36 **Abstract**

37 Tropospheric ozone results from in-situ chemical formation and stratosphere-troposphere  
38 exchange (STE), with the latter being more important in the middle and upper troposphere than in  
39 the lower troposphere. Ozone photochemical formation is nonlinear, and results from the oxidation  
40 of methane and non-methane hydrocarbons (NMHCs) in the presence of nitrogen oxide  
41 ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ). Previous studies showed that  $\text{O}_3$  short- and long-term trends are nonlinearly  
42 controlled by near-surface anthropogenic emissions of carbon monoxide (CO), volatile organic  
43 compounds (VOCs), and nitrogen oxides, which maybe also impacted by the long-range transport  
44 (LRT) of  $\text{O}_3$  and its precursors. In addition, several studies have demonstrated the important role  
45 of STE in enhancing ozone levels, especially in the midlatitudes. In this article, we investigate  
46 tropospheric ozone spatial variability and trends from 2005 to 2019 and relate those to ozone  
47 precursors on global and regional scales. We also investigate the spatiotemporal characteristics of  
48 the ozone formation regime in relation to ozone chemical sources and sinks. Our analysis is based  
49 on remote sensing products of the Tropospheric Column of Ozone (TrC- $\text{O}_3$ ) and its precursors,  
50 nitrogen dioxide (TrC- $\text{NO}_2$ ), formaldehyde (TrC-HCHO), and total column of CO (TC-CO) as  
51 well as ozonesonde data and model simulations. Our results indicate a complex relationship  
52 between tropospheric ozone column levels, surface ozone levels, and ozone precursors. While the  
53 increasing trends of near-surface ozone concentrations can largely be explained by variations in  
54 VOC and  $\text{NO}_x$  concentration under different regimes, TrC- $\text{O}_3$  may also be affected by other  
55 variables such as tropopause height and STE as well as LRT. Decreasing or increasing trends in  
56 TrC- $\text{NO}_2$  have varying effects on the TrC- $\text{O}_3$ , which is related to the different local chemistry in  
57 each region. We also shed light on the contribution of  $\text{NO}_x$  lightning and soil NO and nitrous acid  
58 (HONO) emissions to trends of tropospheric ozone on regional and global scales.

59

## 60 1. Introduction

61 Tropospheric ozone (O<sub>3</sub>) is an important air pollutant due to its diverse effects on air quality,  
62 ecosystem (Mills et al., 2018), health (Lefohn et al., 2018; Fleming et al., 2018), and climate  
63 (Boucher et al., 2013; Myhre et al., 2013; Zanis et al., 2022). O<sub>3</sub> is a photochemical product  
64 that results from the oxidation of methane (CH<sub>4</sub>) and non-methane hydrocarbons (NMHCs) in  
65 the presence of nitrogen oxides (NO<sub>x</sub>). Tropospheric ozone burdens can also be affected by  
66 stratosphere-troposphere exchange (STE) (Stohl et al., 2003; Zeng et al., 2010; Trickl et al.,  
67 2011; Li et al., 2024) and long-range transport (LRT) of ozone (e.g., Hov et al., 1978; Ravetta  
68 et al., 2007; Itahashi et al., 2020). O<sub>3</sub> is considered a short-lived climate forcer (SLCF) and is  
69 the third-most important greenhouse gas with an effective radiative forcing of  $(0.47^{+0.23}_{-0.23})$  W  
70 m<sup>-2</sup>; Forster et al., 2021). Since the mid-1990s, free tropospheric ozone trends based on in situ  
71 measurement and satellite retrievals have increased with high confidence (HC) by 1-4 nmol  
72 mol<sup>-1</sup> decade<sup>-1</sup> across the northern mid-latitudes and 1-5 nmol mol<sup>-1</sup> decade<sup>-1</sup> within the tropics  
73 (Gulev et al., 2021). In the Southern Hemisphere, with more limited observation coverage  
74 compared with the Northern Hemisphere, the tropospheric column ozone shows an increase  
75 since the mid-1990s by less than 1 nmol mol<sup>-1</sup> decade<sup>-1</sup> with medium confidence at southern  
76 mid-latitudes (Gulev et al., 2021, Cooper et al., 2020). Tropospheric O<sub>3</sub> short- and long-term  
77 trends are nonlinearly controlled by anthropogenic emissions of carbon monoxide (CO),  
78 volatile organic compounds (VOCs), and nitrogen oxides (NO<sub>x</sub>=NO+NO<sub>2</sub>) as well as STE,  
79 especially in the midlatitudes (Li et al., 2024). Meteorological parameters such as wind speed  
80 and wind direction may also enhance the LRT of O<sub>3</sub>, affecting regional ozone burdens,  
81 especially in the free troposphere (e.g., Glotfelty et al., 2014; Itahashi et al., 2020). Methane,  
82 with an assessed total atmospheric lifetime of  $9.1 \pm 0.9$  years (Szopa et al., 2021), is also a  
83 crucial driver of tropospheric ozone (Fiore et al., 2002; Isaksen et al., 2014). Its accelerated  
84 growth rate of  $7.6 \pm 2.7$  nmol mol<sup>-1</sup> yr<sup>-1</sup> between 2010 and 2019 (Canadell et al., 2021) is  
85 largely driven by anthropogenic activities (Szopa et al., 2021). NOAA GML observations of  
86 methane (NOAA, 2024) show that methane concentrations in the atmosphere have increased  
87 sharply since 2005 (an 8% increase from 2005 to 2023). Future scenarios show that emission  
88 control measures can influence future changes to air pollutants. Although the global increases  
89 in CH<sub>4</sub> abundance may offset benefits to surface O<sub>3</sub> from local emission reductions (Fiore et  
90 al., 2002; Shindell et al., 2012; Wild et al., 2012; Szopa et al., 2021), recent reports (e.g.,  
91 Itahashi et al., 2020; Zanis et al., 2022), showed the dominant role of precursor emission  
92 changes in projecting surface ozone concentrations under future climate change scenarios. In  
93 this study, we investigate the relation between ozone trends and the trends of its precursors,  
94 with a focus on NO<sub>2</sub>, CO, and HCHO.

