column ozone shows an increase since the mid-1990s by less than 1 $nmol\ mol^{-1}\ decade^{-1}$ with
80 medium confidence at southern mid-latitudes (Gulev et al., 2021, Cooper et al., 2020). Recent
81 studies showed increasing trends of tropospheric O_3 , especially in the temperate and polar
82 regions of the Northern Hemisphere, while the evidence in the Southern Hemisphere is unclear
83 (Tarasick et al., 2019; Archibald et al., 2020). Tropospheric O_3 short- and long-term trends are
84 nonlinearly controlled by anthropogenic emissions of carbon monoxide (CO), volatile organic
85 compounds (VOCs), and nitrogen oxides ($NO_x=NO+NO_2$) as well as STE, especially in the
86 midlatitudes (Li et al., 2024). Coupled Model Intercomparison Project Phase 6 (CMIP6)
87 overestimates observed surface O_3 concentrations in most regions, with larger variability over
88 Northern Hemisphere (NH) continental regions (e.g., Tarasick et al., 2019; Turnock et al.,
89 2020). The higher variability in the northern continental regions is due to the variable emissions
90 of ozone precursors (i.e., CO, VOCs, and NO_x). CMIP6 models simulate large increasing
91 trends of surface concentrations of O_3 and $PM_{2.5}$ in East and South Asia with an annual mean
92 increase of up to 40 ppb and $12\ \mu g\ m^{-3}$, respectively, over the historical periods (1850-2014;
93 Turnock et al., 2020). However, these studies found also that CMIP6 models consistently
94 underestimate $PM_{2.5}$ concentrations in the NH, especially during the winter months, and with
95 larger variability near natural source regions, indicating missing sources (e.g., HONO) of O_3
96 (e.g., Elshorbany et al., 2014). Future scenarios show that emission control measures can
97 influence future changes to air pollutants. Although the global increases in CH_4 abundance
98 may offset benefits to surface O_3 from local emission reductions (Fiore et al., 2002; Shindell
99 et al., 2012; Wild et al., 2012), recent reports (e.g., Zanis et al., 2022), showed the dominant
100 role of precursor emission changes in projecting surface ozone concentrations under future
101 climate change scenarios. In this study, we investigate the relation between ozone trends and
102 the trends of its precursors.

103 Satellite observations have the advantage of large spatial and consistent temporal coverage.
104 Tropospheric columns of ozone ($TrC-O_3$), in Dobson unit ($1\ DU=2.69\times 10^{20}$ molecules m^{-2}),
105 are usually used to represent tropospheric ozone levels. The tropospheric column of a species
106 is the species' concentration integrated from the surface to the top of the troposphere, the
107 tropopause. The tropopause height is dynamically changing, and it varies over time, increasing
108 or decreasing as a function of several factors, including tropospheric and stratospheric
109 temperature (warming or cooling). Steinbrecht et al (1998) found that observed tropospheric
110 warming of 0.7 ± 0.3 K per decade leads to an increase in the tropopause high and a decrease
111 (at a rate of 16 DU/decade) in the observed column ozone levels. Similarly, after removing the

112 variations related to major natural forcings, including volcanic eruptions, ENSO (El Niño–
113 Southern Oscillation), and QBO (Quasi–Biennial Oscillation), Meng et al. (2021) concluded
114 that a continuous rise of the tropopause in the Northern Hemisphere (NH) from 1980 to 2020
115 is evident, which they related mainly to tropospheric warming caused by anthropogenic
116 emissions. ~~Both~~ Steinbrecht et al (1998) and Meng et al. (2021) calculate the same rate of
117 tropopause increase for the periods 1980-2000 and 1980-2020, respectively. ~~These results~~
118 ~~could affect calculated tropospheric ozone trends by changing the volume of the troposphere.~~
119 We investigate the trends in TrC-O₃ and ozone precursors at different column depths and
120 determine their ~~causal~~ relationships.

121 Global models play a vital role in interpreting the observed trends in ozone precursors,
122 verifying the consistency of emission inventories with observed precursor concentrations, and
123 relating trends in ozone precursor emissions to ozone trends. Because satellite measurements
124 are often sensitive to species concentrations above the surface, models provide additional
125 information on the vertical distribution of ozone precursors needed to relate emissions or
126 surface trends to a column or free tropospheric observations. For example, chemical transport
127 models are used to relate Ozone Monitoring Instrument (OMI) NO₂ columns to surface NO₂
128 concentrations and their trends over the United States (e.g. Lamsal et al 2008, 2015; Kharol et
129 al, 2015) since they provide vertical information on the NO₂ distribution. Models are also used
130 to infer NO_x emission trends from observations (e.g. Richter et al., 2005; Stavrou et al.,
131 2008; Miyazaki et al, 2016) or to examine whether simulations driven by state-of-the-art
132 emissions inventories can reproduce observed changes in NO_x (Itahashi et al., 2014;
133 Godowitch et al, 2010). Models also provide insight into the role of background NO₂ versus
134 local sources in relating satellite-observed NO₂ columns to NO_x emissions changes (Silvern et
135 al, 2019). Similarly, global models are vital for understanding trends in CO, since the lifetime
136 of CO allows both local emissions and long-range transport and the global background to
137 influence regional trends of CO and O₃. Duncan and Logan (2008) attributed the decreasing
138 CO in the NH from 1998-1997 to decreasing European emissions and highlighted the role of
139 Indonesian fires in driving interannual variability. Numerical models can also be used to
140 assimilate satellite CO observations to invert for CO emission fluxes, often highlighting
141 differences between bottom-up and top-down inventories (e.g., Kopacz et al., 2010; Fortems-
142 Cheiney et al., 2011; Elguindi et al., 2020; Gaubert et al., 2020). For instance, several modeling
143 studies found that the increasing emissions from China in recent years in some emission
144 inventories were inconsistent with the negative trends observed by MOPITT (Yin et al, 2015;
145 Strode et al., 2016; Zheng et al, 2019), while the decreases over the United States and Europe
146 are supported by the observed decrease in CO. Jiang et al (2017) and Zheng et al (2019) also
147 found that a decrease in biomass burning contributes to the negative CO trend in the NH. Mean
148 calculated O₃ burden using CMIP6 simulation (Griffiths et al, 2021) revealed an increase of
149 44% from 1850 to the mean of the period of 2005-2014 and by another 17% until 2100 using
150 the SSP370 experiments. Other sources of NO_x such as lightning and soil emissions play an
151 important role in controlling the O₃ budget, especially in low-NO_x regions. We investigate
152 these sources and the role they play in determining O₃ trends and variability on regional and
153 global scales, as well as their determining factors.

154 Previous literature demonstrates the importance of controlling the emissions of ozone
155 precursors to effectively reduce surface O₃ levels. Therefore, a thorough and rigorous
156 understanding of the trends and variability for O₃ precursors is of paramount importance for a
157 global abatement strategy of O₃ levels. In this study, we use ozonesonde, remote sensing, and

158 global models to evaluate tropospheric O₃ and O₃ precursor trends of CO, HCHO, and NO₂,
159 on regional and global scales.

160 2. Methodology

161 2.1. Trend Analysis

162 We analyze the historical trends of tropospheric ozone and its precursors CO, NO₂, and HCHO,
163 from 2005 to 2019. For trend analysis, we use two methods, the Quantile regression (QR)
164 method (Chang et al., 2023), and the Weighted Least Squares (WLS). For NO₂, CO, and HCHO
165 ~~, and CO~~ trends are calculated based on the QR method (Chang et al., 2023), as follows: (1) we
166 first compute the deseasonalized monthly time series of NO₂ and HCHO tropospheric columns
167 (hereafter referred to as TrC-NO₂, TrC-HCHO), and CO atmospheric column (TC_CO), (2) we
168 use the quantile regression method for computing the trend, focusing here on the median, and (3)
169 uncertainties at a 95% confidence level are estimated using the block bootstrapping approach,
170 through 1000 iterations with blocks size of N^{0.25} with N the number of monthly values. They are
171 calculated over a 1°x1° grid and only in cells where at least 75% of the monthly values are
172 available. TC_CO column (see sec. 2.2.1) time series trends are also calculated as Weighted
173 Least Squares (WLS) of the monthly anomaly, weighted by the monthly regional standard
174 deviation (for comparison with the QR method). ~~For the CO trend map, we use a 12-month~~
175 ~~running average before computing the linear trend (Buchholz et al., 2021).~~ The tropospheric
176 ozone column (TrC-O₃), trends are calculated based on the WLS method. Tropospheric columns
177 of satellite observations are calculated based on the WMO thermal definition of the tropopause.
178 To account for varying tropospheric column definitions used in previous literature, we also
179 evaluate the trends at different-varying column depths.

180 2.2. Data resources

181 In this section, we present the different data repositories and their characteristics.

182 2.2.1. Satellite data

183 A list of the applied satellite data products and their resolution is shown in Table 1~~Table 1~~. For
184 Tropospheric ozone data, we use the Ozone Monitoring Instrument/Microwave Limb Sounder
185 (OMI/MLS) product (Ziemke et al., 2006). The OMI/MLS product is the residual of the OMI total
186 ozone column and the MLS stratospheric ozone column, available as gridded monthly means. The
187 tropospheric NO₂ column retrievals used were the QA4ECV project (<http://www.qa4ecv.eu/ecvs>)
188 version 1.1 level 2 (L2) product for OMI (Boersma et al., 2017a), GOME-2 (Boersma et al.,
189 2017b), and SCIAMACHY (Boersma et al., 2017c). The ground pixel sizes of the OMI, GOME-
190 2, and SCIAMACHY retrievals are 13 km×24 km, 80 km×40 km, and 60 km×30 km, with local
191 Equator overpass times of 13:45, 09:30, and 10:00 LT, respectively. We also use HCHO
192 tropospheric columns retrieved from OMI (De Smedt et al. 2018) from the QA4ECV project.
193 Atmospheric total column CO daytime observations were obtained from the MOPITT instrument
194 aboard the Terra Satellite (Barret et al., 2003; Buchholz et al., 2017). Monthly daytime L3 data
195 were obtained at 1° gridded horizontal resolution from the NASA Langley Research Center
196 Atmospheric Science Data Center (ASDC, 2024), using version 9 (V9) retrievals, and the joint
197 near-infrared/thermal-infrared product (Deeter et al., 2022).

198

199 Table 1: Satellite data products and their reference periods.

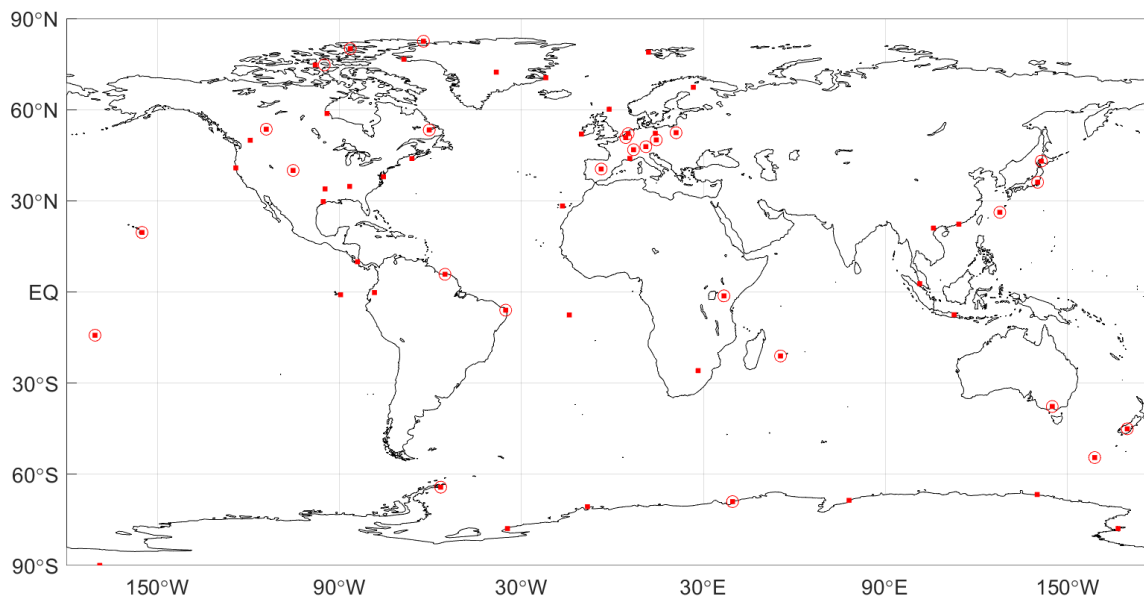

Parameter	Resolution (Satellite pixel size)	Instrument/Platform	Reference Period	Reference
NO ₂	1°x1° (13 km x 24 km)	OMI/Aura	2005–2020	Boersma et al., 2017a
NO ₂	1°x1° (40 km x 80 km)	GOME-2/METOP-A	2007–2018	Boersma et al., 2017b
NO ₂	1°x1° (30 km x 60 km)	SCIAMACHY/ENVISAT	2005–2011	Boersma et al., 2017c
CO	1°x1° (22 km x 22 km)	MOPITT/TERRA	2002–2020	Deeter et al., 2022
HCHO	1°x1° (13 km x 24 km)	OMI/Aura	2004–2020	De Smedt et al., 2018
Ozone	1°x1°	OMI/MLS	2004–2020	Ziemke et al., 2006

200

201 2.2.2. Ozonesonde Data

202 Direct sampling of ozone throughout the atmospheric column by ozonesondes on board of high-
203 altitude balloons is a primary source of information of the ozone abundance and changes in the
204 free troposphere. Ozonesonde data have been used extensively for satellite ozone product
205 validations, trend analyses, and as a priori climatology profiles for satellite retrieval algorithms
206 (McPeters and Labow, 2012; Labow et al., 2015; Hubert et al., 2021; Christiansen et al., 2022;
207 Newton et al., 2016). Ozonesondes networks around the globe have been providing the ozone
208 community with accurate in situ measurements of high vertical resolution (100-m) for the last 5
209 decades in the Northern Hemisphere (Krizan and Lastovicka, 2005), nearing 3 decades at
210 stations in the tropics (Thompson et al., 2017), and in the last decade, new efforts are
211 contributing with data from undersampled regions such as the tropical Andes (Cazorla and
212 Herrera, 2022). Other important contributions include dedicated campaigns for regional studies
213 ([i.e.g.](#) Newton et al., 2016; Fadnavis et al., 2023). Figure 1 shows a map with ozonesonde
214 stations around the globe whose data are publicly available from data providers (station names,
215 coordinates, and links for data access in the Supplementary Material, Table S1). [In this work, we](#)
216 [present a review of ozonesonde trends calculated and published in previous studies \(Wang et al.,](#)
217 [2022 and Christiansen et al., 2022\).](#)

218

219
 220 Figure 1: Ozone-sounding stations around the globe (red squares) whose data are publicly
 221 available (Table S1). Stations that meet the criteria to calculate trends (Wang et al., 2022) are
 222 circled in red.

223
 224 **2.2.3. Model simulations of ozone precursors and their vertical distribution**

225 Model simulations provide information on the vertical distribution of trace gases that can help
 226 interpret the observed columns. Here, we use [the a](#) Goddard Earth Observing System (GEOS)
 227 Earth System Model (Molod et al, 2015) [simulation running](#) with the GMI chemistry mechanism
 228 (Duncan et al, 2007; Strahan et al, 2007; Nielsen et al, 2017) to simulate the contributions of the
 229 lower, middle, and upper troposphere to the tropospheric columns of ozone and its precursors.
 230 [The model configuration is described in Fisher et al \(2024\) and summarized here.](#) The MERRA-
 231 2 reanalysis (Gelaro et al., 2017) constrains the GEOS-GMI meteorology. The GEOS-GMI
 232 meteorology is replayed to the MERRA-2 meteorology as described in Orbe et al (2017).
 233 [Anthropogenic emissions of NO₂, CO, and VOCs are based on the MACCity inventory \(Granier](#)
 234 [et al, 2011\) through 2010 and the RCP8.5 emissions afterward, with NO₂ emissions scaled based](#)
 235 [on OMI. The emissions are downscaled to higher resolution using the EDGAR 4.2 emission](#)
 236 [inventory \(Janssens-Maenhout et al., 2013\). Biomass burning emissions for the analysis period](#)
 237 [come from the Fire Energetics and Emissions Research \(FEER\) product \(Ichoku and Ellison,](#)
 238 [2014\).](#) Liu et al (2022) evaluated another GEOS simulation with GMI chemistry with satellite
 239 observations of TrC-O₃, TrC-NO₂, TrC-HCHO₂ and TC-CO.

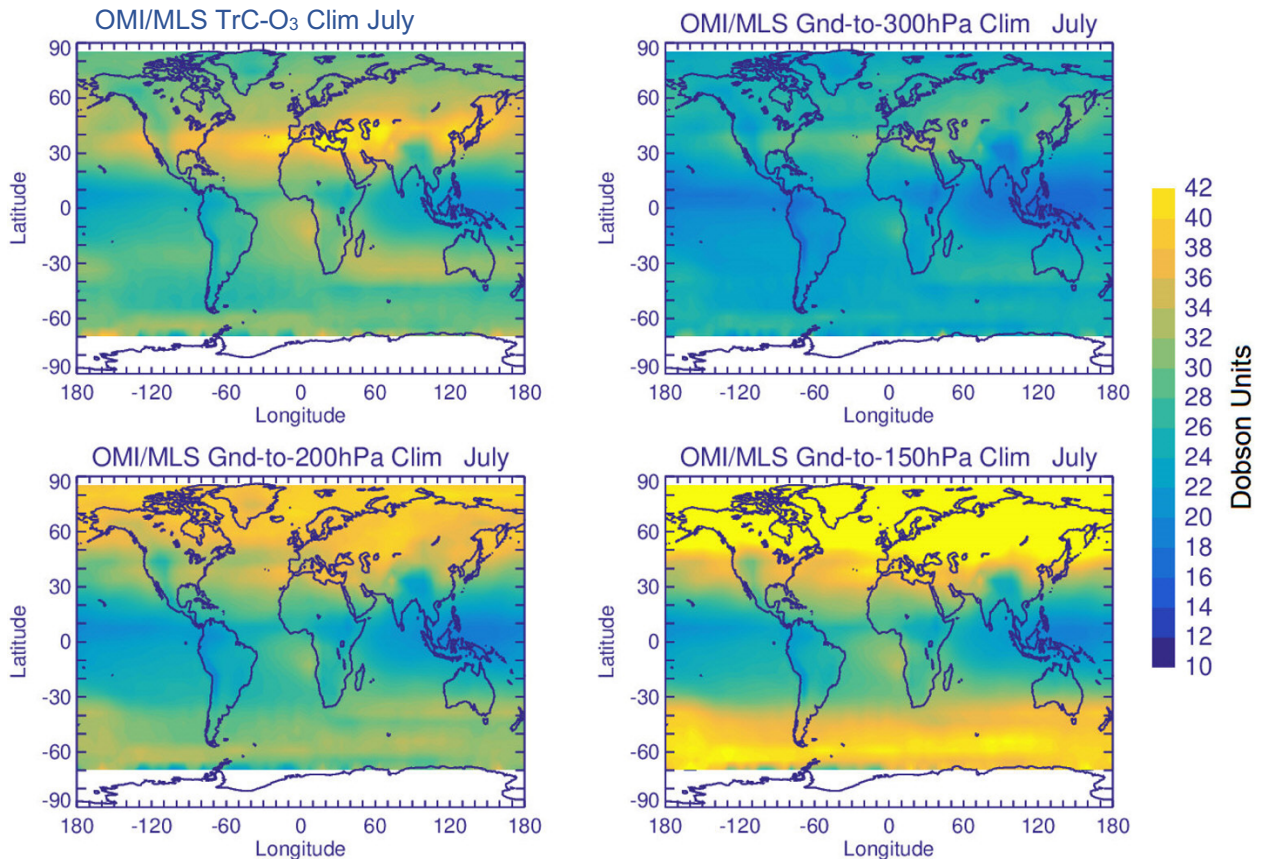

240 **3. Data Analysis and Discussion**

241 **3.1. TrC-O₃ Sensitivity to Tropopause**

242 Calculated TrC-O₃ depends on several factors such as tropospheric ozone levels, atmospheric
 243 warming (e.g., due to GHG emissions) or cooling (stratospheric or tropospheric (e.g., after major
 244 volcanic eruptions), and tropopause height (TH). Atmospheric warming or cooling can lead to a
 245 decrease or an increase, respectively, of TrC-O₃ due to the respective change in the TH. Several
 246 methods are used to determine the TH. The WMO thermal definition (~~WMO~~) for the first TH,
 247 the lowest altitude level at which the lapse rate decreases to 2° K km⁻¹ or less, provided that the
 248 average lapse rate between this level and all higher levels within 2 km does not exceed 2° K km⁻¹

249 ¹. A second tropopause may be also found if the lapse rate above the first tropopause exceeds
 250 $3^{\circ}\text{K km}^{-1}$ (WMO, 1992; Hoffmann and Spang (2022)). Other studies define the TH based on
 251 fixed pressure levels (from ground to 150, 200, 300, and 400 hPa). Mean OMI/MLS TrC-O₃
 252 values in July (2005-2019) calculated based on the WMO thermal definition, are shown in
 253 Figure 2. TrC-O₃ values are comparable to previously reported CMIP6 and satellite
 254 measurements (Griffiths et al., 2021). Partial ozone columns (OC) calculated from the ground to
 255 different pressure levels, 150, 200, and 300 hPa show increasing OC values with increasing
 256 column depth, with calculated OC at 150 and 200 hPa being the closest to the TrC-O₃ WMO
 257 values, still overestimating OC in the northern hemisphere (50-90° N), especially for the 150 hPa
 258 OC, see Figure 2.