95 Coupled Model Intercomparison Project Phase 6 (CMIP6) overestimates observed surface  
96 O<sub>3</sub> concentrations in most regions, with larger variability over Northern Hemisphere (NH)  
97 continental regions (e.g., Tarasick et al., 2019; Turnock et al., 2020). CMIP6 models simulate  
98 large increasing trends of surface concentrations of O<sub>3</sub> and PM<sub>2.5</sub> in East and South Asia with  
99 an annual mean increase of up to 40 ppb and 12 μg m<sup>-3</sup>, respectively, over the historical periods  
100 (1850-2014; Turnock et al., 2020). However, these studies found also that CMIP6 models  
101 consistently underestimate PM<sub>2.5</sub> concentrations in the NH, especially during the winter  
102 months, and with larger variability near natural source regions, indicating missing sources  
103 (e.g., HONO) of O<sub>3</sub> (e.g., Elshorbany et al., 2014).

104 Satellite observations have the advantage of large spatial and consistent temporal coverage.  
105 Tropospheric columns of ozone (TrC-O<sub>3</sub>), in Dobson unit ( $1 \text{ DU} = 2.69 \times 10^{20}$  molecules m<sup>-2</sup>),

106 are usually used to represent tropospheric ozone levels. The tropospheric column of a species  
107 is the species' concentration integrated from the surface to the top of the troposphere, the  
108 tropopause. The tropopause height is dynamically changing, and it varies over time, increasing  
109 or decreasing as a function of several factors, including tropospheric and stratospheric  
110 temperature (warming or cooling). Steinbrecht et al (1998) found that observed tropospheric  
111 warming of  $0.7 \pm 0.3$  K per decade leads to an increase in the tropopause high and a decrease  
112 (at a rate of 16 DU/decade) in the observed column ozone levels. Similarly, after removing the  
113 variations related to major natural forcings, including volcanic eruptions, ENSO (El Niño–  
114 Southern Oscillation), and QBO (Quasi–Biennial Oscillation), Meng et al. (2021) concluded  
115 that a continuous rise of the tropopause in the Northern Hemisphere (NH) from 1980 to 2020  
116 is evident, which they related mainly to tropospheric warming caused by anthropogenic  
117 emissions. Steinbrecht et al (1998) and Meng et al. (2021) calculate the same rate of tropopause  
118 increase for the periods 1980-2000 and 1980-2020, respectively. We investigate the trends in  
119 TrC-O<sub>3</sub> and ozone precursors at different column depths and determine their relationships.

120 Global models play a vital role in interpreting the observed trends in ozone precursors,  
121 verifying the consistency of emission inventories with observed precursor concentrations, and  
122 relating trends in ozone precursor emissions to ozone trends. Because satellite measurements  
123 are often sensitive to species concentrations above the surface, models provide additional  
124 information on the vertical distribution of ozone precursors needed to relate emissions or  
125 surface trends to a column or free tropospheric observations. For example, chemical transport  
126 models are used to relate Ozone Monitoring Instrument (OMI) NO<sub>2</sub> columns to surface NO<sub>2</sub>  
127 concentrations and their trends over the United States (e.g. Lamsal et al 2008, 2015; Kharol et  
128 al, 2015) since they provide vertical information on the NO<sub>2</sub> distribution. Models are also used  
129 to infer NO<sub>x</sub> emission trends from observations (e.g. Richter et al., 2005; Stavrou et al.,  
130 2008; Miyazaki et al, 2016) or to examine whether simulations driven by state-of-the-art  
131 emissions inventories can reproduce observed changes in NO<sub>x</sub> (Itahashi et al., 2014;  
132 Godowitch et al, 2010). Models also provide insight into the role of background NO<sub>2</sub> versus  
133 local sources in relating satellite-observed NO<sub>2</sub> columns to NO<sub>x</sub> emissions changes (Silvern et  
134 al, 2019). Similarly, global models are vital for understanding trends in CO, since the lifetime  
135 of CO allows both local emissions and long-range transport and the global background to  
136 influence regional trends of CO and O<sub>3</sub>. Duncan and Logan (2008) attributed the decreasing  
137 CO in the NH from 1998-1997 to decreasing European emissions and highlighted the role of  
138 Indonesian fires in driving interannual variability. Numerical models can also be used to  
139 assimilate satellite CO observations to invert for CO emission fluxes, often highlighting  
140 differences between bottom-up and top-down inventories (e.g., Kopacz et al., 2010; Fortems-  
141 Cheiney et al., 2011; Elguindi et al., 2020; Gaubert et al., 2020). For instance, several modeling  
142 studies found that the increasing emissions from China in recent years in some emission  
143 inventories were inconsistent with the negative trends observed by MOPITT (Yin et al, 2015;  
144 Strode et al., 2016; Zheng et al, 2019), while the decreases over the United States and Europe  
145 are supported by the observed decrease in CO. Jiang et al (2017) and Zheng et al (2019) also  
146 found that a decrease in biomass burning contributes to the negative CO trend in the NH. Mean  
147 calculated O<sub>3</sub> burden using CMIP6 simulation (Griffiths et al, 2021) revealed an increase of  
148 44% from 1850 to the mean of the period of 2005-2014 and by another 17% until 2100 using  
149 the SSP370 experiments. Other sources of NO<sub>x</sub> such as lightning and soil emissions play an  
150 important role in controlling the O<sub>3</sub> budget, especially in low-NO<sub>x</sub> regions. We investigate  
151 these sources and the role they play in determining O<sub>3</sub> trends and variability on regional and  
152 global scales, as well as their determining factors.

153 Previous literature demonstrates the importance of controlling the emissions of ozone  
154 precursors to effectively reduce surface O<sub>3</sub> levels. Therefore, a thorough and rigorous  
155 understanding of the trends and variability for O<sub>3</sub> precursors is of paramount importance for a  
156 global abatement strategy of O<sub>3</sub> levels. In this study, we use ozonesonde, remote sensing, and  
157 global models to evaluate tropospheric O<sub>3</sub> and O<sub>3</sub> precursor trends of CO, HCHO, and NO<sub>2</sub>,  
158 on regional and global scales.

## 159 **2. Methodology**

### 160 **2.1. Trend Analysis**

161 We analyze the historical trends of tropospheric ozone and its precursors CO, NO<sub>2</sub>, and HCHO,  
162 from 2005 to 2019. For trend analysis, we use two methods, the Quantile regression (QR)  
163 method (Chang et al., 2023), and the Weighted Least Squares (WLS). For NO<sub>2</sub>, CO, and HCHO  
164 trends are calculated based on the QR method (Chang et al., 2023), as follows: (1) we first  
165 compute the deseasonalized monthly time series of NO<sub>2</sub> and HCHO tropospheric columns  
166 (hereafter referred to as TrC-NO<sub>2</sub>, TrC-HCHO), and CO atmospheric column (TC\_CO), (2) we  
167 use the quantile regression method for computing the trend, focusing here on the median, and (3)  
168 uncertainties at a 95% confidence level are estimated using the block bootstrapping approach,  
169 through 1000 iterations with blocks size of  $N^{0.25}$  with N the number of monthly values. They are  
170 calculated over a 1°x1° grid and only in cells where at least 75% of the monthly values are  
171 available. TC\_CO column (see sec. 2.2.1) time series trends are also calculated as Weighted  
172 Least Squares (WLS) of the monthly anomaly, weighted by the monthly regional standard  
173 deviation (for comparison with the QR method). The tropospheric ozone column (TrC-O<sub>3</sub>),  
174 trends are calculated based on the WLS method. Tropospheric columns of satellite observations  
175 are calculated based on the WMO thermal definition of the tropopause. To account for varying  
176 tropospheric column definitions used in previous literature, we also evaluate the trends at varying  
177 column depths.

### 178 **2.2. Data resources**

179 In this section, we present the different data repositories and their characteristics.

#### 180 **2.2.1. Satellite data**

181 A list of the applied satellite data products and their resolution is shown in [Table 1](#). For  
182 Tropospheric ozone data, we use the Ozone Monitoring Instrument/Microwave Limb Sounder  
183 (OMI/MLS) product (Ziemke et al., 2006). The OMI/MLS product is the residual of the OMI total  
184 ozone column and the MLS stratospheric ozone column, available as gridded monthly means. The  
185 OMI/MLS tropospheric column ozone product applies all necessary data quality flags to both OMI  
186 total ozone and MLS profile ozone; the OMI/MLS product further includes cloud filtering by  
187 omitting all scenes with OMI reflectivity greater than 0.30. The tropospheric NO<sub>2</sub> column  
188 retrievals used were the QA4ECV project (<http://www.qa4ecv.eu/ecvs>) version 1.1 level 2 (L2)  
189 product for OMI (Boersma et al., 2017a), GOME-2 (Boersma et al., 2017b), and SCIAMACHY  
190 (Boersma et al., 2017c). The ground pixel sizes of the OMI, GOME-2, and SCIAMACHY  
191 retrievals are 13 km×24 km, 80 km×40 km, and 60 km×30 km, with local Equator overpass times  
192 of 13:45, 09:30, and 10:00 LT, respectively. We also use HCHO tropospheric columns retrieved  
193 from OMI (De Smedt et al. 2018) from the QA4ECV project. Atmospheric total column CO  
194 daytime observations were obtained from the MOPITT instrument aboard the Terra Satellite  
195 (Barret et al., 2003; Buchholz et al., 2017). Monthly daytime L3 data were obtained at 1° gridded  
196 horizontal resolution from the NASA Langley Research Center Atmospheric Science Data Center

197 (ASDC, 2024), using version 9 (V9) retrievals, and the joint near-infrared/thermal-infrared product  
 198 (Deeter et al., 2022). Low-quality data were excluded by applying the provided quality flag.

199

200 Table 1 Satellite data products and their reference periods.

| Parameter       | Resolution<br>(Satellite<br>pixel size) | Instrument/Platform | Reference<br>Period | Reference             |
|-----------------|---|---------------------|---------------------|-----------------------|
| NO <sub>2</sub> | 1°x1°<br>(13 km x 24<br>km)             | OMI/Aura            | 2005–2020           | Boersma et al., 2017a |
| NO <sub>2</sub> | 1°x1°<br>(40 km x 80<br>km)             | GOME-2/METOP-A      | 2007–2018           | Boersma et al., 2017b |
| NO <sub>2</sub> | 1°x1°<br>(30 km x 60<br>km)             | SCIAMACHY/ENVISAT   | 2005–2011           | Boersma et al., 2017c |
| CO              | 1°x1°<br>(22 km x 22<br>km)             | MOPITT/TERRA        | 2002–2020           | Deeter et al., 2022   |
| HCHO            | 1°x1°<br>(13 km x 24<br>km)             | OMI/Aura            | 2004–2020           | De Smedt et al., 2018 |
| Ozone           | 1°x1°                                   | OMI/MLS             | 2004–2020           | Ziemke et al., 2006   |