259

260

261 Figure 2: Global Mean (2005-2019) Column Ozone based on the WMO definition, ~~as well as~~
 262 ~~to and for~~ different ~~pressure levels~~ column depths.

263

264 Steinbrecht et al (1998) found that observed tropospheric warming of 0.7 ± 0.3 K per decade
 265 leads to an increase in the TH and a decrease in total ozone. They also calculated a decrease of
 266 ~~16 DU per kilometer~~ increase in TH. These results indicate the importance of TH on
 267 calculated long-term ozone trends. This could also affect comparisons between trends calculated
 268 based on different TrC-O₃ definitions and near-surface ozone levels. The time series of
 269 deseasonalized TH from 2004 to 2021 are shown in Figure 3 together with their zonal mean
 270 trends. Trends in TH are positive reaching 60 meters/decade except in a narrow band in the
 271 tropics from 10°S to 20°N and at 30°S, where TH decreases at a rate up to 30 meters/decade. TH
 272 in the tropical regions is also characterized by high variability (see Figure 3). These results are

273 also consistent with recent reports showing a positive trend of TH from 20-80°N at a rate of 50-
 274 60 m/decade (Meng et al., 2021). They related this increase primarily to tropospheric warming.
 275 ~~The decrease of the TH in the tropics may contribute by some extent to the increasing TrC-O₃~~
 276 ~~trend in this region (see sec. 3.4).~~ These results show ~~also~~ that using a fixed pressure level for the
 277 tropopause may not be accurate given the change in TH over time. In the following sections,
 278 tropospheric columns will be calculated based on the WMO tropopause definition.
 279

280
 281 Figure 3: National Centers for Environmental Prediction (NCEP) WMO (2K/km) tropopause
 282 log-P height time series with trends (meters/decade) embedded.

283

284 3.2. Spatial Distribution of O₃ and its Precursors

285 Tropospheric O₃ ~~results from in-situ photochemical formation and STE. is a In-~~
 286 ~~situ photochemical product that~~ O₃ results from the photolysis of NO₂. Therefore, the sources and
 287 fate of NO₂ in the atmosphere determine O₃ burden and distribution. NO₂ is formed from the
 288 reaction of hydrogen ~~peroxyperoxyl~~ (HO₂) and alkyl ~~peroxyperoxyl~~ (RO₂) radicals with NO (R
 289 3.2-1~~R 3.2-1~~). While photolysis of NO₂ is the main source of ozone, high NO₂ levels can
 290 suppress O₃ levels as NO₂ reacts with OH radical forming HNO₃ (R 3.2-2~~R 3.2-2~~ to R 3.2-4~~R~~
 291 3.2-4), thus reducing the oxidation rate of hydrocarbons and respectively HO₂ and RO₂ levels,
 292 leading to a net loss of O₃ (e.g., Finlayson-Pitts and Pitts, 2000; Elshorbany et al., 2010,
 293 Archibald et al., 2020). Ozone production efficiency is calculated as the ratio of the number of
 294 NO₂ molecules photolyzed to form O₃ to that lost due to the reaction with OH forming HNO₃.
 295 Under NO-sensitive conditions, the decrease in NO_x leads to a reduction in OH, HCHO, and O₃.
 296 However, under high NO conditions, a reduction in NO_x could lead to an increase in
 297 photochemical products, OH, HCHO, and O₃ because a reduction in NO₂ leads to a decrease in
 298 OH loss rate, thus higher HO₂ and RO₂ production (Elshorbany et al., 2009; 2010; 2012;
 299 Archibald et al., 2020).

304

305 While this paper focuses on ozone precursors with higher reactivity, we note that methane, with
 306 an assessed total atmospheric lifetime of 9.1 ± 0.9 years (Szopa et al., 2021), is also a crucial
 307 driver (Fiore et al., 2002; Isaksen et al., 2014), given its accelerated growing rate of 7.6 ± 2.7
 308 nmol mol⁻¹ yr⁻¹ between 2010 and 2019 (Canadell et al., 2021), largely driven by anthropogenic
 309 activities (Szopa et al., 2021).

310 The observed mean tropospheric columns of O₃, NO₂, and HCHO and atmospheric column of
 311 CO from 2005 to 2019 are shown in Figure 4. The unit for column number density is
 312 Pmolec/cm² ($\times 10^{15}$ molecules per square centimeter), except for TrC-O₃, which is Dobson. NO₂
 313 concentration has ~~been decreasing since 2005 in North America, Europe, and Australia, mainly~~
 314 ~~due to the applied~~decreased since 2005 in North America, Europe, and Australia, mainly due to
 315 strict measures to reduce air pollution (Lamsal et al., 2015). Since O₃ is a photochemical product
 316 that is formed based on non-linear chemistry, a reduction in NO₂ may lead to an increase or
 317 decrease in tropospheric O₃ levels based on the dominant photochemical regime in the respective
 318 region. In addition, tropospheric ozone levels, especially in the middle and upper troposphere
 319 may be affected by STE (Li et al., 2024). The highest values of the NO₂ tropospheric column are
 320 in the northern hemisphere between 10 °N and 50°N, especially over the eastern US, northern
 321 Europe, and east and south Asia, with elevated levels in the Southern Hemisphere (SH) between
 322 10 and 30°S, especially in sub-Saharan Africa, and Brazil. TrC-O₃ is also highest over the band
 323 of 20-50° N, especially over the eastern coast of the US, southern Europe, and east Asia. Some
 324 differences exist between TrC-O₃ and TrC-NO₂ spatial patterns which is due to factors including
 325 ~~the~~different lifetime, photochemical sensitivity (see sec. 3.4), and STE.3.4). On average, the
 326 northern hemisphere has higher TC-CO than the southern hemisphere due to a larger number of
 327 sources (Buchholz et al., 2021). Additionally, high amounts of CO are found in regions with
 328 large anthropogenic sources (e.g., eastern China) or in regions with large and regular fire seasons
 329 (e.g., central Africa) (Buchholz et al., 2021). HCHO and CO show a similar spatial pattern over
 330 western Africa due to emissions from biomass burning (Marais et al., 2012, Buchholz et al.,
 331 2021). In the following sections, global and regional trends of TrC-O₃ are investigated along
 332 with tropospheric ozone precursors.

333

334

335 Figure 4: Mean (2005-2019) of TrC-O₃, TrC-NO₂, TrC-HCHO, and TC-CO.

336 **3.3. Simulated O₃ Precursors**

337 Ozone and its precursors differ in their vertical distribution through the troposphere. In this
 338 section, we use the GEOS ~~GMI~~ simulations to show how the lower, middle, and upper
 339 troposphere contribute to the simulated columns of O₃ and its precursors to complement the
 340 column information from satellites. Figure 5 shows the simulated mean (2005-2019)
 341 contributions to tropospheric columns of O₃, NO₂, formaldehyde, and CO, partitioned into the
 342 lower (up to 700hPa), middle (700-400hPa), and upper (400hPa to tropopause) portions of the
 343 troposphereopause for the tropical band (30°S:30°N) and the global mean. The middle and upper

344 troposphere make large contributions to the simulated TrC-O₃ and its variability (Figure 5),
 345 while the lower troposphere makes the largest contribution to the TrC-HCHO column since it is
 346 mainly a photochemical product (e.g., Elshorbany et al., 2009), and all three levels make
 347 substantial contributions to the CO column. Globally, the relative contributions for TrC-O₃, TrC-
 348 HCHO and CO are similar to those of the tropics. However, for TrC-NO₂ the lower troposphere
 349 makes a smaller contribution in the tropics than globally largest contribution to the simulated
 350 tropospheric NO₂ column due to the larger NO_x emissions in the northern hemisphere.

351

352

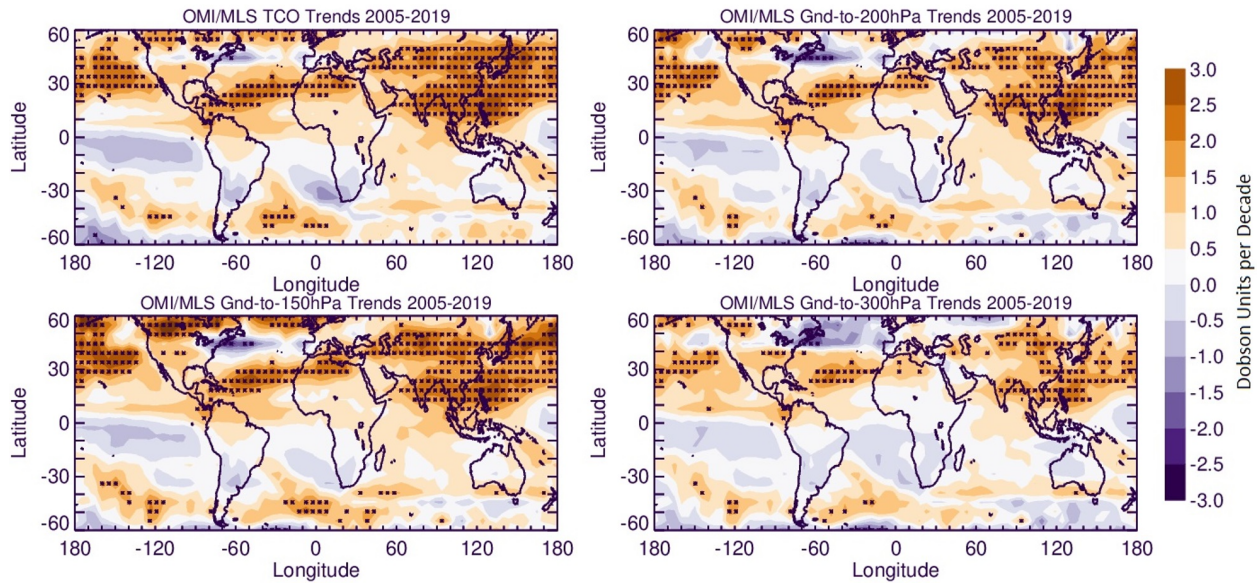

353 Figure 5: Simulated average (2005-2019) contributions to the tropospheric columns of O₃, NO₂,
 354 formaldehyde, and CO from the lower (surface-700hPa), middle (700-400hPa), and upper
 355 troposphere (400hPa-tropopause) using NASA GEOS5-GMI. The top row is for the global
 356 mean, while the bottom row is averaged from 30°S-30°N.

357 3.4. Tropospheric Trends

358 3.4.1. Global Tropospheric Ozone

359 Global TrC-O₃ trends calculated for different column depths are shown in Figure 6. Compared to
 360 TrC-O₃, OC trends up to 150 hPa seem to be the closest despite OC values being much higher
 361 than that of the TrC-O₃ (Figure 2). All significant trends are positive indicating increasing trends
 362 of ozone columns, regardless of the tropopause height. Insignificant (at 2 σ levels) decreasing
 363 TrC-O₃ trends were also found in some locations, e.g., South Australia, South Africa, and the

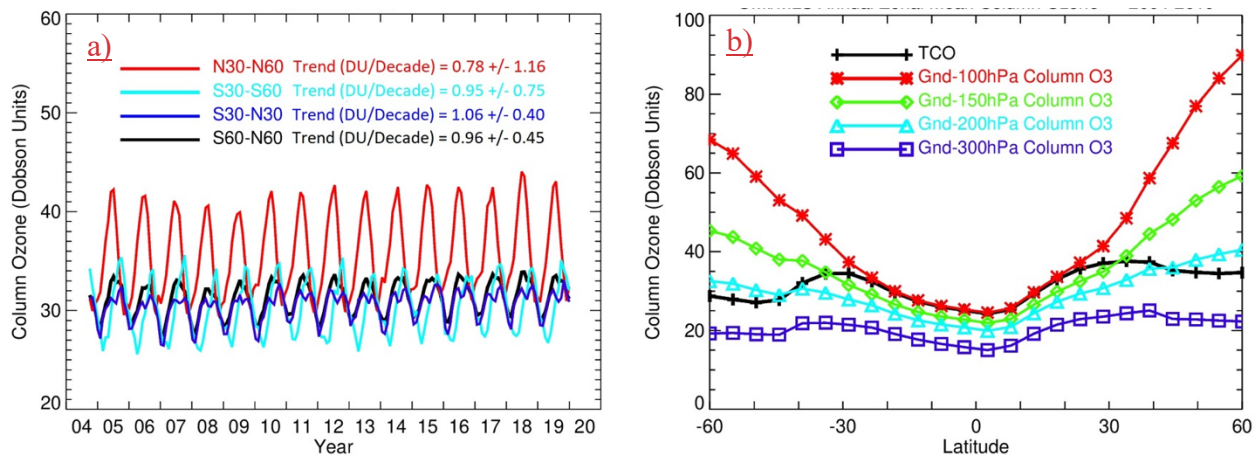

364 northeastern coast of the US. As mentioned in sec. 3.1, TrC-O₃ trends in the northern tropics may
 365 be slightly enhanced by the decreasing TH trends in that region (Steinbrecht et al., 1998). In
 366 contrast, increasing TrC-O₃ trends in other regions may be slightly offset by the increasing TH
 367 trends (see Figure 3). Increasing trends in the northern midlatitudes may also be partially related
 368 to STE (Willimas et al, 2019; Li et al., 2024)

369
 370 Figure 6: Trends in tropospheric column ozone, based on the WMO thermal definition, and the
 371 trends on ozone columns (from ground to 150, 200, and 300 hPa). Trends are calculated based on
 372 deseasonalized monthly data from 2005 to 2019. Asterisks denote significant trends
 373 (different from zero at 2σ level).

374
 375 The time series of OMI/MLS TrC-O₃ averaged over several latitudinal bands as well as and
 376 at different column depths are shown in Figure 7. Zonal mean TrC-O₃ compares well with
 377 partial ozone columns in the tropics (from 30°S to 30°N) with the OC of up to 300 hPa differing
 378 by about 10 DU from the TrC-O₃ (Figure 7b). The lowest TrC-O₃ trends are located in
 379 the northern hemisphere (30°N–60°N) at 0.78±1.16 DU/decade, followed by the southern
 380 hemisphere (30°S–60°S) (0.95±0.75 DU/decade) and the tropical band (30°S–30°N) (1.06±0.40
 381 DU/decade). In addition, the continental trends over Australia, South Africa, and South America
 382 in the 30°S–60°S band are essentially negative and the positive trends in this band are driven
 383 comantributed mainly by oceanic emissions-regions (see Figure 6). The positive trends in the
 384 30°N–60°N band are slightly offset by the negative trends over the northeEastern US and
 385 western Europe (see Figure 6).

386

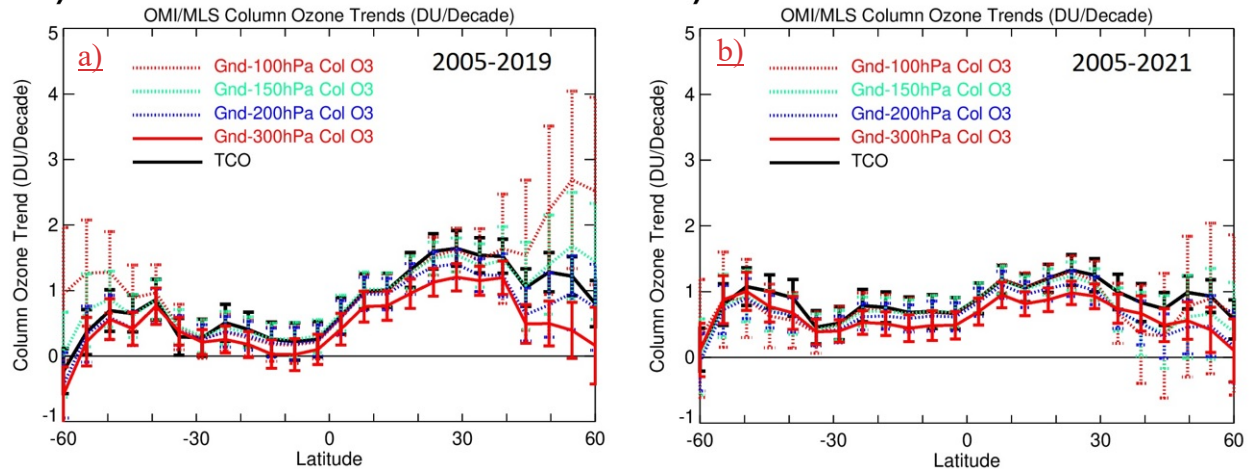

387
 388 Figure 7: Time series and zonal mean trends of OMI/MLS TrC-O₃ in different latitudinal bands
 389 (left) and zonal mean of different column depths (right) from 2005-2019.

390
 391 Observed trends for the time period before COVID-19 (2005-2019) show that OC trends
 392 were highest in the northern latitudes (0-30° N) reaching about 1.5 DU/decade, followed by the
 393 northern midlatitudes 30-60°N (Figure 8). The high trends in the 30-60°N band are dominated by
 394 transpacific impacts as well as some impacts from East Asia. The positive trends in the southern
 395 hemisphere (0-30° S) are mainly over Amazonia and Southeast Asia, being offset by small
 396 negative trends over Western Australia and South Africa. The trends during the time period
 397 (2005-2021) show a ~~significant~~ decline in O₃ column trends in the northern hemisphere but a
 398 slightly increasing trend in the southern hemisphere (Figure 8b). The decreasing trends in the
 399 northern hemisphere during the COVID-19 is consistent with previous literature showing a
 400 ~~significant~~ decrease in several pollutants including NO₂ and O₃ due to the extended lockdown
 401 periods imposed during the pandemic (e.g., Bauwens et al., 2020; Elshorbany et al., 2021;
 402 Steinbrecht et al., 2021; Putero et al., 2023). The decrease of NO₂ ~~under the dominant NO-~~
 403 ~~sensitive conditions~~ in ~~some parts of~~ Europe and the ~~northeastern~~ USA led to a decrease in
 404 tropospheric O₃. ~~The increase in the southern hemisphere is due to a variety of reasons including~~
 405 ~~the lesser impact of the pandemic (Oleribe et al., 2021), and persistent pollution issues, even~~
 406 ~~during the pandemic (Matandirotya et al., 2023). In addition, most regions in the southern~~
 407 ~~hemisphere are VOC sensitive regions, conditions under which the reduction in NO₂ would lead~~
 408 ~~to an increase in tropospheric O₃ (see sec. 3.4)~~

409 Zonal mean trends (Figure 8) show that OC up to 150 hPa is almost identical to that of
 410 TrC-O₃ except for the high latitudes 45°-60° S and 45°-60° N. The decreasing trends above 30°N
 411 and 30°S are due to the offsetting impact of negative trends over ~~the northe~~Eastern US and
 412 ~~western~~ Europe in the north, and Australia and South Africa in the south, respectively. This
 413 impact is less apparent in the 150 hPa OC due to the lower positive trends in that band compared
 414 to TrC-O₃. The 200 hPa OC comes next with a very good agreement from 60° S to 10° N.
 415 followed by the 100 hPa which is only in good agreement from 30° S to 30°N, while the 300 hPa
 416 OC was the farthest from the TrC-O₃. ~~The decrease of O₃ in the northeastern US and western~~
 417 ~~Europe is a result of consistent with decreasing NO₂ trends demonstrating the and NO-sensitive~~
 418 ~~conditions dominating these regions.~~ The decreasing trends ~~of O₃ over Eastern US and Europe~~
 419 ~~are consistent with the decreasing trend~~ of NO₂ (see below), ~~which is~~ due to the successful
 420 measures applied since 2004 to mitigate air pollution in these regions. ~~The decrease of O₃ is a~~

421 ~~result of decreasing NO₂ trends demonstrating the NO-sensitive conditions dominating these~~
422 ~~regions.~~

426
427 Figure 8: Tropospheric column ozone (TrC-O₃) and trends for different column depths before the
428 COVID-19 pandemic (2005-2019) and including the pandemic (2005-2021).