201

### 202 2.2.2. Ozonesonde Data

203 Direct sampling of ozone throughout the atmospheric column by ozonesondes on board of high-  
 204 altitude balloons is a primary source of information of the ozone abundance and changes in the  
 205 free troposphere. Ozonesonde data have been used extensively for satellite ozone product  
 206 validations, trend analyses, and as a priori climatology profiles for satellite retrieval algorithms  
 207 (McPeters and Labow, 2012; Labow et al., 2015; Hubert et al., 2021; Christiansen et al., 2022;  
 208 Newton et al., 2016). Ozonesondes networks around the globe have been providing the ozone  
 209 community with accurate in situ measurements of high vertical resolution (100-m) for the last 5  
 210 decades in the Northern Hemisphere (Krizan and Lastovicka, 2005), nearing 3 decades at  
 211 stations in the tropics (Thompson et al., 2017), and in the last decade, new efforts are  
 212 contributing with data from undersampled regions such as the tropical Andes (Cazorla and  
 213 Herrera, 2022). Other important contributions include dedicated campaigns for regional studies  
 214 (e.g. Newton et al., 2016; Fadnavis et al., 2023). [Figure 1](#) shows a map with ozonesonde stations  
 215 around the globe whose data are publicly available from data providers (station names,  
 216 coordinates, and links for data access in the Supplementary Material, Table S1). In this work, we

217 present a review of ozonesonde trends calculated and published in previous studies (Wang et al.,  
218 2022 and Christiansen et al., 2022).

219

220

221 Figure 1: Ozone-sounding stations around the globe (red squares) whose data are publicly  
222 available (Table S1). Stations that meet the criteria to calculate trends (Wang et al., 2022) are  
223 circled in red.

224

### 225 2.2.3. Model simulations of ozone precursors and their vertical distribution

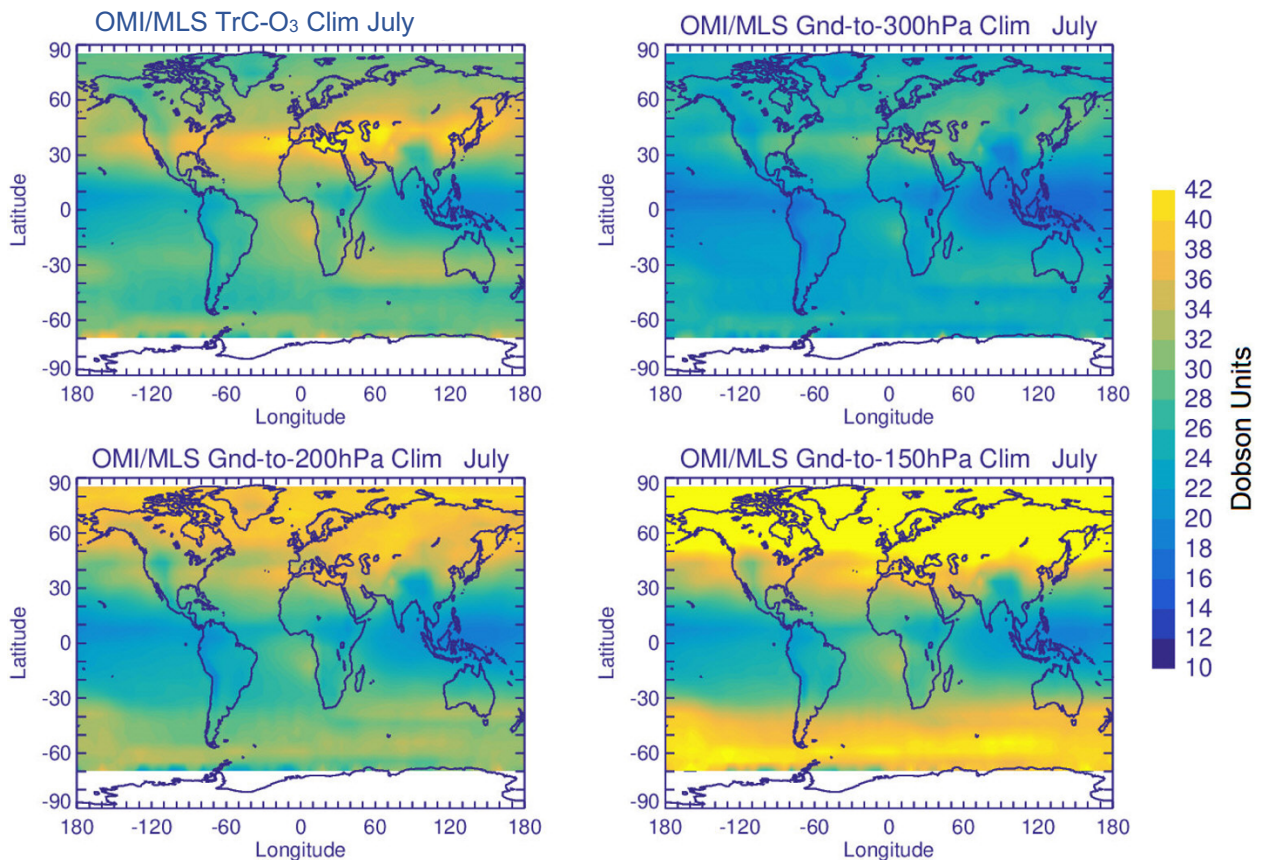

226 Model simulations provide information on the vertical distribution of trace gases that can help  
227 interpret the observed columns. Here, we use a Goddard Earth Observing System (GEOS) Earth  
228 System Model (Molod et al, 2015) simulation run with the GMI chemistry mechanism (Duncan  
229 et al, 2007; Strahan et al, 2007; Nielsen et al, 2017) to simulate the contributions of the lower,  
230 middle, and upper troposphere to the tropospheric columns of ozone and its precursors. The  
231 model configuration is described in Fisher et al (2024) and summarized here. The MERRA-2  
232 reanalysis (Gelaro et al., 2017) constrains the GEOS-GMI meteorology. The GEOS-GMI  
233 meteorology is replayed to the MERRA-2 meteorology as described in Orbe et al (2017).  
234 Anthropogenic emissions of NO<sub>2</sub>, CO, and VOCs are based on the MACCity inventory (Granier  
235 et al, 2011) through 2010 and the RCP8.5 emissions afterward, with NO<sub>2</sub> emissions scaled based  
236 on OMI. The emissions are downscaled to higher resolution using the EDGAR 4.2 emission  
237 inventory (Janssens-Maenhout et al., 2013). Biomass burning emissions for the analysis period  
238 come from the Fire Energetics and Emissions Research (FEER) product (Ichoku and Ellison,  
239 2014). Liu et al (2022) evaluated another GEOS simulation with GMI chemistry with satellite  
240 observations of TrC-O<sub>3</sub>, TrC-NO<sub>2</sub>, TrC-HCHO, and TC-CO.

## 241 3. Data Analysis and Discussion

### 242 3.1. TrC-O<sub>3</sub> Sensitivity to Tropopause

243 Calculated TrC-O<sub>3</sub> depends on several factors such as tropospheric ozone levels, atmospheric  
244 warming (e.g., due to GHG emissions) or cooling (stratospheric or tropospheric (e.g., after major  
245 volcanic eruptions), and tropopause height (TH). Atmospheric warming or cooling can lead to a

246 decrease or an increase, respectively, of TrC-O<sub>3</sub> due to the respective change in the TH. Several  
 247 methods are used to determine the TH. The WMO thermal definition for the first TH, the lowest  
 248 altitude level at which the lapse rate decreases to 2° K km<sup>-1</sup> or less, provided that the average  
 249 lapse rate between this level and all higher levels within 2 km does not exceed 2° K km<sup>-1</sup>. A  
 250 second tropopause may be also found if the lapse rate above the first tropopause exceeds 3°K  
 251 km<sup>-1</sup> (WMO, 1992; Hoffmann and Spang (2022)). Other studies define the TH based on fixed  
 252 pressure levels (from ground to 150, 200, 300, and 400 hPa). Mean OMI/MLS TrC-O<sub>3</sub> values in  
 253 July (2005-2019) calculated based on the WMO thermal definition, are shown in [Figure 2](#). TrC-  
 254 O<sub>3</sub> values are comparable to previously reported CMIP6 and satellite measurements (Griffiths et  
 255 al., 2021). Partial ozone columns (OC) calculated from the ground to different pressure levels,  
 256 150, 200, and 300 hPa show increasing OC values with increasing column depth, with calculated  
 257 OC at 150 and 200 hPa being the closest to the TrC-O<sub>3</sub> WMO values, still overestimating OC in  
 258 the northern hemisphere (50-90° N), especially for the 150 hPa OC, see [Figure 2](#).  
 259

260  
 261 Figure 2: Global Mean (2005-2019) Column Ozone based on the WMO definition, and for  
 262 different column depths.

263  
 264 Steinbrecht et al (1998) found that observed tropospheric warming of  $0.7 \pm 0.3$  K per decade  
 265 leads to an increase in the TH and a decrease in total ozone. They also calculated a decrease of  
 266 16 DU per kilometer increase in TH. These results indicate the importance of TH on calculated  
 267 long-term ozone trends. This could also affect comparisons between trends calculated based on  
 268 different TrC-O<sub>3</sub> definitions and near-surface ozone levels. The time series of deseasonalized TH  
 269 from 2004 to 2021 are shown in [Figure 3](#) together with their zonal mean trends. Trends in TH are

270 positive reaching 60 meters/decade except in a narrow band in the tropics from 10°S to 20°N and  
 271 at 30°S, where TH decreases at a rate up to 30 meters/decade. TH in the tropical regions is also  
 272 characterized by high variability (see [Figure 3](#)). These results are also consistent with recent  
 273 reports showing a positive trend of TH from 20-80°N at a rate of 50-60 m/decade (Meng et al.,  
 274 2021). They related this increase primarily to tropospheric warming. These results show that  
 275 using a fixed pressure level for the tropopause may not be accurate given the change in TH over  
 276 time. In the following sections, tropospheric columns will be calculated based on the WMO  
 277 tropopause definition.

278

 281 log-P height time series with trends (meters/decade) embedded.

282

### 283 3.2. Spatial Distribution of O<sub>3</sub> and its Precursors

284 Tropospheric O<sub>3</sub> results from in-situ photochemical formation and STE. In-situ O<sub>3</sub> results from  
 285 the photolysis of NO<sub>2</sub>. Therefore, the sources and fate of NO<sub>2</sub> in the atmosphere determine O<sub>3</sub>  
 286 burden and distribution. NO<sub>2</sub> is formed from the reaction of hydrogen peroxy (HO<sub>2</sub>) and alkyl  
 287 peroxy (RO<sub>2</sub>) radicals with NO ([R 3.2-1](#)). While photolysis of NO<sub>2</sub> is the main source of ozone,  
 288 high NO<sub>2</sub> levels can suppress O<sub>3</sub> levels as NO<sub>2</sub> reacts with OH radical forming HNO<sub>3</sub> ([R 3.2-2](#) to  
 289 [R 3.2-4](#)), thus reducing the oxidation rate of hydrocarbons and respectively HO<sub>2</sub> and RO<sub>2</sub> levels,  
 290 leading to a net loss of O<sub>3</sub> (e.g., Finlayson-Pitts and Pitts, 2000; Elshorbany et al., 2010,  
 291 Archibald et al., 2020). Ozone production efficiency is calculated as the ratio of the number of  
 292 NO<sub>2</sub> molecules photolyzed to form O<sub>3</sub> to that lost due to the reaction with OH forming HNO<sub>3</sub>.  
 293 Under NO-sensitive conditions, the decrease in NO<sub>x</sub> leads to a reduction in OH, HCHO, and O<sub>3</sub>.  
 294 However, under high NO conditions, a reduction in NO<sub>x</sub> could lead to an increase in  
 295 photochemical products, OH, HCHO, and O<sub>3</sub> because a reduction in NO<sub>2</sub> leads to a decrease in

296 OH loss rate, thus higher HO<sub>2</sub> and RO<sub>2</sub> production (Elshorbany et al., 2012; Archibald et al.,  
297 2020).