430 3.4.2. Free tropospheric trends

431 Trends of ozone in the free troposphere presented here are based on previous work published in
432 ozonesonde data from the literature. Despite the high stability of ozonesonde measurements
433 across the global networks over several decades (Stauffer et al., 2022), the spatial sparsity of
434 sounding stations and non-uniform sampling frequency among sites is a limitation in using these
435 data to produce trends. These shortcomings have constrained the ability to include data from
436 many stations in previously published analyses. For example, Chang et. al (2020) estimated that
437 at least 18 profiles per month are needed at a single station to calculate accurate long-term
438 trends, while uncertainty increases at lower sampling rates (Chang et al 2024). However, such
439 high sampling frequency is only achieved at three European stations (Hohenpeissenberg,
440 Germany; Payerne, Switzerland, and Uccle, Belgium), while the rest of the global stations work
441 at lower sampling rates. Nonetheless, high-quality ozonesonde observations continue to be the
442 gold standard against which satellite measurements are validated. Likewise, ozonesonde data
443 continue to provide spaceborne observations with climatological feedback. Thus, recent studies
444 have softened the sampling frequency criteria in order to take advantage of the valuable data set
445 collected by the global ozonesonde networks. For example, the latest trend studies establish the
446 Recently, it was proven that ~~minimum temporal-frequency requirements~~ to calculate trends to
447 from ozonesondes demand sampling to be executed at ~~at~~ least three times-profiles per month
448 (Wang et al., 2022; Christiansen et al., 2022) with at least eight months of sampling in a year,
449 and at least 15 annual means for an analysis of about two decades (Wang et al., 2022). With
450 these criteria, recent ozonesonde trend analyses indicate that ozone concentration increased
451 globally by 1.8+/-1.3 ppbv/decade in the free troposphere within 800 to 400 hPa (Christiansen et
452 al., 2022). However, there is significant regional variability, as illustrated in Figure 9 where
453 ozone trends published by Wang et. aAl. (2022) (1995-2017 data between 950-250 hPa) are

454 organized by regions and stations. For example, ozone in East Asia (Japan) has been increasing
 455 at a rate of 3.5 to 5 ppbv/decade, particularly since 2010 (Christiansen et al., 2022). Over the
 456 Southwestern Indian Ocean (La Réunion), trends are of similar magnitude (>4.5 ppbv/decade).
 457 In tropical South America, over the Atlantic basin region (Paramaribo and Natal), sounding
 458 measurements also show ozone increases by almost 3 ppbv/decade (Natal), but other regions in
 459 South America continue to lack sufficient measurements to produce trends. At tropical stations in
 460 Africa (Nairobi) and the Pacific Ocean (Hilo and American Samoa) trends are also positive,
 461 although of lower magnitudes (0.83-1.7 ppbv/decade). In contrast, polar stations both at the
 462 Arctic and Antarctica as well as the Southern Ocean show overall decreasing ozone
 463 concentrations to non-significant trends. Exceptions are the Eureka station in Canada and Lauder
 464 station in New Zealand, which both show slight ozone increases (less than 0.5 ppbv/decade). The
 465 direction of regional trends by Wang et. al. (2022) is consistent with regional trends presented in
 466 similar independent research (Christiansen et al., 2022). As atmospheric composition continues
 467 to become modified under the current regime of climate change, building consistent and longer
 468 time series of ozonesonde measurements at other regions will continue to be an important source
 469 of firsthand information to assess tropospheric ozone changes and trends.

470

471
 472 Figure 9: Ozone trends in the free troposphere from ozonesonde measurements calculated by
 473 Wang et. Al. (2022) and organized by region and station. Data covers the 1995-2017 period
 474 within 950 to 250 hPa. Error bars show 1- σ uncertainty. The coordinates of ozonesonde stations
 475 are listed in Table S1.

476

477 3.4.3. Regional Ozone Trends

478 As shown in Figure 10, the highest OMI/MLS regional trend is observed over East Asia
 479 (2.16 ± 1.27 DU/decade) while the lowest trend is calculated over Eastern USA (0.63 ± 1.72)
 480 followed by Western Europe (0.89 ± 1.60) and Australia (1.05 ± 1.44) DU/decade. We next
 481 calculate the monthly trends from the GEOS-GMI simulation to investigate how the simulated
 482 trends vary by altitude through the tropospheric column.

483

485

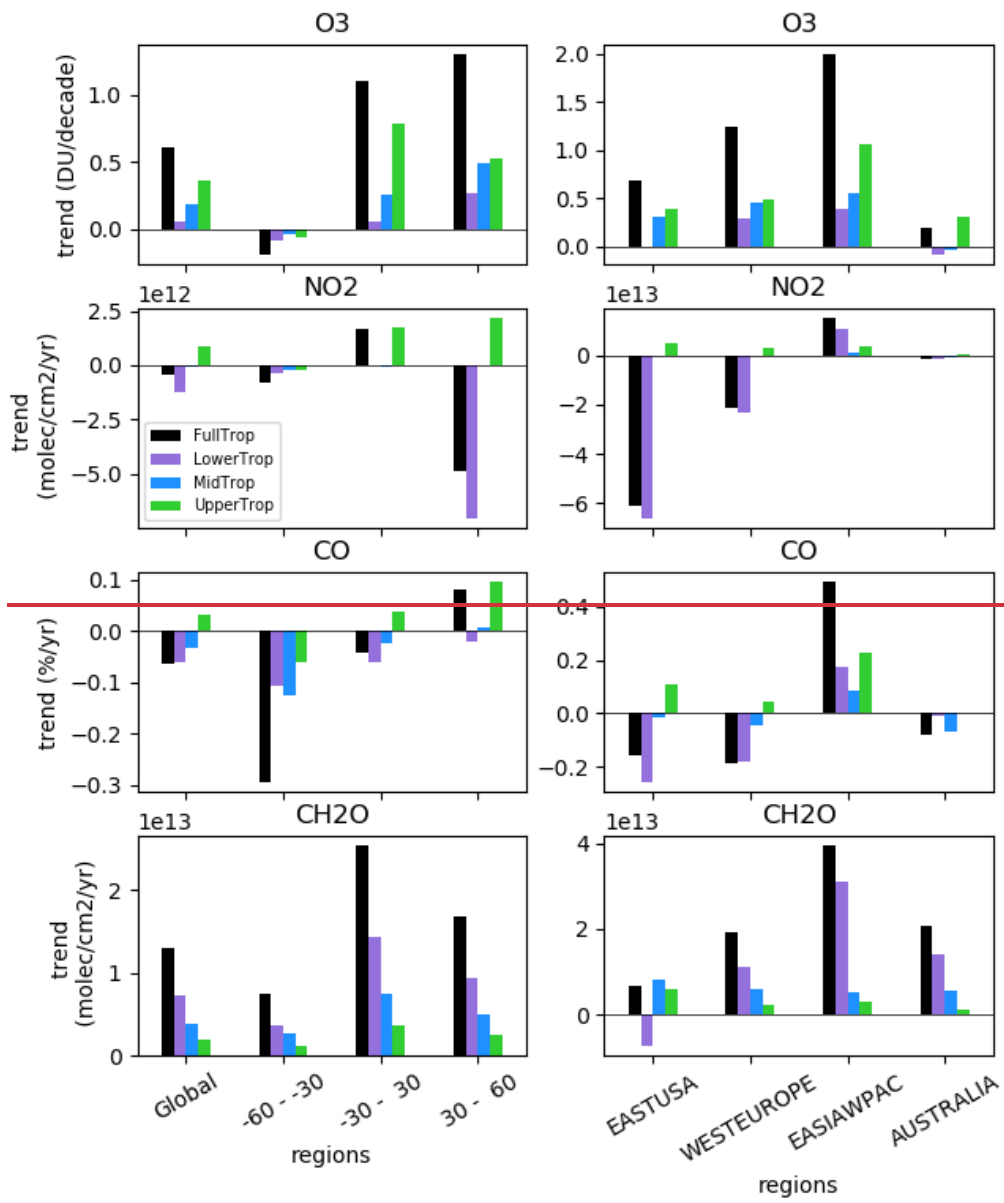

486 Figure 10: OMI/MLS observed regional mean trends of TrC-O₃.

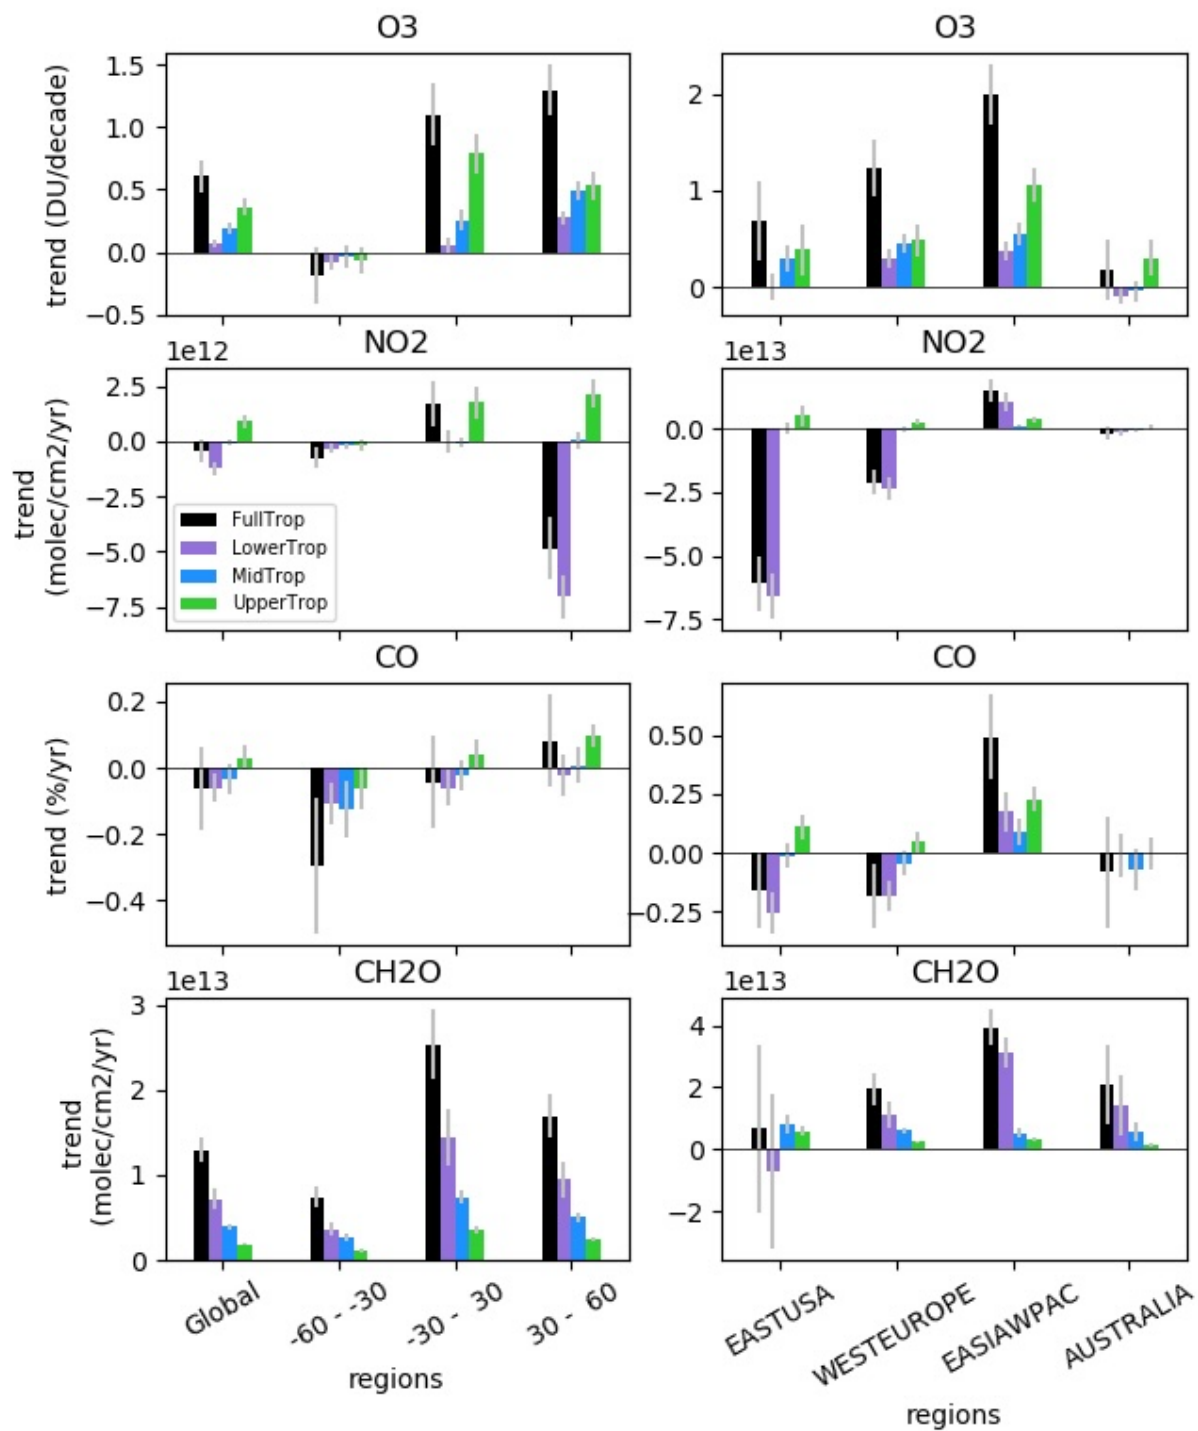

487

488 The simulated trends in partial columns (lower, middle, and upper troposphere) of O₃, NO₂,
 489 formaldehyde, and CO from 2005 to 2019 for different pressure levels as well as the tropospheric
 490 columns, as well as the TrC-O₃, TrC-NO₂, TrC-HCHO, and TC-CO from 2005 to 2019, -are
 491 shown in Figure 11 ~~Figure 11~~. The simulated tropospheric columns of TrC-O₃ and TrC-HCHO
 492 show a positive trend in most regions (Figure 11 ~~Figure 11~~), consistent with the results of Liu et al
 493 al (2022) -using a different GEOSCCM simulation. Liu et al (2022) highlighted the importance
 494 of formaldehyde trends for analyzing the simulated trends in tropospheric ozone. Considering
 495 different latitude bands, the highest trends are simulated between 30° S and 60° N, consistent
 496 with calculated trends based on satellite observations (see sec. 3.4). In contrast, the simulated
 497 NO₂ and CO trends are mostly negative, although positive trends are simulated over East Asia.
 498 The largest NO₂ negative trends are in the northern hemisphere between 30°N and 60°N. The
 499 decrease in NO₂ trends is consistent with the successful measures to curb emissions of pollution
 500 criteria in the US and Europe ~~The decreasing NO₂ trends but increasing O₃ and HCHO trends in~~
 501 ~~the northern hemisphere are due to the NO-sensitive conditions prevailing over Europe and the~~
 502 ~~USA~~. The increased trends in TrC-O₃ but decreased trends in TrC-NO₂, and TC-CO might
 503 indicate STE contribution (Trickl et al., 2020; Li et al., 2024) in addition to the local chemistry.

504

505

507
 508 Figure 11: Global and regional trends in O₃, NO₂, CO, and HCHO calculated from the GEOS-
 509 GMI simulation for the tropospheric column (black), lower troposphere (purple), middle
 510 troposphere (blue), and upper troposphere (green) from 2005 to 2019. The lower, middle, and
 511 upper troposphere are defined as in Figure 5.

512
 513 The GEOS-GMI simulation provides an estimate of the relative contribution from different
 514 portions of the tropospheric column to the column trends and shows that this contribution varies

515 by region and constituent. The middle and upper troposphere make the largest contributions to
 516 the simulated TrC-O₃ trend globally, with large contributions from the upper troposphere driving
 517 the simulated TrC-O₃ trend at 30°S-30°N ~~and counteracting the negative TrC-O₃ trend in the~~
 518 ~~southern midlatitudes (Figure 11Figure 11). However, the middle and lower troposphere make~~
 519 ~~larger contributions to the positive TrC-O₃ trends in the northern middle and high latitudes.~~ The
 520 middle and upper troposphere contribute most of the simulated positive TrC-O₃ trend over the
 521 eastern USA, while ~~the lower and middle troposphere are more important over western Europe,~~
 522 ~~and all three levels contribute over western Europe and East Asia.~~ The upper troposphere makes
 523 the primary contribution to the simulated trend over Australia. Simulated TrC-O₃ trends are also
 524 quite comparable to those observed by OMI/MLS within the measurement model uncertainty
 525 (see Figure 10 and Figure 7). Over Australia, the OMI/MLS trend of 1.05±1.44 DU/decade is
 526 higher than the model trend of about 0.2-18±0.308 DU/decade (see Figure 11Figure 11).
 527 However, since OMI/MLS trend has a calculated uncertainty (2σ) of 1.44 DU/decade, both the
 528 model and OMI/MLS for Australia are not statistically different.

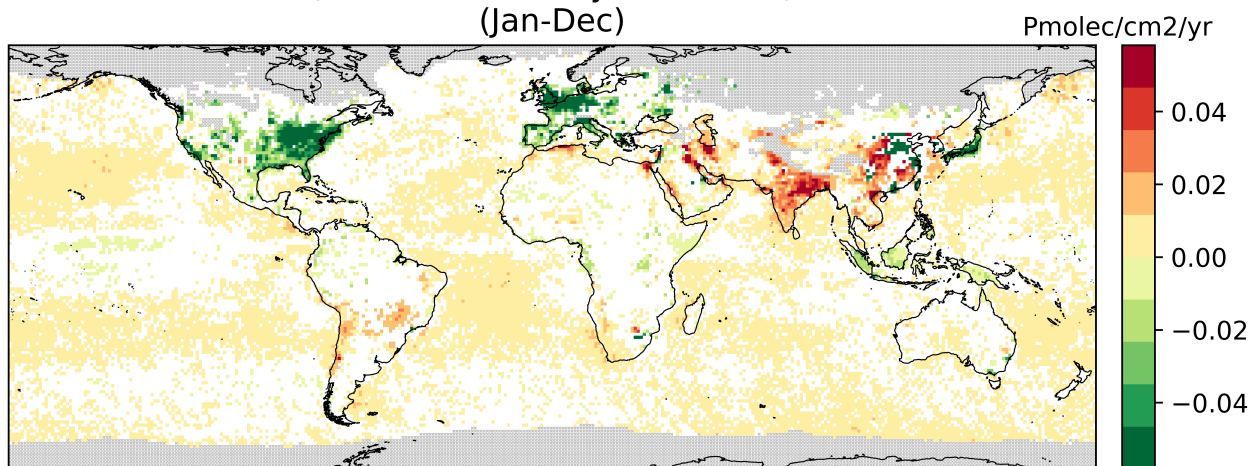

529 While the upper troposphere is a major driver of the simulated TrC-O₃ trends, the lower
 530 troposphere is the largest contributor to the simulated trends in the tropospheric NO₂, CO, and
 531 HCHO ~~trends~~ globally and over many regions (Figure 11Figure 11). Exceptions include the
 532 simulated NO₂ in the tropics (30°S-30°N), which is dominated by the upper troposphere, the
 533 simulated HCHO column over the eEastern USA, which is driven by the middle and upper
 534 troposphere; an important role for upper tropospheric CO over East Asia; and the CO trend over
 535 Australia driven by the middle tropospheric contribution. Figure 11Figure 11 also shows that in
 536 some regions, such as the eastern USA for all 3 precursors, the upper and lower tropospheric
 537 trends counteract each other, reducing the magnitude of the column trend. In the following
 538 sections, we investigate trends and variability in O₃ precursors, NO₂, CO, and HCHO.