302

303 The observed mean tropospheric columns of O<sub>3</sub>, NO<sub>2</sub>, and HCHO and atmospheric column of  
304 CO from 2005 to 2019 are shown in [Figure 4](#). The unit for column number density is  
305 Pmolec/cm<sup>2</sup> (×10<sup>15</sup> molecules per square centimeter), except for TrC-O<sub>3</sub>, which is Dobson. NO<sub>2</sub>  
306 concentration has decreased since 2005 in North America, Europe, and Australia, mainly due to  
307 strict measures to reduce air pollution (Lamsal et al., 2015). Since O<sub>3</sub> is a photochemical product  
308 that is formed based on non-linear chemistry, a reduction in NO<sub>2</sub> may lead to an increase or  
309 decrease in tropospheric O<sub>3</sub> levels based on the dominant photochemical regime in the respective  
310 region. In addition, tropospheric ozone levels may be affected by STE especially in the middle  
311 and upper troposphere (Li et al., 2024), as well as LRT, especially in the free troposphere (e.g.,  
312 Glotfelty et al, 2014; Itahashi et al., 2020). The highest values of the NO<sub>2</sub> tropospheric column  
313 are in the northern hemisphere between 10 °N and 50°N, especially over the eastern US, northern  
314 Europe, and east and south Asia, with elevated levels in the Southern Hemisphere (SH) between  
315 10 and 30°S, especially in sub-Saharan Africa, and Brazil. TrC-O<sub>3</sub> is also highest over the band  
316 of 20-50° N, especially over the eastern coast of the US, southern Europe, and east Asia. Some  
317 differences exist between TrC-O<sub>3</sub> and TrC-NO<sub>2</sub> spatial patterns which is due to factors including  
318 different lifetime, photochemical sensitivity (see sec. 3.4), and STE. On average, the northern  
319 hemisphere has higher TC-CO than the southern hemisphere due to a larger number of sources  
320 (Buchholz et al., 2021). Additionally, high amounts of CO are found in regions with large  
321 anthropogenic sources (e.g., eastern China) or in regions with large and regular fire seasons (e.g.,  
322 central Africa) (Buchholz et al., 2021). HCHO and CO show a similar spatial pattern over  
323 western Africa due to emissions from biomass burning (Marais et al., 2012, Buchholz et al.,  
324 2021). In the following sections, global and regional trends of TrC-O<sub>3</sub> are investigated along  
325 with tropospheric ozone precursors.

326

327  
 328 Figure 4: Mean (2005-2019) of TrC-O<sub>3</sub>, TrC-NO<sub>2</sub>, TrC-HCHO, and TC-CO.

329 **3.3. Simulated O<sub>3</sub> Precursors**

330 Ozone and its precursors differ in their vertical distribution through the troposphere. In this  
 331 section, we use the GEOS -simulations to show how the lower, middle, and upper troposphere  
 332 contribute to the simulated columns of O<sub>3</sub> and its precursors to complement the column  
 333 information from satellites. [Figure 5](#) shows the simulated mean (2005-2019) contributions to  
 334 tropospheric columns of O<sub>3</sub>, NO<sub>2</sub>, formaldehyde, and CO, partitioned into the lower (up to  
 335 700hPa), middle (700-400hPa), and upper (400hPa to tropopause) portions of the troposphere for  
 336 the tropical band (30°S:30°N) and the global mean. The middle and upper troposphere make

337 large contributions to the simulated TrC-O<sub>3</sub> and its variability (Figure 5). The lower troposphere  
 338 makes the largest contribution to the TrC-HCHO since it is mainly a photochemical product  
 339 (e.g., Elshorbany et al., 2009), and all three levels make substantial contributions to the CO  
 340 column. Globally, the relative contributions for TrC-O<sub>3</sub>, TrC-HCHO and CO are similar to those  
 341 of the tropics. However, for TrC-NO<sub>2</sub> the lower troposphere makes a smaller contribution in the  
 342 tropics than globally.

343

344

345 Figure 5: Simulated average (2005-2019) contributions to the tropospheric columns of O<sub>3</sub>, NO<sub>2</sub>,  
 346 formaldehyde, and CO from the lower (surface-700hPa), middle (700-400hPa), and upper  
 347 troposphere (400hPa-tropopause) using NASA GEOS-GMI. The top row is for the global mean,  
 348 while the bottom row is averaged from 30°S-30°N.

349

### 3.4. Tropospheric Trends

350

#### 3.4.1. Global Tropospheric Ozone

351 Global TrC-O<sub>3</sub> trends calculated for different column depths are shown in Figure 6. Compared to  
 352 TrC-O<sub>3</sub>, OC trends up to 150 hPa seem to be the closest despite OC values being much higher  
 353 than that of the TrC-O<sub>3</sub> (Figure 2). All trends with high confidence, HC (at 95% confidence) are  
 354 positive indicating increasing trends of ozone columns, regardless of the tropopause height. Low  
 355 confidence, LC (at 2  $\sigma$  levels) decreasing TrC-O<sub>3</sub> trends were also found in some locations, e.g.,  
 356 South Australia, South Africa, and the northeastern coast of the US. Increasing trends in the

357 northern midlatitudes may also be partially related to STE (Willimas et al, 2019; Li et al., 2024).  
 358 While the annual trends inform about overall trends, seasonal trends provide insights into local  
 359 chemistry and meteorology. For example, during the boreal summer months, June, July, and  
 360 August (JJA), TrC-O<sub>3</sub> HC trends are similar to the annual trends except for HC decreasing trends  
 361 over South America and South Africa and HC increasing trends over the west and central Africa  
 362 and Central America (Figure S7). During the boreal winter months, HC trends are also similar to  
 363 the annual trends (Figure 6) except for HC increasing trends over Europe, North America, South  
 364 America, and South Africa (Figure S7).