539 3.4.4. NO₂ Trends

540 The TrC-NO₂ trends over 2005-2019 are shown in Figure 12 with a regional summary in Figure
 541 13. On a global scale, there is a strong spatial variability of the TrC-NO₂ trends. About a third of
 542 the oceans show significantly increasing TrC-NO₂ (at 95% confidence level), especially at mid-
 543 latitude, with trends up to +0.01 Pmolec/cm²/yr; while only a few cells in the equatorial Pacific
 544 show a significant decrease.

545

Annual trend of OMI TrC-NO₂
 (based on monthly anomalies)
 (Jan-Dec)

546

547 Figure 12: Global trends of OMI NO₂ tropospheric column (TrC-NO₂) over 2005-2019 (see text
548 for details on the calculation of the trends). Grey areas correspond to areas without enough data,
549 white areas correspond to regions where the trends remain statistically insignificant at a 95%
550 confidence level.

551 Regional trends are shown in Figure 13. For significant trends in a given region, the
552 numbers correspond to the percentiles 5/50/95 of trends among the different cells of the region
553 where trends are significant. Each region is tagged with a circle whose size is proportional to the
554 p50 of the significant trends (red for positive and green for negative), which allows us to quickly
555 see regions where the trend is strong. For instance, for Eastern Asia (this region includes 1442
556 1°x1° grid cells) about 15% of the grid cells (about 216 grid cells) in this region show a
557 significant decrease in TrC-NO₂. Over these specific 216 cells with a significant decrease of
558 TrC-NO₂, the 5th and 95th percentile of the trend is -0.34 and -0.01, respectively,
559 Pmolec/cm²/yr. About 28% of the grid cells in this region show a significant increase of TrC-
560 NO₂ (which means about 403 grid cells). Over these specific 403 cells with a significant increase
561 of TrC-NO₂, the 5th (resp 95th) percentile of the trend is +0.01 (resp 0.05) Pmolec/cm²/yr.
562 Therefore, the Eastern Asia region shows sub-regions with significantly decreasing TrC-NO₂,
563 others with significantly increasing TrC-NO₂, and the rest with non-significant (positive and
564 negative) trends. This figure allows us to quickly understand the distribution of the trends within
565 ~~at~~ this given region while the overall regional trend is given by the 50th percentile and the circles
566 tagging each region. It's a regional summary of what is shown in the trend global map. In Eastern
567 Asia, the area where trends are significantly positive is more extended than for the significant
568 decrease (28% versus 15%), but the trend values tend to be smaller (at least when comparing the
569 50th percentiles, -0.05 versus +0.01 Pmolec/cm²/yr). The map of regions is included in the
570 supplement. Canada is included in northern America but as shown in the trend map, most of
571 Canada does not have OMI data

572 Over continental areas, significant positive and negative trends are found in about 15-
573 20% of the grid cells each (Figure 12). Regions with predominantly decreasing TrC-NO₂ include
574 western and southern Europe (where about 50-60% of cells with a significant decrease), northern
575 America (40% of cells with a significant decrease, mostly located in the eastern United States),
576 Japan, and Indonesia. In absolute terms, these negative trends reach values of about -0.03
577 Pmolec/cm²/yr. Specific eastern regions of China also show similar significant TrC-NO₂
578 decreases but overall, a larger part of the country faces increasing trends up to +0.03
579 Pmolec/cm²/yr. ~~Similar p~~Positive trends ~~of similar magnitude~~ are observed over most of India, as
580 well as in specific parts of south-eastern Asia (mainly Vietnam) and the Middle East (mainly
581 Iran and Iraq). Conversely, TrC-NO₂ trends in Africa and South America remain mainly
582 insignificant, except in a few specific regions with significant increases (e.g. South Africa, ~~Chile,~~
583 Morocco, ~~Chile,~~ and parts of Brazil).

584 ———The trends in NO₂ have varying effects on the tropospheric ozone column, which
585 is related to the different local chemistry in each region. The concomitant ~~increase or~~ decrease in
586 TrC-O₃ and TrC-NO₂ trends over ~~some parts of the~~ the eastern US, and ~~westerneentral~~ Europe is
587 ~~due to consistent with the dominant NO-sensitive condition due to~~ the strict NO_x control
588 measures that were applied over the last two decades. ~~STE can also contribute to increased TrC-~~
589 ~~O₃ trends, especially in the mid-latitudes. The A~~ decreasing trend of TrC-NO₂ but ~~an~~ increasing
590 trend of TrC-O₃ ~~is present in some in othersome~~ regions ~~such as~~ in the central US, ~~which might~~
591 ~~be due to local chemistry and STE, e.g., over Chicago is due to the high NO_x conditions in these~~
592 ~~regions (e.g., Elshorbany et al., 2021 and references therein). The increasing TrC-O₃ trends as~~

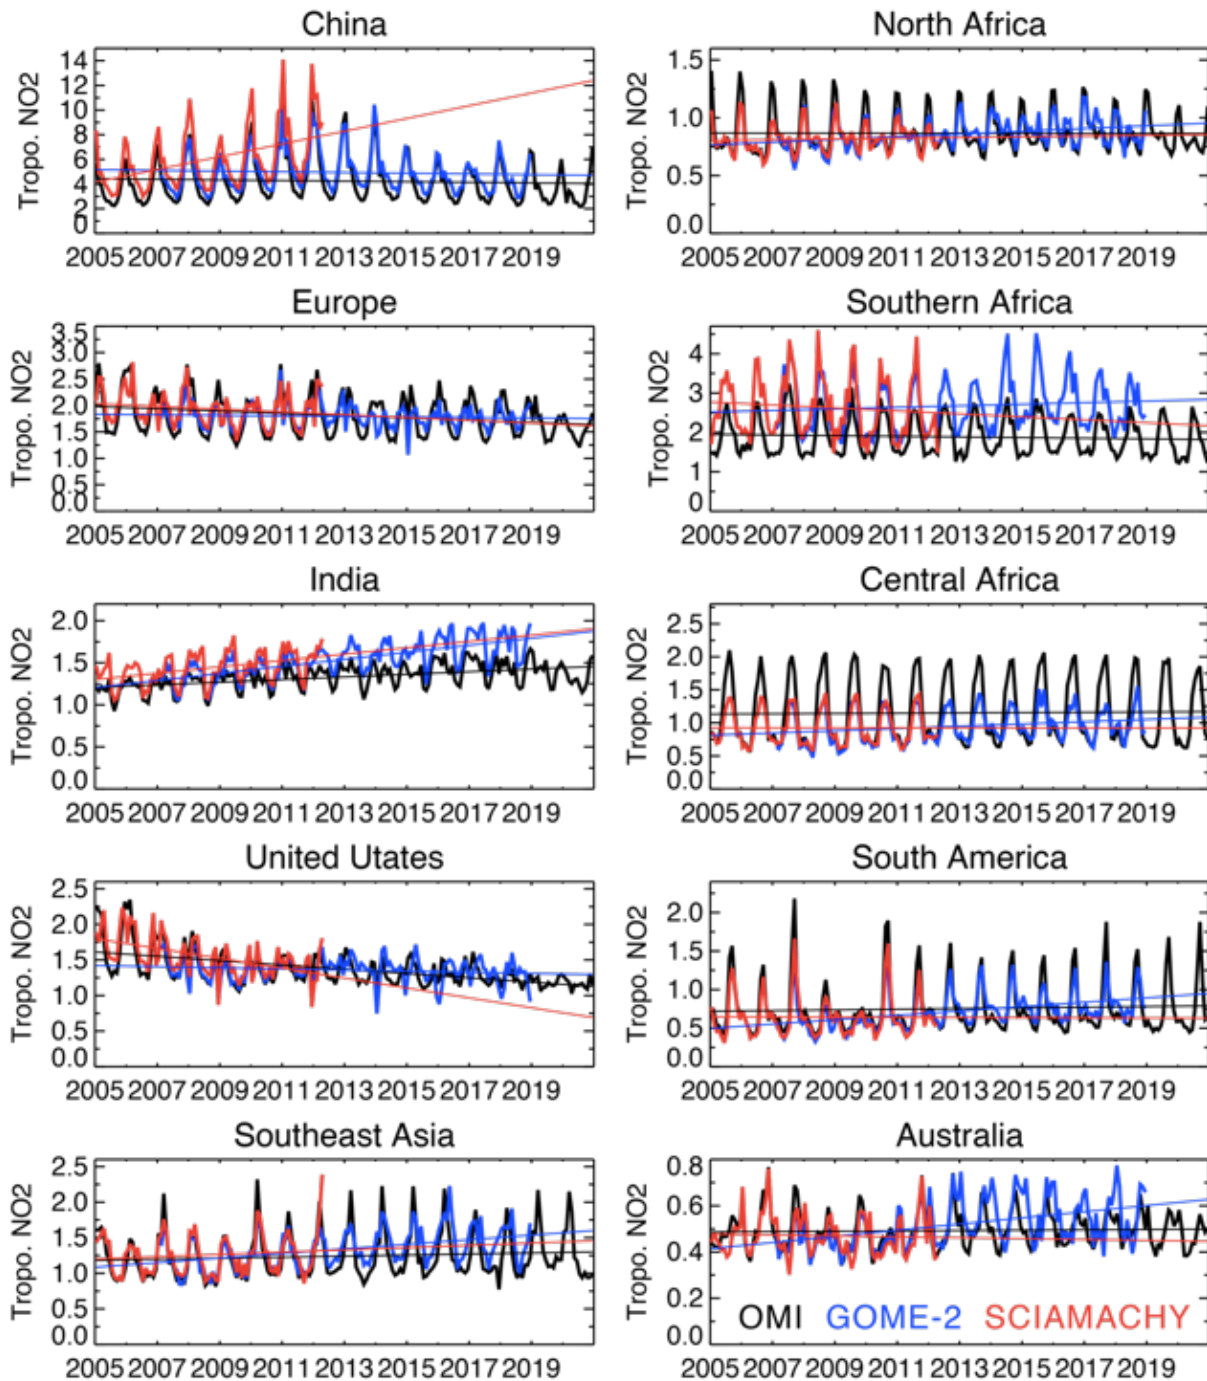

593 TrC-NO₂ decreases over China and parts of eastern Asia can also be explained by the high NO_x
 594 levels dominated in these regions.
 595
 596

597
 598 Figure 13: Summary of the statistically significant and insignificant regional trends of OMI NO₂
 599 tropospheric column (TrC-NO₂) trends over 2005-2019, at a 95% confidence level (see text for
 600 details on the calculation of the trends). For each region, the trend on the bars is in the format:
 601 p50 [p5; p95], which represents the 50th[5th, and 95th] percentiles of the trends.

602
 603 Figure 14 shows the time series of regional mean tropospheric NO₂ concentrations from
 604 three satellite instruments, OMI for 2005-2020, GOME-2 for 2007-2018, and SCIAMACHY for
 605 2005-2012. All the instruments exhibit common large seasonal and year-to-year variations over
 606 both industrial regions and biomass-burning areas. Slight systematic differences among the

607 instruments can mainly be attributed to the different overpass times. The satellite observations
 608 show positive trends over China by 2010, followed by a continued decrease. Over the USA and
 609 Europe, all the retrievals show a downward trend over the analysis period. Over the US, the
 610 observed TrC-NO₂ levels decreased rapidly during 2005–2009 and subsequently show weaker
 611 reductions, as discussed by Jiang et al. (2018). A similar slowdown trend is found in Europe. Over
 612 India, the OMI observations show positive trends over the 14 years (+1.6 % yr⁻¹). The seasonal
 613 and year-to-year variations over Southeast Asia and northern and central Africa are associated with
 614 changes in biomass-burning activity (Ghude et al., 2009).
 615

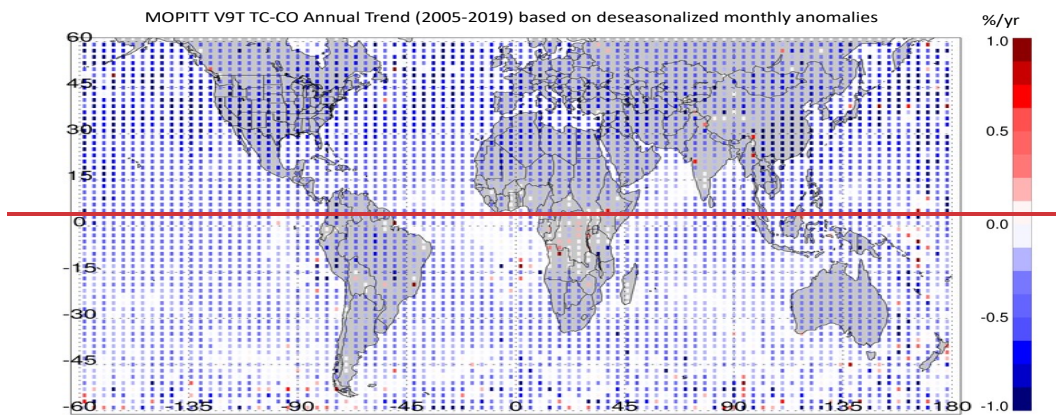

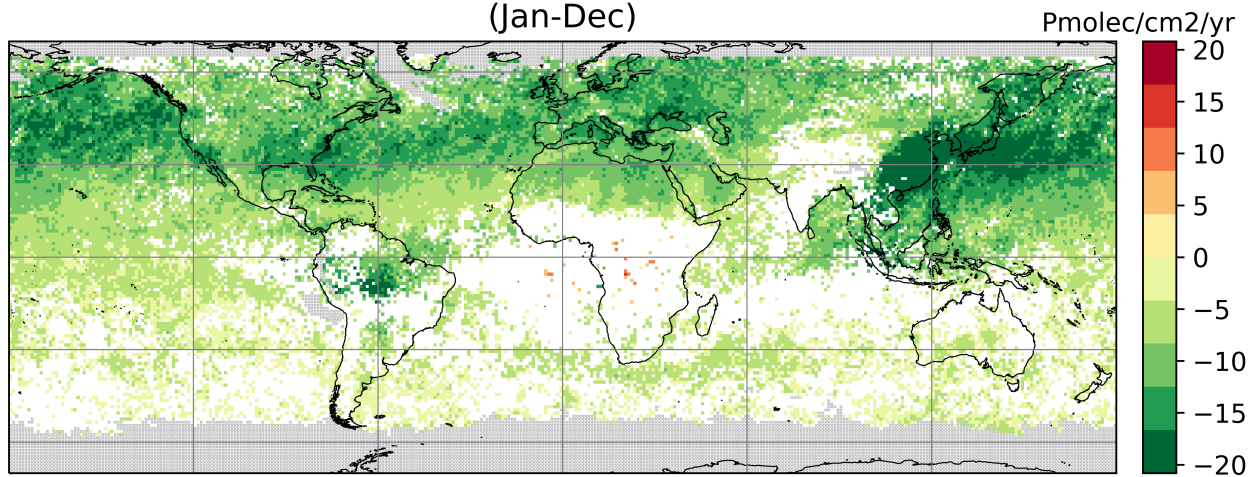

616

617 Figure 14: Time series of regional monthly mean tropospheric NO₂ columns (in 10¹⁵ molecules
 618 cm⁻²) averaged over China (110–123° E, 30–40° N), Europe (10° W–30° E, 35–60° N), the US
 619 (70–125° W, 28–50° N), India (68–89° E, 8–33° N), South America (50–70° W, 20° S–Equator),
 620 northern Africa (20° W–40° E, Equator–20° N), central Africa (10–40° E, Equator–20° S),
 621 southern Africa (25–34° E, 22–31° S), southeastern Asia (96–105° E, 10–20° N), and Australia
 622 (113–155° E, 11–44° S) obtained from OMI (black), GOME-2 (blue), and SCIAMACHY (red).

623 **3.4.5. Carbon Monoxide CO Trends**

624 CO trends are calculated based on MOPITT v9 products (~~adapted from Buchholz et al. (2021),~~
 625 see sec. 2.2.1). Observed CO trends below show a slowing in the trend compared to ~~the a~~
 626 previous analysis (Buchholz et al. (2021)). ~~In the northern hemisphere, CO trends are largely~~
 627 ~~negative over the US and Europe, which is consistent with the implemented policies to reduce air~~
 628 ~~pollution since 2005. In the northern hemisphere, CO trends are largely negative over the US and~~
 629 ~~Europe, which is consistent with improvements in combustion efficiency and policies~~
 630 ~~implemented to reduce air pollution since 2004.~~ Except for small sporadic positive trends, no
 631 significant trends can be calculated over Central Asia (India and China), while there is a strong
 632 negative trend in East China due to ~~the~~ recent strong focus on air quality improvement, and no
 633 significant trend in the SH (~~relative to slope error~~).

634 Annual trend of MOPITT TC-CO
 (based on monthly anomalies)
 (Jan-Dec)

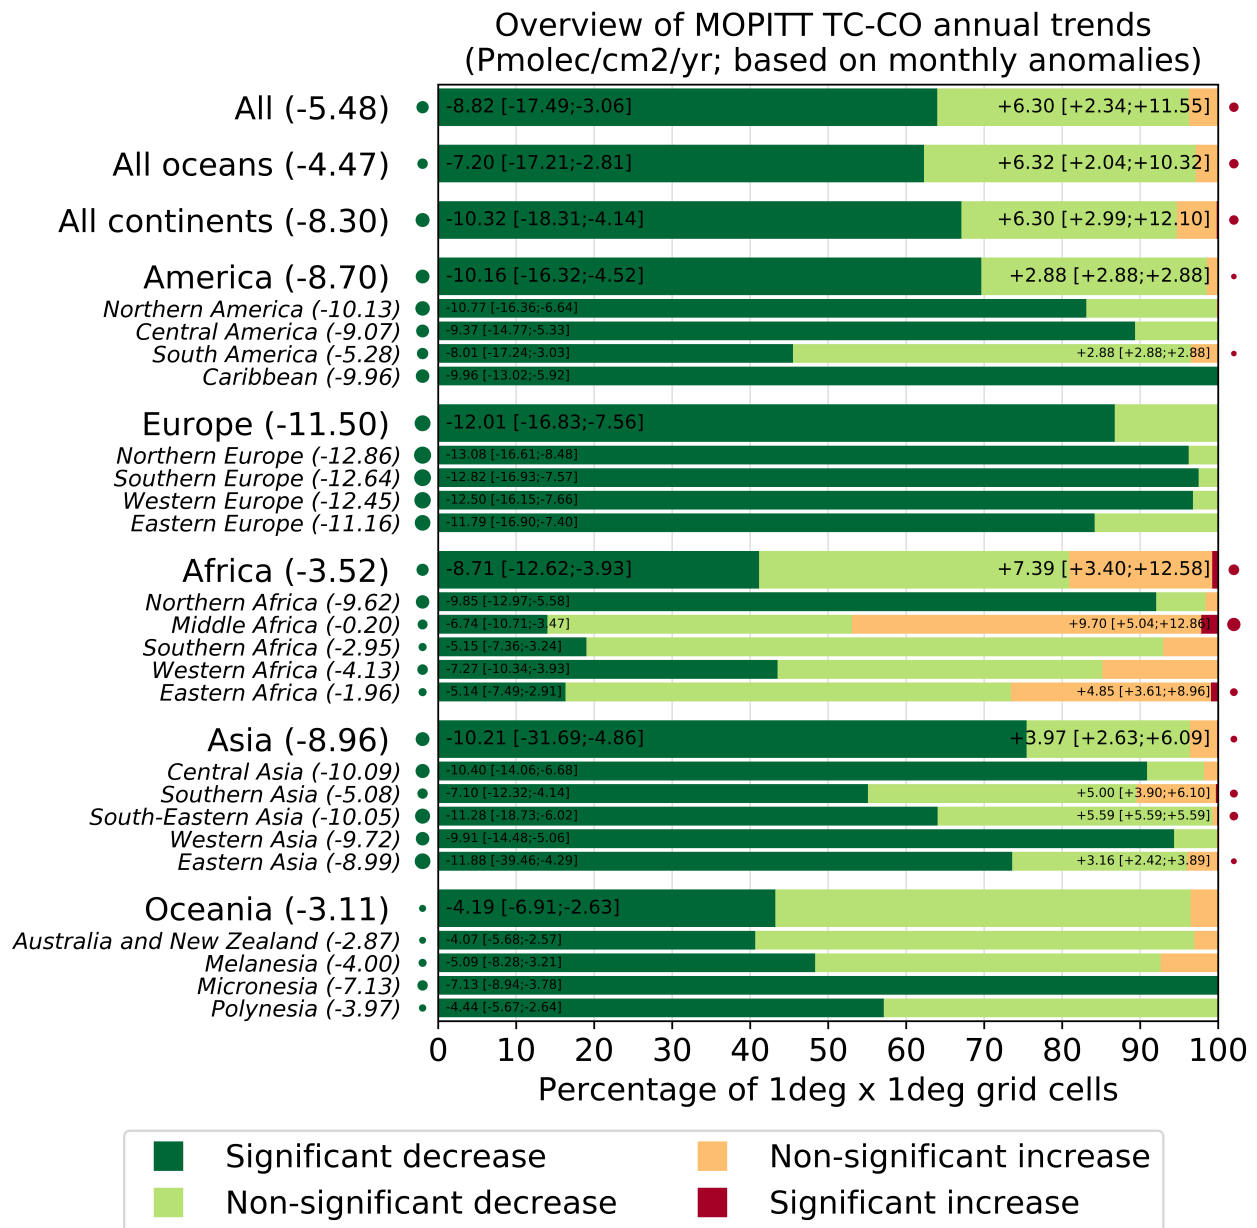

637 Figure 15: Trends in TC-CO from MOPITT V9JF data, 2005-2019 (see text for details on the
638 calculation of the trends). Grey areas correspond to areas without enough data, white areas
639 correspond to regions where the trends remain statistically insignificant at a 95% confidence
640 level.

641 Trends are computed from deseasonalized monthly anomalies.

643 Calculated global CO trends are driven mainly by the decreasing trends in the NH. Shown below
644 are the trends in the MOPITT column average volume mixing ratio (VMR) anomalies from 2005
645 to 2019 (Figure 16) using QR as well as Weighted least squares (WLS)) as Buchholz et al.
646 (2021). The region boundaries are the same as used in Fig. 10 and 11. Results show a significant
647 decreasing trend in the NH ($-0.35 \pm 0.1\%$ annually), a smaller decreasing trend in the Mid-
648 latitudes ($-0.26 \pm 0.1\%$ annually) and no significant trend in the SH ($-0.14 \pm 0.1\%$ annually). The
649 three anthropogenic regions investigated in the NH all show strong decreases in CO. The larger
650 negative trend over Australia ($-0.2 \pm 0.1\%$ annually) than the average SH, suggests sources from
651 the other two land regions (Southern Africa and South America) may be counteracting negative
652 trends in CO for the SH.

653 We also compare CO trends with Community Earth System Model (CESM) simulations
654 (Supplement Fig S1). While the magnitude of modeled CO tends to be underestimated relative to
655 observations, the anomalies between model and measurements are comparable, indicating the
656 model reproduces interannual variability well. The negative trends in the NH are also reproduced
657 by CESM, although to a smaller degree than observations, suggesting that the trends in sources
658 or loss processes (such as OH oxidation) are underestimated in the model. These processes will
659 impact the feedback into modeled ozone and the resulting interpretation of driving factors for
660 ozone abundance and variability. Interestingly, CESM correctly represents a negative trend in
661 CO for the NH and East Asia while GEOS GMI has a positive CO trend in those regions (Fig.
662 11), likely due to the well-known misrepresentation of East Asia air quality improvements in
663 models (Yin et al, 2015; Strode et al., 2016; Zheng et al, 2019). In the SH, CESM does not
664 predict significant trends.

665 A regional summary of the trends in the global map is shown in Figure 16. CO trends are
666 predominantly negative everywhere except for some sporadic positive trends over middle Africa.
667 Decreasing TC-CO trends are highest in Europe, followed by Asia and America with about 86%,
668 75%, and 69% of their cells being negative, respectively. The 50 percentiles of the trends in
669 these cells are -12.01 , -10.21 , and -10.16 Pmolec/cm²/yr, respectively. Africa shows the lowest
670 decreasing trends as the negative trends in North Africa are being offset by small increasing
671 trends in middle Africa. Overall, about 41% of the cells in Africa show decreasing trends, and
672 50% of the trends in these cells account for -8.71 Pmolec/cm²/yr. Thus, even though the NH
673 accounts for most of CO emissions, decreasing trends of TC-CO are evident in these regions.

675

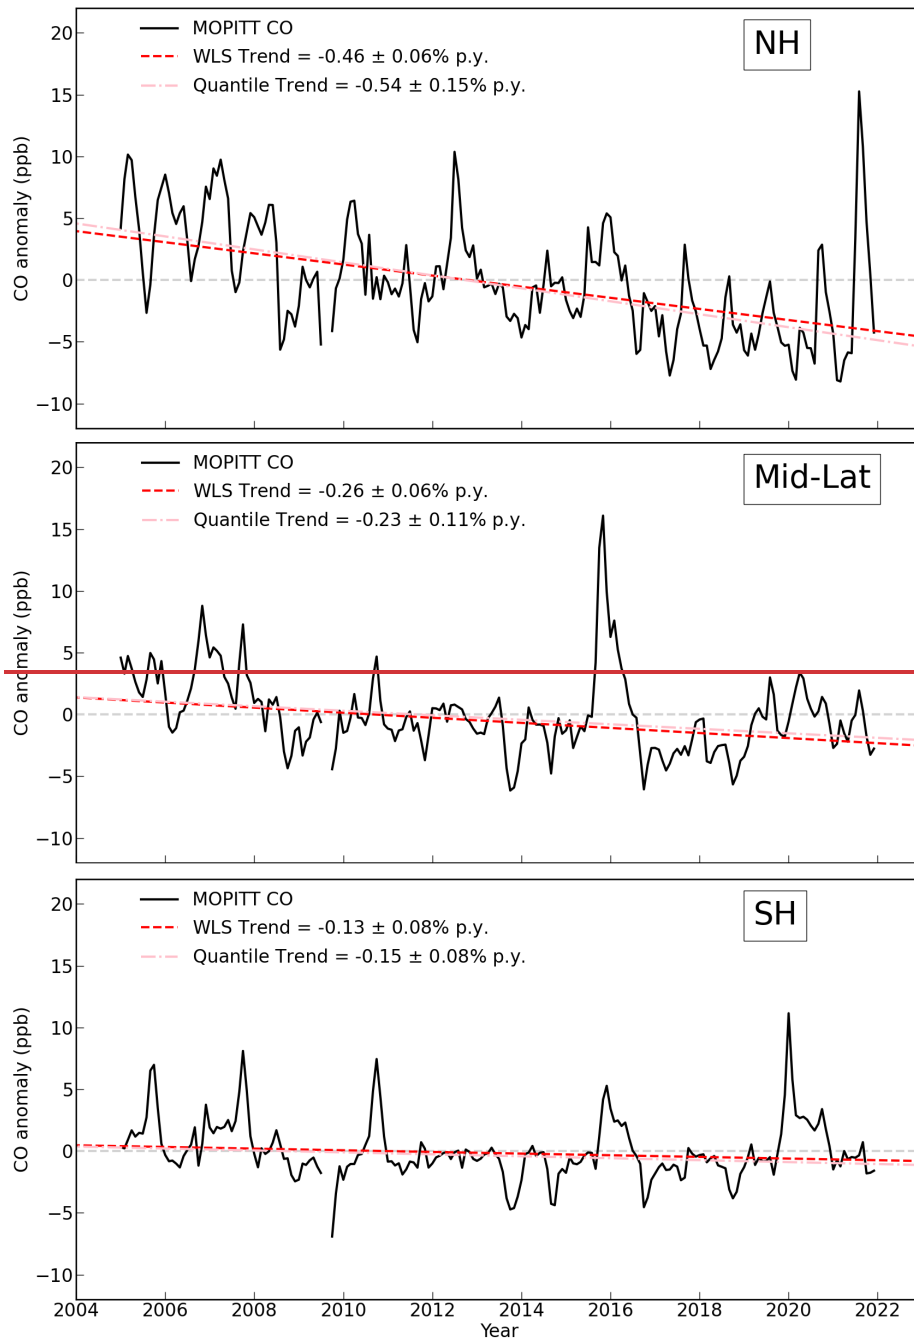

676 Figure 16: Summary of the statistically significant and insignificant regional trends of MOPITT
 677 TC-CO trends over 2005-2019, at a 95% confidence level (see text for details on the calculation
 678 of the trends). For each region, the trends reported on the left (resp. right) represent the 5th, 5^{0th}
 679 and 9^{5th} percentiles of the trends calculated over the different grid cells showing a significant
 680 TC-CO increase or decrease.

681

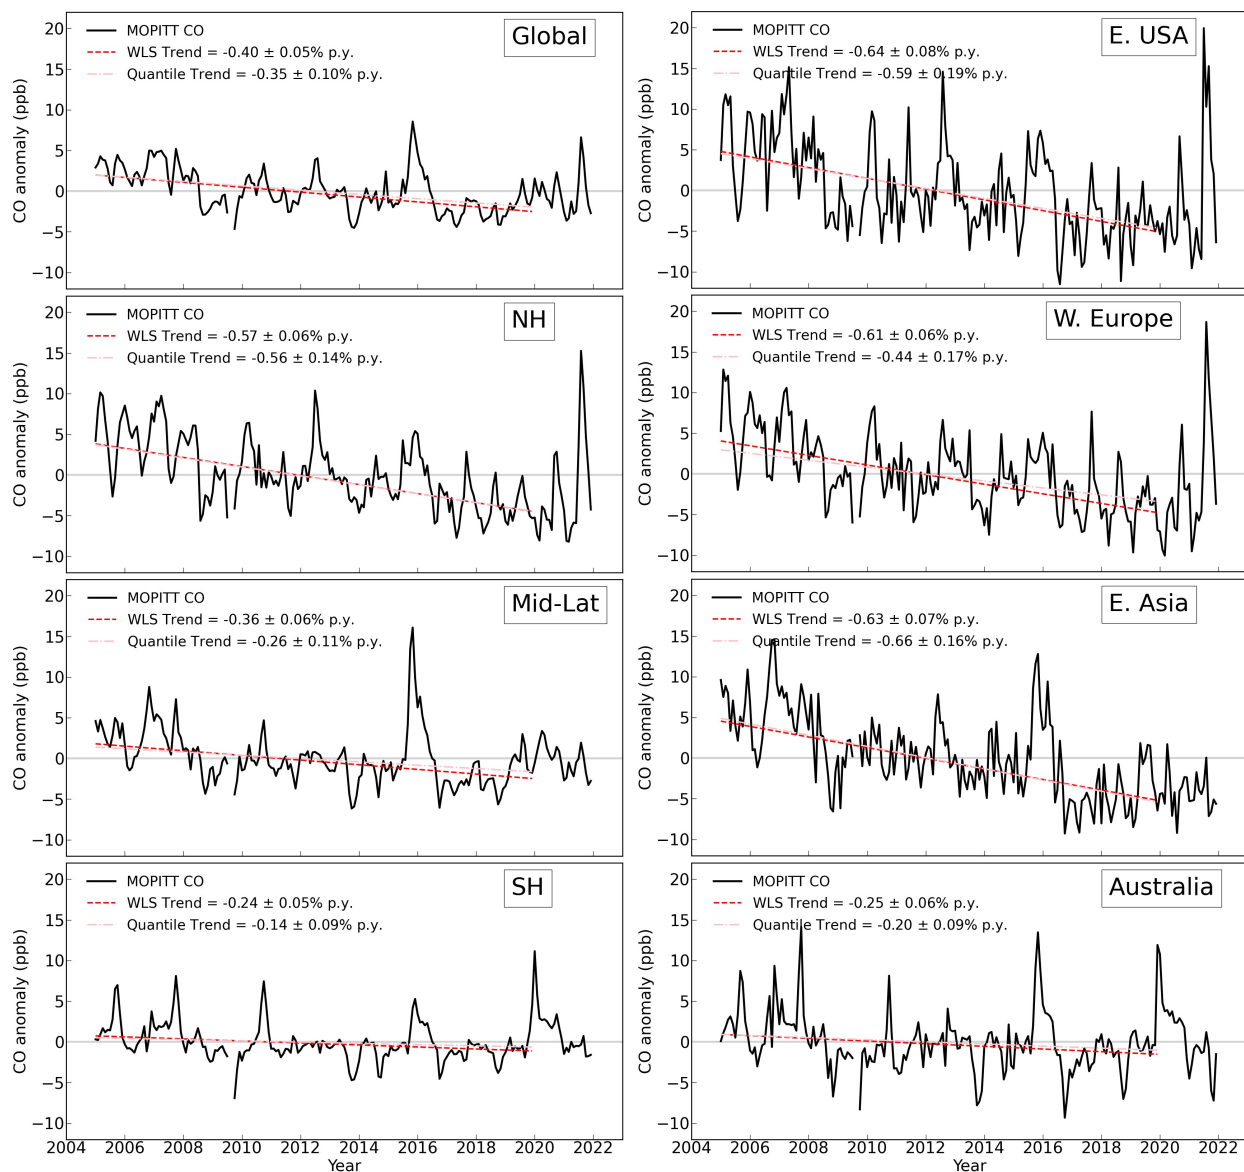

682 Shown below are also the trends in the MOPITT column average volume mixing ratio (VMR)
 683 anomalies from 2005 to 2019 (Figure 17) using QR as well as Weighted least squares (WLS)) as
 684 Buchholz et al. (2021). The region boundaries are the same as used in Fig. 10 and 11. Results
 685 show a significant decreasing trend in the NH (-0.35 ±0.1% annually), a smaller decreasing trend
 686 in the Mid-latitudes (-0.26 ±0.1% annually) and no significant trend in the SH (-0.14 ±0.1%
 687 annually). The three anthropogenic regions investigated in the NH all show strong decreases in
 688 CO. The larger negative trend over Australia (-0.2 ±0.1% annually) than the average SH,

689
690
691
692

suggests sources from the other two land regions (Southern Africa and South America) may be counteracting negative trends in CO for the SH.

693

694

695 Figure 17: MOPITT monthly average CO anomalies in column average volume mixing ratio
 696 (VMR, ppb), 2005-2021 (black). Updated dataset based on Buchholz et al. (2021). Data is Level
 697 3, monthly average daytime observations, using version 9 joint NIR/TIR retrievals (V9J).
 698 Regions are defined in Figure 10 and [Figure 11](#). Trends are calculated on anomalies
 699 2005-2019. The weighted Least Squares trend (red) is weighted by the monthly regional standard
 700 deviation. The quantile regression trend is also shown (pink). Grey dashed lines indicate a zero
 701 trend.

702

703 We also compare CO trends with Community Earth System Model (CESM) simulations
 704 (Supplement Fig S1). While the magnitude of modeled CO tends to be underestimated relative to
 705 observations, the anomalies between the model and measurements are comparable, indicating the
 706 model reproduces interannual variability well. The negative trends in the NH are also reproduced
 707 by CESM, although to a smaller degree than observations, suggesting that the trends in sources
 708 or loss processes (such as OH oxidation) are underestimated in the model. These processes will
 709 impact the feedback into modeled ozone and the resulting interpretation of driving factors for

ozone abundance and variability. Interestingly, CESM correctly represents a negative trend in CO for the NH and East Asia while GEOS-GMI has a positive CO trend in those regions (Fig. 11), likely due to the well-known misrepresentation of East Asia air quality improvements in emission inventories (Yin et al, 2015; Strode et al., 2016; Zheng et al, 2019). In the SH, CESM does not predict significant trends.

3.4.6. HCHO Trends

HCHO, mainly a photochemical product results from hydrocarbon oxidation. HCHO is itself a source of OH and ozone through its photolysis producing HO₂, which can be recycled back to OH if sufficient NO levels are present.

Unlike higher aldehydes, the OH reaction with HCHO leads also to the formation of a formyl radical (HCO), which ultimately forms HO₂ (R 3.4-3R 3.4-3).

Due to its solubility, the variability of HCHO also depends on the presence of clouds, and wet deposition ultimately represents another important sink for HCHO (Lelieveld and Crutzen, 1991). Overall, HCHO plays a key role in the O₃ budget, both in polluted and remote regions.

Trends of the OMI HCHO tropospheric columns (hereafter referred to as TrC-HCHO) are computed as described for OMI TrC-NO₂. TrC-HCHO trends over 2005-2019 are shown in Figure 1817Figure 17 with a regional summary in Figure 1918Figure 18. The first global feature to highlight on the global trends map is the presence of stripes along the OMI orbits. The number of rows affected by the OMI row anomaly has increased over the years (Boersma et al., 2018). The affected rows are filtered out in the HCHO data, but the change in the sampling and the related increase in the noise impact the trend analysis. Along orbit stripes in the trend analysis should be ignored but zonal trends are still valid (Figure 1817Figure 17).

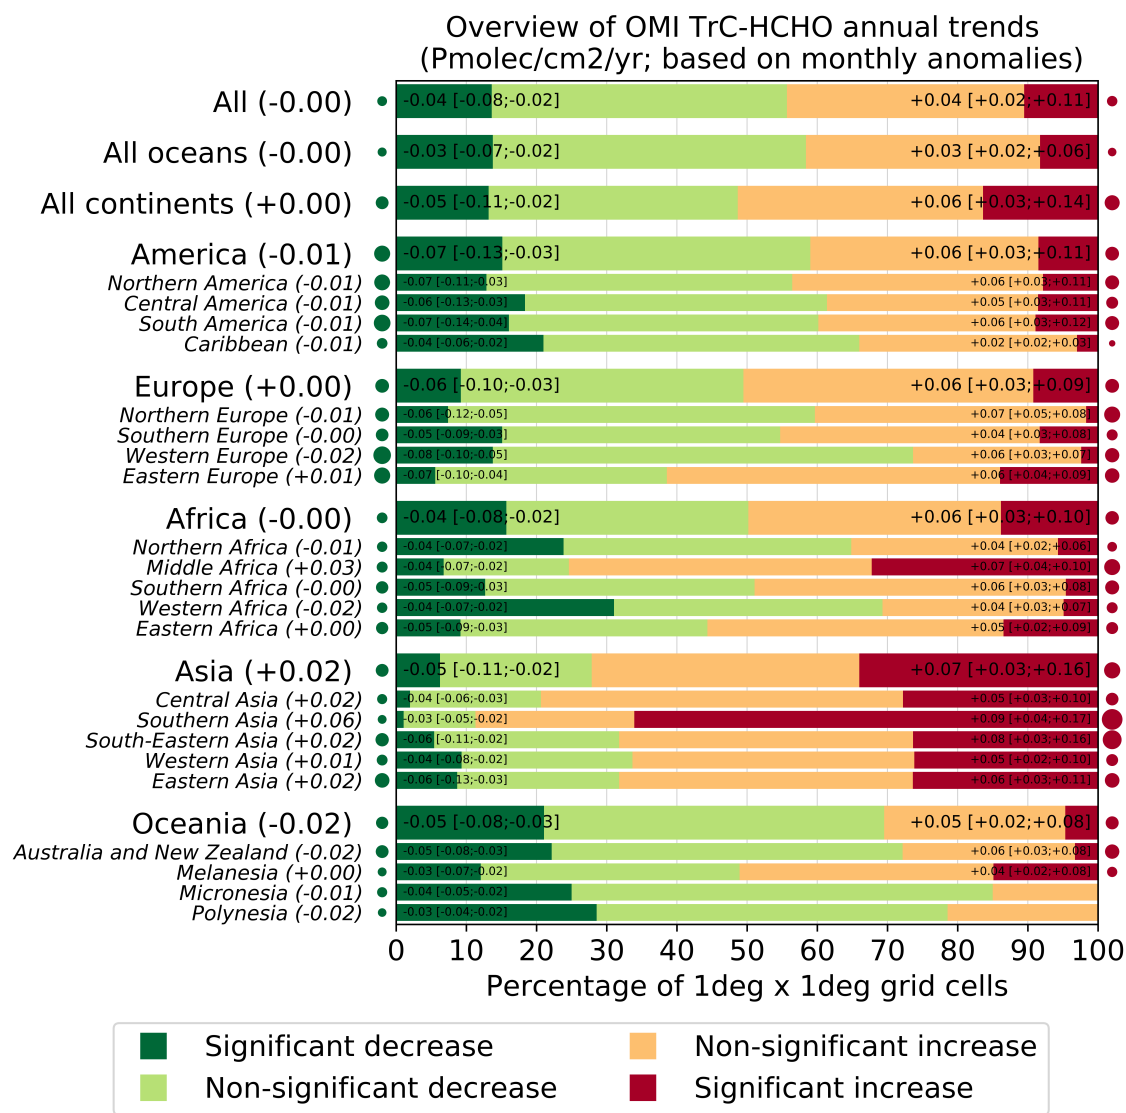

Annual trend of OMI TrC-HCHO
(based on monthly anomalies)
(Jan-Dec)

739
740 Figure 1847: Global trends of OMI HCHO tropospheric column (TrC-HCHO) over 2005-2019
741 (see text for details on the calculation of the trends). Grey areas correspond to areas without
742 enough data, white areas correspond to regions where the trends remain statistically insignificant
743 at a 95% confidence level.