365

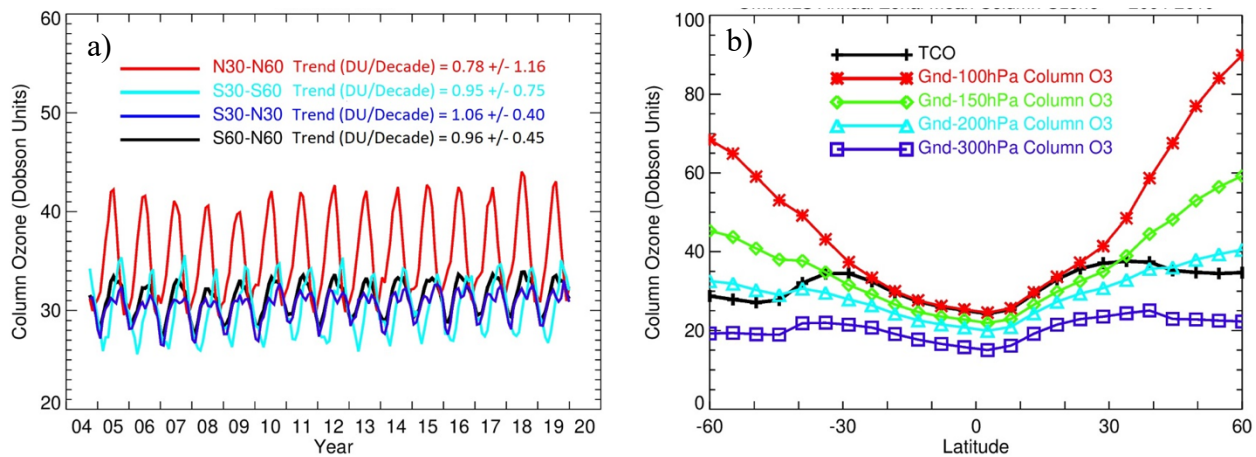

366  
 367 Figure 6: Trends in tropospheric column ozone, based on the WMO thermal definition, and the  
 368 trends on ozone columns (from ground to 150, 200, and 300 hPa). Trends are calculated based on  
 369 deseasonalized monthly data from 2005 to 2019. Asterisks denote 95% confidence trends.

370

371 The time series of OMI/MLS TrC-O<sub>3</sub> averaged over several latitudinal bands and at different  
 372 column depths are shown in Figure 7. Zonal mean TrC-O<sub>3</sub> compares well with partial ozone  
 373 columns in the tropics (from 30°S to 30°N) with the OC of up to 300 hPa differing by about 10  
 374 DU from the TrC-O<sub>3</sub> (Figure 7b). The lowest TrC-O<sub>3</sub> trends are located in the northern  
 375 hemisphere (30 – 60°N) at  $0.78 \pm 1.16$  DU/decade, followed by the southern hemisphere (30-60°S  
 376 ( $0.95 \pm 0.75$  DU/decade) and the tropical band (30°S-30°N ( $1.06 \pm 0.40$  DU/decade). In addition, the  
 377 continental trends over Australia, South Africa, and South America in the 30 °S -60°S band are  
 378 essentially negative and the positive trends in this band are contributed mainly by oceanic  
 379 regions (see Figure 6). The positive trends in the 30°N -60°N band are slightly offset by the  
 380 negative trends over the northeastern US and western Europe (see Figure 6).

381

382

383 Figure 7: Time series and zonal mean trends of OMI/MLS TrC-O<sub>3</sub> in different latitudinal bands  
 384 (left) and zonal mean of different column depths (right) from 2005-2019.

385 Observed trends for the time period before COVID-19 (2005-2019) show that OC trends  
 386 were highest in the northern latitudes (0-30° N) reaching about 1.5 DU/decade, followed by the  
 387 northern midlatitudes 30-60°N (Figure 8). The high trends in the 30-60°N band are dominated by  
 388 transpacific impacts as well as some impacts from East Asia. The positive trends in the southern  
 389 hemisphere (0-30° S) are mainly over Amazonia and Southeast Asia, being offset by small  
 390 negative trends over Western Australia and South Africa. The trends during the time period  
 391 (2005-2021) show a decline in O<sub>3</sub> column trends in the northern hemisphere but a slightly  
 392 increasing trend in the southern hemisphere (Figure 8b). The decreasing trends in the northern  
 393 hemisphere during the COVID-19 is consistent with previous literature showing a decrease in  
 394 several pollutants including NO<sub>2</sub> and O<sub>3</sub> due to the extended lockdown periods imposed during  
 395 the pandemic (e.g., Bauwens et al., 2020; Elshorbany et al., 2021; Steinbrecht et al., 2021; Putero  
 396 et al., 2023). The decrease of NO<sub>2</sub> in some parts of Europe and the northeastern USA led to a  
 397 decrease in tropospheric O<sub>3</sub>.

398 Zonal mean trends (Figure 8) show that OC up to 150 hPa is almost identical to that of  
 399 TrC-O<sub>3</sub> except for the high latitudes 45°-60° S and 45°-60° N. The decreasing trends above 30°N  
 400 and 30°S are due to the offsetting impact of negative trends over the northeastern US and western  
 401 Europe in the north, and Australia and South Africa in the south, respectively. This impact is less  
 402 apparent in the 150 hPa OC due to the lower positive trends in that band compared to TrC-O<sub>3</sub>.  
 403 The 200 hPa OC comes next with a very good agreement from 60° S to 10° N. followed by the  
 404 100 hPa which is only in good agreement from 30° S to 30°N, while the 300 hPa OC was the  
 405 farthest from the TrC-O<sub>3</sub>. The decrease of O<sub>3</sub> in the northeastern US and western Europe is  
 406 consistent with decreasing NO<sub>2</sub> trends and NO-sensitive conditions dominating these regions.  
 407 The decreasing trends of NO<sub>2</sub> (see below) are due to the successful measures applied since 2004  
 408 to mitigate air pollution in these regions. The increase of O<sub>3</sub> in the western US maybe due to  
 409 LRT from eastern Asia (e.g., Itahashi et al., 2020).