744 Despite the fact that TrC-HCHO trends remain insignificant over a large part of the globe,
745 specific regions do highlight clear trends. The region with clearest changes is unambiguously
746 southern Asia where about 65% of the cells show increasing trends with a median of +0.09
747 Pmolec/cm²/yr. The other regions with a large portion (25-30% of the cells) of increasing trends
748 include the rest of Asia and Middle-central Africa, with median TrC-HCHO trends ranging
749 between +0.05 and +0.08 Pmolec/cm²/yr, as well as some parts of central Brazil (Amazonians).
750 Conversely, some significant decreases of TrC-HCHO are observed in the south-eastern US, the
751 southern half of Southern America, North and western Africa, and southern Australia, although
752 part of them overlap with the aforementioned stripes and might thus not be real.

753

754

755 Figure 1948: Summary of the statistically significant and insignificant regional trends of OMI
 756 HCHO tropospheric column (TrC-HCHO) trends over 2005-2019, at a 95% confidence level
 757 (see text for details on the calculation of the trends). For each region, the trends reported on the
 758 left (resp. right) represent the 5th, 50th and 95th percentiles of the trends calculated over the
 759 different grid cells showing a significant TrC-HCHO increase or decrease.

760

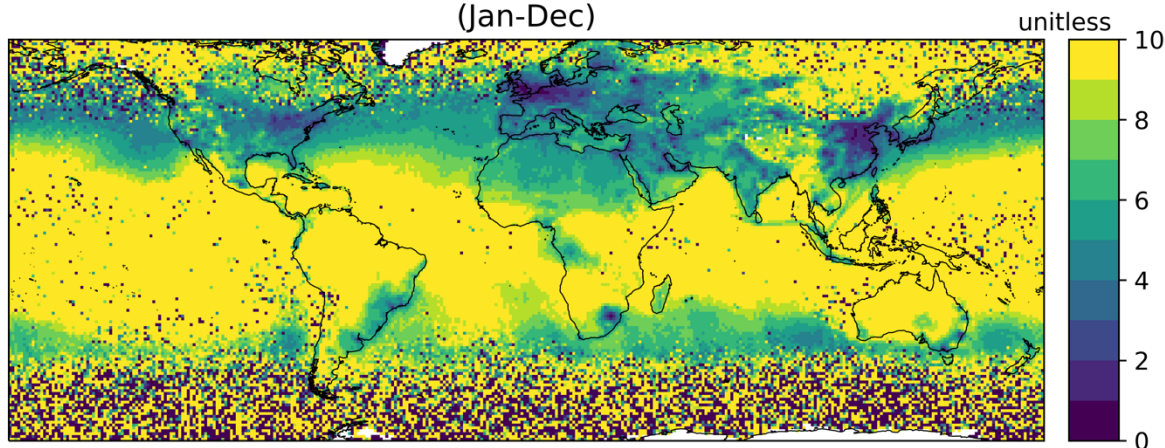

761 HCHO trends are inconsistent with that of O₃ (sec. 3.4.1) in some regions which might be due to
 762 several factors, such as their different sensitivity to NO_x and hydrocarbons (Luecken et al., 2018)
 763 but also possible STE contribution to tropospheric ozone levels, especially in midlatitudes
 764 (Willimas et al., 2019; Li et al., 2024). For example, while TrC-O₃ is increasing in the
 765 southeastern US, TrC-NO₂, TC-CO, and TrC-HCHO are decreasing, which, in addition to the
 766 local chemistry, might indicate a STE signal. O₃ and HCHO trends are consistent with NO₂ over
 767 Eastern US and Europe. However, TrC-NO₂ trends are decreasing over the northern coast of
 768 Australia while those of TrC-O₃ and TrC-HCHO are increasing. While the increase of
 769 HCHO/NO₂ might indicate a trend toward NO-limited conditions (see below), the increase of
 770 TrC-O₃ trends in this region might also indicate increasing trends of STE contribution (Li et al.,

771 2024). Similarly, while NO_2 trends are slightly increasing over central and southern Australia,
772 trends of TrC-O_3 and TrC-HCHO ~~are~~ decreasing, which indicates a trend toward VOC-
773 limited conditions (see below). ~~The decreasing trends of HCHO and O_3 as NO_2 increases is~~
774 ~~evidence of the VOC limited conditions in these regions. Under these conditions, increased NO_2~~
775 ~~levels lead to a reduction of OH via $\text{OH}+\text{NO}_2=\text{HNO}_3$, which decreases the oxidation capacity~~
776 ~~and thus lowers the photochemical formation of HCHO and O_3 .~~

778 3.4.7. HCHO/ NO_2

779 ~~Since the pioneer study of Martin et al. (2004), t~~The ratio of $\text{TrC-HCHO}/\text{TrC-NO}_2$ observed from
780 space (e.g., Martin et al., 2004) has been used in a number of studies to give insights on the O_3
781 chemical regime, higher (resp. lower) $\text{TrC-HCHO}/\text{TrC-NO}_2$ ratios ~~coming with more~~ indicate
782 NO_x -limited (resp. RO_x -limited) regimes. Although imperfect (e.g. Souri et al., 2023), this
783 indicator yet provides some qualitative information on the evolution of the O_3 regime over the last
784 years (Nussbaumer et al., 2023). ~~We note that this analysis does not consider variations in the~~
785 ~~ratios and their trends with respect to season or altitude.~~ The mean $\text{TrC-HCHO}/\text{TrC-NO}_2$ over
786 2005-2019 are shown in ~~Figure 2019~~Figure 19, and the trend results in ~~Figure 2120~~Figure 20 with
787 a regional summary in ~~Figure 2221~~Figure 21. The highest ratios are observed in the tropical regions
788 due to strong TrC-HCHO ~~due to high~~from biogenic sources and fire NMVOC emissions in tropical
789 South America and Africa combined with relatively low TrC-NO_2 . Conversely, lower TrC-
790 $\text{HCHO}/\text{TrC-NO}_2$ ratios are observed across western Europe and north-eastern Asia, and to a lesser
791 extent, the north-eastern US.

Mean OMI TC-HCHO/TC- NO_2
(Jan-Dec)

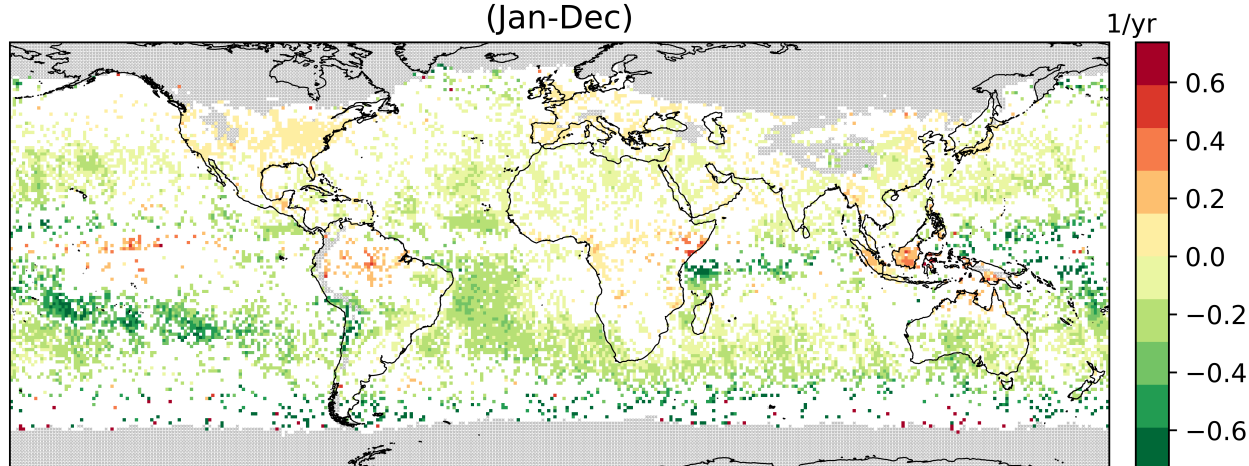

793 Figure 2049: Global mean OMI HCHO/NO_2 tropospheric column ratio over 2005-2019.

796 At a global scale, the significant changes in $\text{TrC-HCHO}/\text{TrC-NO}_2$ ~~ratios-trends~~ (Figure 2120-
797 Figure 2221) mostly go in the direction of a reduction, with about 25% of the grid cells showing a
798 median trend of -0.52 yr^{-1} . (while only 5% of the cells show a significant increase of $+0.03 \text{ yr}^{-1}$) as
799 shown in Figure 2221. This suggests that these areas are evolving toward more NO_x/VOC -sensitive
800 conditions (which does not necessarily imply that they are already in this regime). This situation
801 is observed over a large part of Oceania (especially Polynesia) and specific parts of Africa, Asia,
802 and South America. The opposite significant trends, toward more RO_x/NO -sensitive conditions,
803 are mainly observed over Europe and northern America, as well as south-~~eastern~~ Asia. We note

804 that the mean TrC-HCHO/TrC-NO₂ indicates the mean status of the chemical regime over this
805 period of time (2005-2019). However, the trends of the TrC-HCHO/TrC-NO₂ ratio show the
806 changing sensitivity of the chemical regime over this period of time. For example, while the ratio
807 in Eastern US indicates VOC-sensitive conditions, the trends of TrC-HCHO/TrC-NO₂ indicate a
808 direction toward NO-sensitive conditions.

809
810

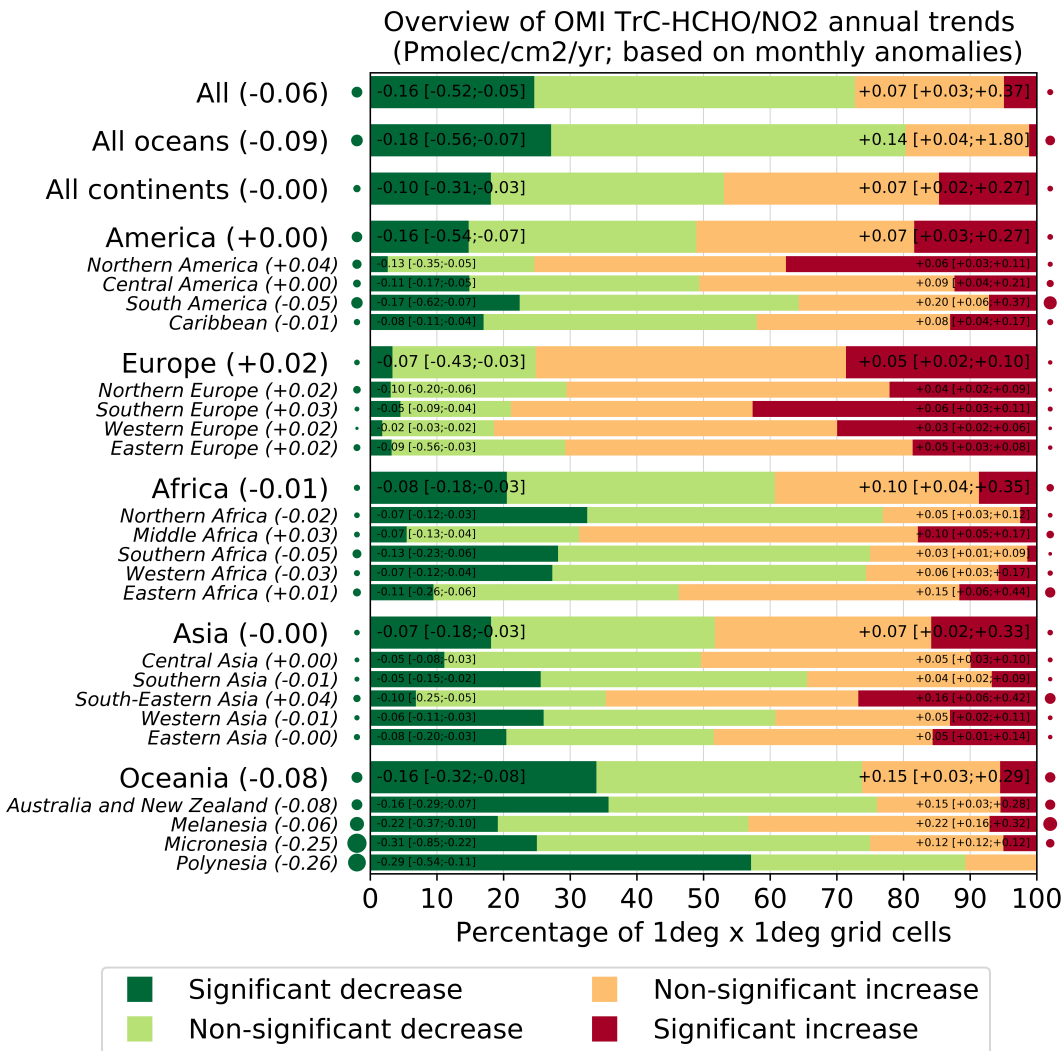

Annual trend of OMI TrC-HCHO/NO₂
(based on monthly anomalies)
(Jan-Dec)

811
812 Figure 2120: Global trends of OMI HCHO/NO₂ tropospheric column ratio over 2005-2019 (see
813 text for details on the calculation of the trends). Grey areas correspond to areas without enough
814 data, white areas correspond to regions where the trends remain statistically insignificant at a
815 95% confidence level.

816
817 These trends on the TrC-HCHO/-TrC-NO₂ ratio ~~can be~~ is mainly driven by specific trends on TrC-
818 HCHO and/or TrC-NO₂, depending on the region. The ratio increase in southern and western
819 Europe and southeast Asia appears primarily due to decreasing TrC-NO₂, since TrC-HCHO does
820 not change significantly. Over North America, observed TrC-HCHO values ~~do~~ decrease but ~~the~~
821 less than TrC-NO₂, which thus drives the ratio toward an increase. Conversely, the increase of
822 ~~TrC~~ TrC-HCHO/TrC-NO₂ in equatorial Africa and Amazonians appears mainly driven ~~to~~ by
823 increasing TrC-HCHO. The regions where TrC-HCHO/TrC-NO₂ is significantly decreasing
824 include Chile and Australia, due to both decreasing TrC-HCHO and increasing TrC-NO₂ (Figure
825 2221), indicating a trend towards a VOC-limited regime. Note that over the US, Jin et al. (2020)
826 demonstrated the reasonable ability of the OMI-based TrC-HCHO/TrC-NO₂ trends to capture the
827 transition from RO_x-limited to NO_x-limited regimes over main US cities and found a relatively
828 good consistency between observed changes of the surface O₃ and space-based HCHO/NO₂
829 increasing trends. ~~The regions where TrC~~ ~~TrC-HCHO/TrC-NO₂ is significantly decreasing~~
830 ~~include southwestern America and Australia, due to both decreasing TrC-HCHO and increasing~~
831 ~~TrC-NO₂ (Figure 21).~~

832
833

834
 835 Figure 2224: Summary of the statistically significant and insignificant regional trends of OMI TrC-
 836 HCHO/TrC-NO₂ tropospheric column ratio trends over 2005-2019, at a 95% confidence level (see
 837 text for details on the calculation of the trends). For each region, the trends reported on the left
 838 (resp. right) represent the 5th, 50th and 95th percentiles of the trends calculated over the different
 839 grid cells showing a significant TrC-HCHO/TrC-NO₂ increase or decrease.

840

841

843 3.5. Lightning NO_x and Its Effects on ~~NO_x~~ and Tropospheric NO_x and O₃

844 Nitric oxide (NO) is produced in lightning flash channels and quickly comes into equilibrium with
 845 NO₂. Cloud-scale simulations of thunderstorms indicate that 55-75% of lightning NO_x (LNO_x) is
 846 detrained above 8 km (Pickering et al., 1998) where it enhances upper tropospheric NO_y, OH, and
 847 O₃ (Labrador et al., 2005; Allen et al., 2010; Liaskos et al., 2015) and contributes to enhanced
 848 longwave radiative absorption ~~positive radiative forcing~~ by O₃ (Lacis et al., 1990; Finney et al.,
 849 2018) ~~and negative radiative forcing by CH₄~~. Enhanced OH leads to a decrease in CH₄ lifetime
 850 and decreased longwave radiative absorption (Fiore et al., 2006; Finney et al., 2018). The lifetime
 851 of NO_x in the upper troposphere is controlled by the chemical cycling of NO_x with reservoir species
 852 and is 10-20 days away from deep convection (Prather and Jacob, 1997) but only 2-12 hours in the
 853 vicinity of convection (Nault et al., 2016, 2017). This chemical recycling provides a source of NO_x
 854 downwind of thunderstorms, which causes the ozone production efficiency of emitted NO_x to be
 855 4-20 times higher in the upper troposphere than at the surface. Thus, LNO_x has a disproportionate
 856 impact on the tropospheric O₃ budget (Pickering et al., 1990; Grewe et al., 2001; Sauvage et al.,
 857 2007).

858 The distribution of lightning is fairly well known over much of the Earth due to remote
 859 sensing observations and an increase in the number and capability of ground-based lightning
 860 networks. However, the LNO_x production efficiency (PE, mol fl⁻¹) is a continued source of
 861 uncertainty. Schumann and Huntrieser (2007) reviewed the literature on LNO_x production, finding
 862 a best estimate of 250 moles per flash, with uncertainty factors ranging from 0.13 to 2.7. The PE
 863 can be estimated from theoretical and laboratory considerations (Price et al., 1997; Koshak et al.,
 864 2014), using thunderstorm anvil observations by aircraft (Ridley et al., 2004; Huntrieser et al.,
 865 2008, 2011; Pollack et al., 2016; Nault et al., 2017; Allen et al., 2021a), based on satellite data
 866 (Bucsela et al., 2010; Beirle et al., 2010; Pickering et al., 2016; Bucsela et al., 2019; Lapierre et
 867 al., 2020; Zhang et al., 2020; Allen et al., 2019, 2021b), or using cloud-resolved (e.g., DeCaria et
 868 al., 2000; 2005; Fehr et al., 2004; Ott et al., 2007, 2010; Cummings et al., 2013; Pickering et al.,
 869 2023) or global model simulations with chemistry (e.g. Martin, et al., 2007; Murray et al., 2012;
 870 Miyazaki et al., 2014; Marais et al., 2018). These various techniques have yielded PE estimates
 871 ranging from <50 to >1000 mol fl⁻¹, with most estimates in the 100-400 mol fl⁻¹ range. Miyazaki
 872 et al. (2014) assimilated OMI NO₂, MLS and TES O₃, and MOPITT CO into a chemical transport
 873 model to provide comprehensive constraints on the global LNO_x source, resulting in an estimate
 874 of mean PE of 310 moles per flash. Marais et al. (2018) used cloud-sliced upper tropospheric NO₂
 875 from OMI together with the GEOS-Chem model to estimate a mean LNO_x PE of 280 moles per
 876 flash. Lightning is the dominant source of NO_x in the tropical upper troposphere year-round and
 877 in the northern mid-latitudes in summer. Lightning is responsible for 10-15% of NO_x emissions
 878 globally. Assuming 100-400 mol fl⁻¹, the global LNO_x production is likely 2 – 8 Tg N a⁻¹
 879 (Schumann and Huntrieser, 2007; Verma et al., 2021).

880 LNO_x impacts air quality and deposition (Kaynak et al., 2008; Allen et al., 2012). On
 881 average LNO_x adds 1-2 ppbv to surface O₃ (Kang et al., 2019b), although contributions as large as
 882 18 ppbv have been seen for individual events (Murray et al., 2016). Allen et al. found that the
 883 addition of LNO_x to the Community Multiscale Air Quality (CMAQ) model increased wet
 884 deposition of oxidized nitrogen at National Atmospheric Deposition Program (NADP) sites by
 885 43%, reducing low biases from 33% to near-zero. Kang et al. (2019b) found similar improvements
 886 for wet deposition and also found that including LNO_x resulted in smaller biases with respect to
 887 ozonesondes and aircraft profiles taken during the NASA DISCOVER-AQ field campaign (Flynn

888 et al., 2016). Thus, to accurately assess its impacts on air quality, it is critical that LNO_x-producing
889 deep convection is accurately simulated.

890 ~~Lightning is the dominant source of NO_x in the tropical upper troposphere year-round and~~
891 ~~in the northern mid-latitudes in summer. Lightning is responsible for 10–15% of NO_x emissions~~
892 ~~globally. This is 2–8 Tg N a⁻¹ (Schumann and Huntrieser, 2007; Verma et al., 2021) or 100 to~~
893 ~~400 mol per flash. Much of the uncertainty stems from limited knowledge of lightning NO_x PE per~~
894 ~~flash or per unit flash length. Most LNO_x is injected into the mid- and upper troposphere where~~
895 ~~(away from deep convection) its lifetime is longer relative to lower troposphere NO_x. LNO_x plays~~
896 ~~an important role in determining mid- and upper tropospheric concentrations of the hydroxyl~~
897 ~~radical (OH), the atmosphere’s cleanser; CH₄, an especially potent greenhouse gas; and O₃, a~~
898 ~~greenhouse gas and pollutant.~~

899 Only in recent years with the advent of satellite observations of lightning flashes and improved
900 coverage by ground-based lightning networks has there been sufficient data to make estimates of
901 trends in the occurrence of lightning. However, it is unknown whether trends in LNO_x production
902 are similar to those of lightning itself. Lightning characteristics such as the ratio of intracloud (IC)
903 flashes to cloud-to-ground (CG) flashes, the multiplicity (i.e., the number of strokes per flash), and
904 the peak current or energy associated with flashes may vary over time. All of these lightning
905 characteristics may have effects on the magnitude of LNO_x production. We have insufficient data
906 to take into account these possible effects on LNO_x production over large spatial domains or over
907 sufficiently long periods of time.

908 3.5.1. Global Historical ~~trends~~ Trends of Lightning ~~LNO_x~~

909 The first attempts at an examination of trends in thunderstorm activity were conducted in terms of
910 thunder-days (in Japan by Kitagawa et al., 1989; in Brazil by Pinto et al., 2013). A more recent
911 global analysis was conducted by Lavigne et al. (2019), who analyzed trends in thunder-days
912 (number of days with audible thunder at weather observation stations) over 43 years and in flashes
913 recorded by the Lightning Imaging Sensor (LIS) on the Tropical Rainfall Measuring Mission
914 (TRMM) for 16 years. Thunder-days increased since the 1970s in the Amazon Basin, the Maritime
915 Continent, India, Congo, Central America, and Argentina. Decreases in thunder-days were found
916 in China, Australia, and the Sahel region of Africa. Lavigne et al. (2019) do not provide a global
917 trend in thunder days, but an average trend computed over the nine primary lightning regions that
918 they considered, weighted by the mean annual thunder days in each region, yields a near global
919 estimate of +3.8% per decade. How well do thunder-days represent lightning flash rate? Lavigne
920 et al. found a positive correlation between thunder-days and LIS flash rates in China, the Maritime
921 Continent, South Africa and Argentina, but disagreement on the trend in India and West Africa.

922 Large-scale (±38° latitude) trends in lightning flashes have been examined in the data collected by
923 the LIS on the TRMM satellite (January 1998 – December 2014) and on the International Space
924 Station (February 2017 – December 2021). Füllekrug et al. (2022; see Figure SB2.1b) demonstrate
925 that the annual mean deviations from the 1998 – 2021 mean are no more than ~5% except for ~
926 10% in 2020 and ~-8% in 2021. However, no long-term trend is evident from the LIS data. The
927 possibility that these larger negative deviations in 2020 and 2021 are due to Covid-19 lockdowns
928 and general declines in economic activity has been speculated. The link may be provided by
929 changes in Aerosol Optical Depth (AOD) as suggested by Liu et al. (2021) who demonstrated 10-
930 20% flash reductions in March – May 2020 relative to the 2018 – 2021 mean for those months
931 from the GLD360 and WWLLN ground-based lightning networks. Regional lightning reductions
932 were consistent with AOD reductions noted by Sanap (2021). Larger reductions in lightning were
933 noted over Africa/Europe and Asia/Maritime Continent and lesser reductions over the Americas.

3.5.2. Regional Historical Trends of Lightning LN0*

934
935 Widely varying trends in lightning over China have been reported in the literature. To some extent,
936 whether the trend in lightning is upward or downward depends on the particular region studied and
937 on the period of time considered. Yang and Li (2014) were the first to report on lightning trends
938 in China. They used lightning data from the TRMM/LIS sensor and human-observed thunderstorm
939 day occurrence over the period 1990 to 2012 in southeastern China. Thunderstorms and lightning
940 occurrence increased over the period as well as LIS precipitation radar echo tops heights. These
941 increases were accompanied by decreases in visibility, indicating increases in pollution aerosol.
942 Detailed work on lightning trends in China has been performed in relation to aerosols. Shi et al.
943 (2020) correlated flashes from the TRMM/LIS Low-Resolution Monthly Time Series (2.5 deg.
944 resolution) with AOD from MODIS-Terra V6.1 Level 3 over the period 2001 to 2014. For AOD
945 < 1.0 , $r = 0.64$, indicating a likely microphysical effect on lightning flash rate. For AOD > 1.0 , $r =$
946 -0.06 , which could indicate that with higher aerosol concentration there is a radiation effect
947 stabilizing the atmosphere and/or a decrease in the number of graupel particles in the mixed-phase
948 region of the storms that is important for charging. Flashes were also correlated with surface
949 relative humidity and Convective Available Potential Energy (CAPE). As AOD generally
950 increased over much of the early portion of this time period and then decreased, lightning flash
951 rates followed similar trends. Wang et al. (2021) examined a 9-year record (2010- 2018) of CG
952 lightning from the China Lightning Detection Network in three polluted urban areas of China
953 (Chengdu, Wuhan, and Jinan). They found decreasing trends (see Wang et al., 2021) in CG
954 lightning and total AOD (from the MERRA-2 reanalysis). Annual mean lightning density in these
955 three regions decreased by 50 – 75% as annual mean AOD fell from 0.70 – 0.75 to 0.53 to 0.62.

956 Qie et al. (2022) analyzed the OTD/LIS record from 1996 through 2013, and found that lightning
957 increased over the eastern Tibetan Plateau by $0.072 \pm .069$ fl km² yr⁻¹. Over the 18 years, this
958 increase amounted to a total of 1.3 fl km² yr⁻¹, compared with a climatological value of 7.7 fl km²
959 yr⁻¹, thereby indicating a significant increase. The ground-based World Wide Lightning Location
960 Network (WWLLN) also showed an increase in strokes in this region. The increase in lightning
961 frequency in this region was found to be due to an increase in thunderstorm frequency, and not
962 due to increased storm intensity. ~~Xue et al. (2021) found a highly significant downward trend of~~
963 ~~thunder and lightning days observed at surface weather stations in China between 1961 and 2013,~~
964 ~~particularly in the warm season. The decrease amounted to 6.5 days per decade, averaged over~~
965 ~~mainland China. Factors thought to be contributing to this decrease include a decrease in the north-~~
966 ~~south geopotential height gradient, weakening of the westerly jet stream, decreased relative~~
967 ~~humidity in the lower troposphere and a decrease in the vertical wind shear between the surface~~
968 ~~and 6 km altitude.~~

969 Koshak et al. (2015) analyzed National Lightning Detection Network (NLDN) CG flashes over
970 the contiguous United States (CONUS) from 2003 to 2012. The five-year mean flashes over 2008
971 to 2012 decreased by 12.8% from the five-year mean for 2003 to 2007 (Table 1). The CONUS
972 average wet bulb temperature also trended downward during this period, which may have led to
973 lesser or weaker storms. However, US Environmental Protection Agency air quality trends show
974 an 18% decrease in PM_{2.5} concentrations over CONUS between the two subperiods, which also
975 could have had an influence on the flash rates. ~~The decrease in CG flashes was slightly larger~~
976 ~~(14.8%) over the region of CONUS south of 38 deg. N latitude. However, the TRMM/LIS~~
977 ~~instrument, which detects both CG and IC flashes, showed little change in flashes over the period~~
978 ~~of interest south of 38 degrees, suggesting that perhaps the number of IC flashes increased in this~~
979 ~~region.~~ A recent effort to update the Koshak et al. (2015) analysis is underway. NLDN flashes
980 have been reprocessed (Kenneth Cummins, personal communication) from 2015 through 2021 to

981 ensure that the classification of IC and CG flashes is done consistently with data prior to 2015.
 982 Trend analysis of NLDN CG flashes from 2003 (a major upgrade of the NLDN network hardware)
 983 through 2022 (William Koshak, personal communication) shows a significant reduction in CG
 984 flashes over CONUS, comparing the mean CG flashes over 2003-2004 with the mean over 2021 -
 985 2022. Within this period a major decrease (~25%) in CONUS CG flashes occurred from 2011 to
 986 2012. Flashes in 2013 remained low, but recovered by 2014-2015. A major decrease (~27%)
 987 occurred from 2019 to 2020, with a small increase in 2021. These results have been obtained from
 988 ongoing efforts by Dr. William Koshak of the NASA Marshall Space Flight Center, and are
 989 presently part of a draft manuscript by lead author Koshak that extends and refines the earlier work
 990 in Koshak et al. (2015). Details concerning these trends will be contained in that manuscript.

991 A possible contributing factor to the CONUS decline in CG flashes over 2003 to 2021 is the
 992 substantial decrease in aerosol. Surface annual average PM2.5 concentrations averaged over
 993 CONUS decreased by 37% from 2000 to 2021 according to the EPA National Air Quality Trends
 994 Report (<https://www.epa.gov/air-trends/air-quality-national-summary>). However, no decrease in
 995 CONUS annual average PM2.5 was seen from 2019 to 2020. As mentioned previously, AOD may
 996 be a better indicator of the aerosol amount that may become incorporated into thunderstorm clouds.
 997 Sanap (2021) showed negative anomalies of AOD of ~0.1 in portions of CONUS in March and
 998 April 2020 and 0.1 to 0.2 in May 2020. The major decrease in CONUS CG flashes from 2011 to
 999 2012 has been related to drought conditions during Summer 2012 over the South Central and
 1000 Southeastern US (Koshak et al., 2015). The reason for the number of CONUS flashes remaining
 1001 lower in 2013 is uncertain. Koehler (2020) analyzed 26 years (1993 – 2018) of NLDN CG
 1002 lightning data to construct a thunder-day climatology for CONUS. Positive anomalies from the
 1003 26-year mean were found from Texas to Colorado during 2003 to 2007, and negative anomalies
 1004 in this region during 2008 to 2012. These anomalies were consistent with precipitation anomalies
 1005 associated with ENSO.

1006

1007 ~~Table 1. The 5-year flash counts and associated percent changes over CONUS. From Koshak et~~
 1008 ~~al. (2015).~~

Period	NLDN	NLDN (up to 38°N)	LIS (raw)	LIS (corrected ^a)
2003–2007	25,204,345.8	15,931,940.6	92,655.0	46,997,805.4
2008–2012	21,986,578.8	13,574,876.0	92,659.4	47,175,192.4

1010

1011

1012 Holzworth et al. (2021) analyzed primarily CG lightning data from WWLLN for June, July, and
 1013 August for the years 2010 through 2020. The ratio of lightning strokes north of 65° N latitude to
 1014 the total global strokes increased by a factor of three over this period. This increase occurred as
 1015 the surface temperature anomaly in this region increased by 0.3°C (see Holzworth et al., 2021).
 1016 These results suggest a substantial increase in upper tropospheric NO_x and subsequent ozone
 1017 production at high northern latitudes.

1018

1019 **3.5.3. Future Lightning–NO_x trends**

1020 ~~Price (2013) discusses an apparent paradox concerning lightning in future climate. On one hand~~
 1021 ~~increased tropical convection will transport more water vapor to the upper troposphere where it is~~

~~a strong greenhouse gas, causing further warming of the upper troposphere and stabilization of the tropical atmosphere, leading to less lightning. On the other hand, in the current climate as CAPE increases, lightning increases. However, higher latitudes are warming more rapidly, decreasing the north-south temperature gradient, acting to suppress mid-latitude storms. Hence, there is large uncertainty concerning future lightning trends.~~

Parameterizations in global chemistry and climate models have been developed for lightning flash rate. These schemes typically use kinematic, thermodynamic or microphysical variables from the model as predictors. In some studies such predictors have simply been applied to output from multiple climate models. This is the case with the Romps et al. (2014) work, which showed that when a lightning parameterization scheme using CAPE x Precipitation Rate is applied to 11 climate models an increase in CG lightning by 12 +/- 5% per degree Celsius of climate warming was computed. This work simply used the 12-hour resolution time series of spatial means of these variables over CONUS as input. Changes in IC lightning flashes were not considered. IC flashes typically outnumber CG flashes by a factor of 3 averaged over CONUS. Therefore, the result of this work is unknown with respect to the amount of change in LNO_x emission. Romps et al. (2018) updated their analysis using CAPE from 3-hourly North American Regional Reanalysis (NARR) data and hourly precipitation from NOAA River Forecast Centers, finding that CAPE x Precipitation Rate captures the spatial, seasonal, and diurnal variations of NLDN CG flash rate over land, but does not predict the pronounced land-ocean contrast in flash rates. Therefore, these analyses are of limited value in estimating trends of LNO_x over broader-scale regions. Romps et al (2019) tested four lightning proxies in a cloud-resolved 4-km resolution simulation over CONUS with the Weather Research and Forecasting (WRF) model, and over the tropical oceans with a Radiative Convective Equilibrium model. The proxies were CAPE x Precipitation Rate, precipitation with vertical velocity > 10 m/s, vertical ice flux at the 260K isotherm, and vertical integral of cloud ice and graupel product. The fractional change in proxy values per 1 degree Celsius of warming over CONUS was +8 to +16%. Over the tropical oceans the changes in proxy values per degree ranged from +12% for CAPE x Precipitation Rate to -1% for ice flux and -3% for the cloud ice and graupel product. Therefore, over broad regions of the Earth, there is great uncertainty on future trends in lightning.

Finney et al. (2016; 2018) compared lightning projections for 2100 using vertical ice flux (Finney et al., 2014) and cloud-top height parameterizations for flash rate in the UK Chemistry and Aerosols Model. They obtained -15% global change in total flash rate with ice flux under a strong global warming scenario (see Finney et al., 2018), which was composed of a greater decrease in the tropics and small increases in mid-latitudes. In terms of LNO_x emissions this work using the ice flux scheme produced -0.15 TgN K⁻¹ change over the years from 2000 to 2100, implying less O₃ production. With the cloud-top height scheme they obtained +0.44 TgN K⁻¹ LNO_x change, implying increased O₃ production. However, the ice flux scheme provided a more realistic representation of global lightning for present day. Therefore, the negative LNO_x emissions change from this scheme may be more realistic. If indeed the ice flux scheme better represents the current distribution of lightning, both the Romps and Finney results suggest no significant increase in LNO_x emission in future climate, and possibly a small global decrease. Murray (2018) points out that the ice flux scheme is a closer representation of the underlying charging mechanism, but this scheme needs to be tested in multiple global chemistry and climate models.

1066 **3.5.4. Recent findings concerning LNO_x PE**

1067 Recent satellite-based estimates of LNO_x production (Figure 2322Figure 22) have suggested a
 1068 possible flash rate dependence of LNO_x production per flash (Bucsela et al., 2019; Allen et al.,
 1069 2019; 2021). Smaller values of LNO_x PE in these studies were found to be associated with high
 1070 flash rates, likely due to smaller flashes in these conditions (Bruning and Thomas, 2015). Allen et
 1071 al. (2021a) noted positive correlations (Figure 2322Figure 22) of LNO_x PE with flash energy and
 1072 with flash multiplicity (number of strokes per flash). Laboratory studies by Wang et al. (1998)
 1073 found a positive correlation between peak current and LNO_x production. Koshak et al. (2015)
 1074 found an 8% increase in peak current from the 2003-2007 period to the 2008-2012 period that
 1075 accompanied the 12.8% decrease in CG flashes. These findings make it difficult to project future
 1076 LNO_x production given only a prediction of future lightning flashes.

1077

1078

1079 Figure 2322. Scatterplots showing the GLMa-derived relationship between (a) LNO_x PE (mol
 1080 per flash) and flash density (flashes km⁻²), (b) LNO_x PE and flash energy (fJ), (c) flash energy
 1081 and flash multiplicity, and (d) LNO_x PE and flash multiplicity. Colors are used to separate flight
 1082 days while symbols are used to separate system within each flight day. Correlations are shown in
 1083 the upper right. LNO_x PE derived from airborne remote sensor, the Geo-CAPE Airborne
 1084 Simulator (GCAS) during the GOES-R Post-launch Test field campaign. GLMa indicates
 1085 Geostationary Lightning Mapper data adjusted for missing data. From Allen et al. (2021a).

1086

1087 3.5.5. Impacts of LNO_x on upper tropospheric O₃

1088 The literature concerning the effects of lightning NO_x production on upper tropospheric ozone
1089 focuses on photochemical ozone production in storm outflow. The STERAO-A storm simulation
1090 by DeCaria et al. (2005) indicated that additional ozone production attributable to lightning NO
1091 within the storm cloud during the lifetime of the storm was very small (~2 ppbv). However,
1092 simulation of the photochemistry over the 24 hours following the storm showed that an additional
1093 10 ppbv of ozone production in the upper troposphere can be attributed to lightning NO production.
1094 Convective transport of HO_x precursors led to the generation of a HO_x plume, which substantially
1095 aided the downstream ozone production. Ott et al. (2007) simulated the July 21, 1998 EULINOX
1096 thunderstorm. During the storm, the inclusion of lightning NO_x in the model combined with
1097 convectively-transported boundary layer NO_x from the Munich, Germany region resulted in
1098 sufficiently large NO_x mixing ratios to cause a small titration loss of ozone (on average less than
1099 4 ppbv) at all model levels. Simulations of the chemical environment in the 24 hours following the
1100 storm show on average a small increase in the net production of ozone at most levels resulting
1101 from lightning NO_x, maximizing at approximately 5 ppbv per day at 5.5 km. Between 8 and 10.5
1102 km, lightning NO_x caused decreased net ozone production. Ren et al. (2008) found that net
1103 tropospheric ozone production proceeded at a median rate of ~11 ppbv per day above 9 km in the
1104 Intercontinental Transport Experiment (INTEX-A) in which the effects of frequent deep
1105 convection over the United States dominated the upper troposphere. Apel et al. (2012) noted that
1106 a box model calculation indicated a net ozone increase of ~10 ppbv over a few hours following
1107 observed convection with lightning over Canada in the Arctic Research of the Composition of the
1108 Troposphere from Aircraft and Satellite (ARCTAS) experiment. Apel et al. (2015) performed box
1109 modeling of the chemistry downwind of two DC3 storms in northeast Colorado on June 22, 2012
1110 ~~–finding The northern storm ingested fresh biomass burning smoke, and the southern storm was~~
1111 ~~affected by more aged biomass burning emissions. The model predicted substantial downwind~~
1112 ~~ozone production in the UT for both storms. The southern storm was predicted to produce~~
1113 ~~more greater ozone production over 2 days (14 ppbv) in the southern storm with more LNO_x than~~
1114 ~~in the northern storm (11 ppbv) despite having lower VOC-OH reactivity. Sensitivity tests showed~~
1115 ~~that this was principally due to more NO_x being present in the southern storm outflow because of~~
1116 ~~LNO_x. Brune et al. (2018) studied ozone production in found general agreement between observed~~
1117 ~~and modeled OH and HO₂ in the outflow of the June 21, 2012 DC3 mesoscale convective system.~~
1118 ~~Their In this study the DC-8 made multiple passes through the outflow as it moved downwind.~~
1119 Box model calculations yielded a 13 ppbv increase in ozone over 5 hours, similar to the observed
1120 14 ppbv increase (see Brune et al., 2018). This rate of increase is larger than others in the literature,
1121 perhaps because for a portion of the 5 hours the outflow was in cirrus cloud, in which photolysis
1122 rates may have been larger than clear-sky values due to multiple scattering. Using a regional
1123 chemistry model, Pickering et al. (2023) estimated that net ozone production in the upper
1124 tropospheric outflow of a severe high flash rate storm observed over Oklahoma proceeded at a rate
1125 of 10-11 ppbv day⁻¹ during the first 24 hours of downwind transport. Downwind photochemical
1126 production of ozone due to LNO_x accounted for much of the recovery of upper tropospheric ozone
1127 following large reductions due to convective transport of lower ozone boundary layer air.

1128 3.5.6. Summary of LNO_x

1129 LNO_x is responsible for the largest fraction of upper tropospheric ozone in the tropics year-round
1130 and in the mid-latitudes in summer. ~~Effects on longwave radiation Radiative forcing~~ due to ozone
1131 ~~are is~~ most sensitive due to the ozone near the tropopause. Therefore, it is of great importance to
1132 have knowledge of the trends in ozone in this region that are due to changes in frequency and
1133 characteristics of lightning flashes. ~~Considerable~~ While uncertainty remains concerning trends in

1134 global [thunder days flash rates](#). [No long-term trend in global flash rates has been found](#). However,
1135 regionally important trends have been noted in CONUS and in China, which tend to be correlated
1136 to the decreasing atmospheric aerosol content. An increasing trend at Arctic latitudes has been
1137 noted, as that region rapidly warms. Future trends in flash rate also are uncertain, with conflicting
1138 predictions coming from models with differing flash rate parameterizations. Flash characteristics
1139 (e.g., [flash rate](#), flash extent, flash energy or peak current, intracloud fraction) have been found to
1140 have important implications for LNO_x production per flash. Insufficient knowledge of these
1141 characteristics [on a global scale](#) makes it highly uncertain to estimate changes in LNO_x production,
1142 even with knowledge of flash rate trends.

1143

1144 **3.6. Soil NO and HONO emissions and their impacts on O₃**

1145 Nitrous acid (HONO) is produced from microbial activity in soils with a similar mechanism and
1146 strength as NO (Oswald et al., 2013). This emission source may partially account for the current
1147 mismatch between observed and simulated HONO levels in the lower troposphere (Su et al.,
1148 2011; Yang et al., 2020). Zhang et al. (2016) estimate a 29 % contribution of soil-HONO to the
1149 HONO sources in China. This may also contribute significantly to OH production with important
1150 implications for the HO_x and O₃ budget. To account for this emission source and assess the
1151 global potential for atmospheric pollution soil-HONO emissions have been parameterized based
1152 on the HONO/NO emission ratio measured at multiple field samples (taken from different
1153 regions of the world) and up-scale it to the 4 major land cover types applied to the whole globe.
1154 The study estimates a global emission source of 7 TgN/yr from soil-HONO in 2009 (Emmerichs
1155 et al., 2023). This is at the lower end of the estimated range of 7.4-12 TgN/yr presented by Wu et
1156 al. (2022) for 2017 who employ an empirical and statistical model in combination with
1157 observations. Due to the importance of NO and HONO soil emissions for the O₃ budget their
1158 variability and historical and future trends are described here and linked to O₃. Additionally, we
1159 discuss a modification of the soil NO emission scheme.

1160 **3.6.1. Global modeling of reactive nitrogen emissions from soil**

1161 In this section, we present a short overview of the soil-NO emission algorithms and estimates for
1162 regional and global emissions. The emission of nitrogen oxides (NO) from the soil is the major
1163 source of NO_x in unpolluted regions accounting for 15-25 % of global emissions (Weng et al.,
1164 2020, Vinken et al., 2014). Thereby, NO is produced from the nitrification in soil (microbial
1165 activity) and depends non-linearly on soil properties like pH, carbon and nutrient content,
1166 temperature, and soil moisture (Gödde and Conrad 2000, Oswald et al. 2013). Model algorithms
1167 estimate soil-NO emissions with a function dependent on biological and meteorological drivers.
1168 The common empirical approach by Yienger and Levy (1995), which is used in the current
1169 CMIP6 simulations (Szopa et al. 2022), is based on a biome-specific emission factor, soil
1170 temperature, precipitation, and the canopy uptake reduction factor. The resulting global estimate
1171 is in the range of 3.3-7.7 TgN/yr which is, however, only at the lower end of the more recent
1172 model and observation-based estimates. The Yienger and Levy (1995) approach generally
1173 underestimates soil NO for all landcover types except in the tundra and rainforest due to the
1174 pulsing parameterization, which describes a large NO_x release at the wetting of very dry soil and
1175 the subsequent rapid decay (Steinkamp et al., 2009). This is accounted for in the more
1176 mechanistic approach by Hudman et al. (2012) representing pulsing of the emissions following
1177 dry spells and N-inputs from chemical fertilizer and atmospheric N-deposition. This approach
1178 calculates spatial and temporal patterns of soil moisture, temperature, pulsing, fertilizer, manure
1179 and atmospheric N deposition and biome overall replacing the emission factors by Yienger and

1180 Levy (1995) which yields in comparison 34 % more annual global soil emissions of nitrogen
 1181 oxide (10.7 TgN/yr). Satellite top-down estimates range from 7.9 TgN/yr (Miyazaki et al., 2017:
 1182 2005-2014, assimilation of satellite data sets) to 16.7 TgN/yr (Vinken et al., 2014; GEOS-Chem
 1183 and OMI). The emission of soil-NO varies regionally with small sources in Australia (~0.5
 1184 TgN/yr), Europe, Russia and Southern Hemisphere (SH) Africa (0.7 TgN/yr, 0.8 TgN/yr),
 1185 America (0.9-1 TgN/yr) and high values in S.E. Asia and Northern Hemisphere (NH) Africa (2-
 1186 2.1 TgN/yr). The emission estimates (here for 0.25° lat. × 0.3125° lon.) increase with resolution
 1187 in some regions like Europe by 38 % (Weng et al., 2020).

1188 Nitrous acid (HONO), a major OH source, is also produced from microbial activity in soils with
 1189 a similar mechanism and strength as NO (Oswald et al., 2013). This additional emission source
 1190 may account for the current mismatch between models and measurements representing HONO
 1191 levels in the lower troposphere (Su et al., 2011; Yang et al., 2020). Soil emissions of HONO play
 1192 a major role in the daytime-HONO concentrations in rural areas (in the lowest layers) where
 1193 traffic emissions and NO₂ heterogeneous reactions occur less than in urban areas (Wu et al.
 1194 2022). HONO photolysis is a main OH source and impacts the oxidation capacity of the
 1195 atmosphere (Zhang 2016, 2019). Therefore, this may also contribute significantly to OH
 1196 production with important implications for the HO_x and O₃ budget.

1197 3.6.2. Variability and trends of soil emissions of NO and HONO in the last 15 years

1198 The magnitude of soil emissions varies strongly with season where the emissions rise from
 1199 January and July by a factor of 2.5 (Weng et al., 2020). This follows the meteorological
 1200 variability as for instance, heavy rainfall over dry grasslands/forests causes a pulse of soil NO
 1201 emissions coupled with the usage of fertilizer (Hudman et al., 2012). According to the CCM1
 1202 simulations by Jöckel et al. (2016) (following the future ('medium high') climate scenario
 1203 RCP6.0 the soil NO emissions show a positive trend since pre-industrial times with a steeper
 1204 increase of up to 0.3 TgN/decade from the year 2000. As soil emissions of HONO rely on the
 1205 same biogeochemical process with similar dependencies on temperature and water content as NO
 1206 also increased from 2000 to 2019.

1207 For soil-HONO, however, the trend over 2005-2019 is much smaller, most pronounced in
 1208 Central Africa ([Figure 2524Figure 24](#)). Thereby, the highest positive monthly anomalies occur
 1209 mainly in the 5 most recent years which is likely due to the more frequent heat wave occurrence,
 1210 e.g. in Europe and North America. Overall, Africa relates the most (~30%) to the global anomaly
 1211 ([Figure 2423Figure 23](#) - [Figure 2524Figure 24](#)).

1212

1213

1214 Figure 2423: Time series of soil-HONO and soil-NO emissions and their trends (left) and the
 1215 mean global distribution of the soil-HONO emission trend for 2005-2019 based on monthly
 1216 anomalies (right).

1217
 1218 ~~Since soil HONO emissions contribute 10-20 % to surface O₃, most significantly in the Southern~~
 1219 ~~Hemisphere (Wu et al., 2022), its positive emission trends may have contributed to the decrease~~
 1220 ~~in O₃ over the last 15 years (see other sections).~~

1221

1222

1223

 1225 given in 10⁻⁵, including the uncertainty estimate (2*standard deviation).

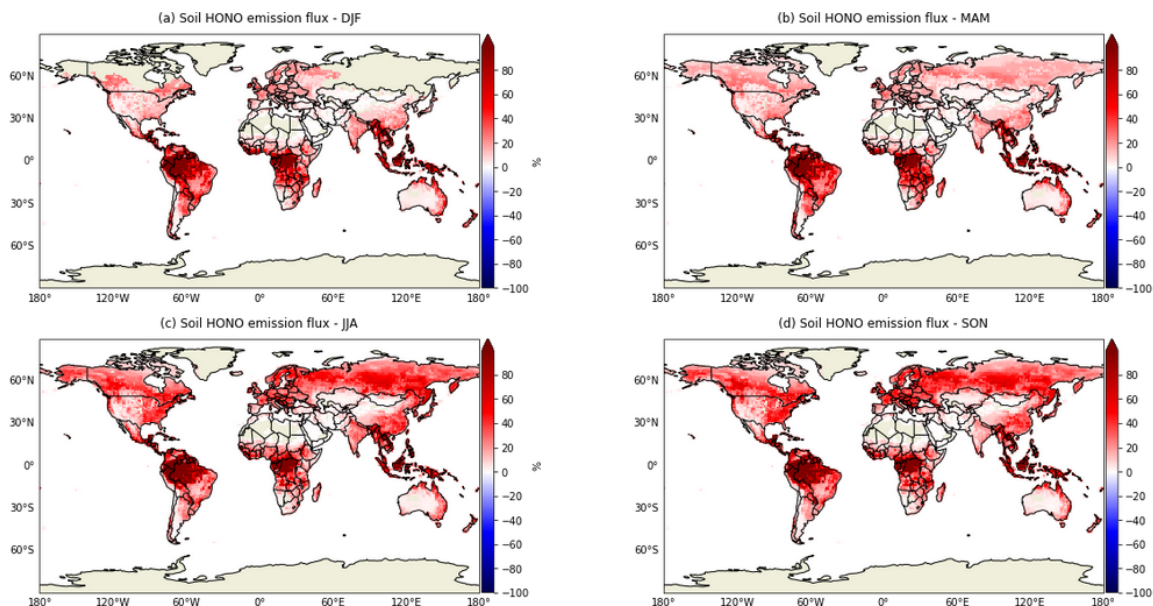

1226

1227

1228 **3.6.5.3.6.3. Canopy Reduction Factor**

1229 Most NO soil emission models (Yienger and Levy, 1995; Hudman et al., 2012) rely on an
1230 empirical canopy reduction scheme which represents loss processes in plants as the diffusion of
1231 NO₂ through the stomata and direct deposition to the cuticle. In particular, a large fraction of
1232 NO_x (and peroxyacyl nitrate) loss during the night may be only explainable by non-stomatal
1233 processes (Delaria et al., 2020b). Mechanistically, the canopy reduction can be described by an
1234 efficient NO_x deposition to plants. Thus, Delaria et al. (2020a) points out that models already
1235 represent the uptake by vegetation and do not need to use a canopy reduction scheme. The
1236 potential change of NO soil emissions is shown by employing the global model
1237 ECHAM/MESSy (1°x1°) with an explicit trace gas uptake at stomata and cuticle (Emmerichs et
1238 al., 2021) for two different seasons in 2005 and 2006. Removing the canopy reduction factor in
1239 the model leads to a significant increase of soil NO emissions highest over tropical forests
1240 (Figure 2625 Figure 25). The temporal variation follows the vegetational growth as in the
1241 Northern Hemisphere summer 50% higher emissions occur. These findings are reasonable as
1242 Hudman et al. (2012) estimated that the canopy reduction scheme overall lowers the NO
1243 emissions by 10-15% at grasslands and up to 85% over forests (GEOS-Chem at 2°x2.5° in
1244 2006). Consequently, improper accounting for the canopy reduction factor may imply a strong
1245 underestimation of the soil-N in densely forested regions and globally by about 31% (2005-
1246 2006).

1247

1248

1249 Figure 2625: Relative difference Canopy Reduction soil HONO

1250

1251 **3.6.6.3.6.4. Projections of soil NO and variability in different climates**

1252 The future land use is predicted to change as a consequence of the growing demand for
1253 nutrition and biofuels which implies an increasing use of fertilizer. Consequently, NO soil
1254 emissions are estimated to rise by ~28% during the century to 11.5 TgN/yr at the end of 2100
1255 (Fowler et al., 2015). Similarly, Liu et al. (2021) estimate an increasing soil NO emission of 8.9
1256 TgN/yr by the year 2050 due to intensive nitrification processes.

1257 An increase of LAI by 10 %, in contrast, would lead to 1% lower emissions. In addition, several
1258 responses are expected from the changing climate. In fact, the 1°C higher temperature would
1259 cause ~5% increase of emissions (Weng et al., 2020). Following the future ('medium high')
1260 climate scenario RCP6.0 (Representative Concentration Pathway, 6 W/m² radiative forcing until
1261 2500, stabilization after 2150) used for the CMIP5 (Climate Model Intercomparison Project)
1262 simulations. Jöckel et al. (2016) suggest an increase of ~15 % soil NO emissions due to
1263 increasing soil temperature (an increase of soil microbes) since present-day (2010) until 2100.
1264 However, the most significant implications for large-scale denitrification activity are changing
1265 rainfall and the regional hydrological cycles (Fowler et al., 2015). In general, soil NO_x will play
1266 a more important role for the global budget in the troposphere due to the decreasing
1267 anthropogenic emissions in the future. Therefore, increasing NO_x-soil emissions may slow down
1268 the decrease of O₃ in response to declining anthropogenic emissions (Wu et al. 2022).

1269

1270 **3.6.7.3.6.5. Next steps with biogeochemical models implemented in ESMs**

1271 Uncertainties of modeling soil nitrogen emissions are associated with the model input and
1272 parameters (Wang and Chen 2012). Process-based biogeochemical models which also consider
1273 the complexity of soil emission processes as DNDC (Denitrification–Decomposition) are needed
1274 (Li et al., 2011). The capability to represent interactive biogeochemical cycles allows for
1275 instance for the online calculation of crop nutrition from soil. Also, a model like CLM5
1276 distinguishes between natural and agricultural soils which more accurately predicts the fertilizer
1277 usage (Fung et al., 2022). Resolving the soil and litter biogeochemical dynamics vertically, in
1278 addition, lead to a more efficient retainment and recycling of N by the ecosystem (Koven et al.,
1279 2013). However, these models should be calibrated to multiple sites (Wang et al., 2019) which is
1280 limited by the availability of measurement data, especially when it comes to global modeling.

1281

1282 **4. Conclusion**

1283 In this article, we investigate temporal and spatial trends and variability of tropospheric ozone in
1284 relation to its precursors using satellite products, ozonesonde measurements, and model
1285 simulations. Our results show that ozone has positive trends at all latitudes and column depths
1286 regardless of the tropopause height within ±100 hPa. The positive trends in the 30-60°N band are
1287 due to increasing trends over Canada and Alaska and are slightly offset by the small negative
1288 trends over the ~~northe~~Eastern US and Europe. The ~~decreasing-lower~~ trends ~~above-in the bands~~
1289 ~~30-60°N and 30-60°S~~ are due to the offsetting impact of negative trends over Eastern US and
1290 Europe in the north, and Australia and South Africa in the south, respectively. The decreasing
1291 trends of TrC-O₃ over ~~parts of the northe~~Eastern US and Europe are ~~consistent-with~~ ~~likely due to~~
1292 the decreasing trend of TrC-NO₂, which is due to the effective measures applied over the last two
1293 decades to mitigate air pollution in these regions. ~~The decrease of TrC-O₃ as a result of~~
1294 ~~decreasing TrC-NO₂ trends is due to the NO-sensitive conditions dominating most of these~~
1295 ~~regions. The increasing trends of TrC-O₃ in the other regions of the world where TrC-NO₂ is~~
1296 ~~decreasing as a result of VOC-sensitive conditions, especially over East Asia.~~ TrC-HCHO trends
1297 are decreasing in the Eastern US, some parts of northern and western Africa, and western and
1298 northern Europe, ~~and~~ increasing in South Asia, central Africa, northern Australia, and Brazil.
1299 TrC-HCHO trends are consistent with that of TrC-O₃ over Eastern US and Europe. ~~The~~
1300 ~~decreasing trends of HCHO and O₃ as NO₂ increases is evidence of the VOC-limited conditions~~
1301 ~~in these regions. Under these conditions, increased NO₂ levels lead to a reduction of OH, which~~

1302 decreases the oxidation capacity and thus lowers the photochemical formation of HCHO and O₃.
1303 Simulated O₃ and its precursors are in good agreement with satellite measurements. Considering
1304 different latitude bands, the TrC-O₃ highest trends are simulated between 30° S and 60° N,
1305 consistent with calculated trends based on satellite observations. The middle and upper
1306 troposphere make the largest contributions to the simulated TrC-O₃ trend globally, with large
1307 contributions from the upper troposphere driving the simulated TrC-O₃ trend at 30°S-30°N and
1308 counteracting the negative TrC-O₃ trend in the southern midlatitudes.

1309 We have also shed light on NO_x lightning and its relation to ozone trends. LNO_x is responsible
1310 for the largest fraction of upper tropospheric ozone in the tropics year-round and in the mid-
1311 latitudes in summer. Ozone Radiative forcing is due to the ozone near the tropopause. An
1312 increasing trend of LNO_x at Arctic latitudes has been noted, as that region rapidly warms.
1313 However, future trends in flash rate are uncertain, with conflicting predictions coming from
1314 models with differing flash rate parameterizations. Soil HONO emissions had their highest
1315 positive monthly anomalies mainly in the 5 most recent years which is likely due to the more
1316 frequent heat wave occurrence, e.g. in Europe and North America. Soil HONO trends are highest
1317 in Africa accounting for ~30% of the global anomaly. Soil NO_x emissions could play an
1318 important role in the tropospheric NO_x global budget due to the decreasing anthropogenic
1319 emissions in the future. Therefore, the expected increase in NO_x-soil emissions may slow down
1320 the decrease of O₃ in response to declining anthropogenic emissions. Overall, this study
1321 presented a comprehensive overview of tropospheric ozone trends in relation to its precursors in
1322 different spatial and temporal scales.