410  
 411 Figure 8: Tropospheric column ozone (TrC-O<sub>3</sub>) and trends for different column depths before the  
 412 COVID-19 pandemic (2005-2019) and including the pandemic (2005-2021).

413

### 414 3.4.2. Free tropospheric trends

415 Trends of ozone in the free troposphere presented here are based on previous work published in  
 416 the literature. Despite the high stability of ozonesonde measurements across the global networks  
 417 over several decades (Stauffer et al., 2022), the spatial sparsity of sounding stations and non-  
 418 uniform sampling frequency among sites is a limitation in using these data to produce trends.  
 419 These shortcomings have constrained the ability to include data from many stations in previously  
 420 published analyses. For example, Chang et. al (2020) estimated that at least 18 profiles per  
 421 month are needed at a single station to calculate accurate long-term trends, while uncertainty  
 422 increases at lower sampling rates (Chang et al 2024). However, such high sampling frequency is  
 423 only achieved at three European stations (Hohenpeissenberg, Germany; Payerne, Switzerland,  
 424 and Uccle, Belgium), while the rest of the global stations work at lower sampling rates.  
 425 Nonetheless, high-quality ozonesonde observations continue to be the gold standard against  
 426 which satellite measurements are validated. Likewise, ozonesonde data continue to provide  
 427 spaceborne observations with climatological feedback. Thus, recent studies have softened the  
 428 sampling frequency criteria in order to take advantage of the valuable data set collected by the  
 429 global ozonesonde networks. For example, the latest trend studies establish the minimum  
 430 frequency requirement to calculate trends to at least three profiles per month (Wang et al., 2022;  
 431 Christiansen et al., 2022) with at least eight months of sampling in a year, and at least 15 annual  
 432 means for an analysis of about two decades (Wang et al., 2022). With these criteria, recent  
 433 ozonesonde trend analyses indicate that ozone concentration increased globally by 1.8+/-1.3  
 434 ppbv/decade in the free troposphere within 800 to 400 hPa (Christiansen et al., 2022). However,  
 435 there is high regional variability, as illustrated in [Figure 9](#) where ozone trends published by  
 436 Wang et. al. (2022) (1995-2017 data between 950-250 hPa) are organized by regions and  
 437 stations. For example, ozone in East Asia (Japan) has been increasing at a rate of 3.5 to 5  
 438 ppbv/decade, particularly since 2010 (Christiansen et al., 2022), which may lead to transpacific  
 439 LRT of O<sub>3</sub> to the western US (e.g., Itahashi et al., 2020). Over the Southwestern Indian Ocean  
 440 (La Réunion), trends are of similar magnitude (>4.5 ppbv/decade). In tropical South America,  
 441 over the Atlantic basin region (Paramaribo and Natal), sounding measurements also show ozone  
 442 increases by almost 3 ppbv/decade (Natal), but other regions in South America continue to lack  
 443 sufficient measurements to produce trends. At tropical stations in Africa (Nairobi) and the

444 Pacific Ocean (Hilo and American Samoa) trends are also positive, although of lower  
 445 magnitudes (0.83-1.7 ppbv/decade). In contrast, polar stations both at the Arctic and Antarctica  
 446 as well as the Southern Ocean show overall decreasing ozone concentrations to low-confidence  
 447 trends. Exceptions are the Eureka station in Canada and Lauder station in New Zealand, which  
 448 both show slight ozone increases (less than 0.5 ppbv/decade). The direction of regional trends by  
 449 Wang et. al. (2022) is consistent with regional trends presented in similar independent research  
 450 (Christiansen et al., 2022). As atmospheric composition continues to become modified under the  
 451 current regime of climate change, building consistent and longer time series of ozonesonde  
 452 measurements at other regions will continue to be an important source of firsthand information to  
 453 assess tropospheric ozone changes and trends.  
 454

455 Figure 9: Ozone trends in the free troposphere from ozonesonde measurements calculated by  
 456 Wang et. Al. (2022) and organized by region and station. Data covers the 1995-2017 period  
 457 within 950 to 250 hPa. Error bars show 1- $\sigma$  uncertainty. The coordinates of ozonesonde stations  
 458 are listed in Table S1.  
 459

460

### 461 3.4.3. Regional Ozone Trends

462 As shown in Figure 10, the highest OMI/MLS regional trend is observed over East Asia  
 463 (2.16±1.27 DU/decade) while the lowest trend is calculated over Eastern USA (0.63±1.72)  
 464 followed by Western Europe (0.89±1.60) and Australia (1.05±1.44) DU/decade. We next  
 465 calculate the monthly trends from the GEOS-GMI simulation to investigate how the simulated  
 466 trends vary through the tropospheric column.

467

468

469

470 Figure 10: OMI/MLS observed regional mean trends of TrC-O<sub>3</sub>.

471

472 The simulated trends in partial columns (lower, middle, and upper troposphere), as well as the  
 473 TrC-O<sub>3</sub>, TrC-NO<sub>2</sub>, TrC-HCHO, and TC-CO from 2005 to 2019, are shown in [Figure 11](#). The  
 474 simulated tropospheric columns of TrC-O<sub>3</sub> and TrC-HCHO show a positive trend in most  
 475 regions ([Figure 11](#)), consistent with the results of Liu et al (2022) using a different GEOSCCM  
 476 simulation. Liu et al (2022) highlighted the importance of formaldehyde trends for analyzing the  
 477 simulated trends in tropospheric ozone. Considering different latitude bands, the highest trends  
 478 are simulated between 30° S and 60° N, consistent with calculated trends based on satellite  
 479 observations (see sec. 3.4). In contrast, the simulated NO<sub>2</sub> and CO trends are mostly negative,  
 480 although positive trends are simulated over East Asia. The largest NO<sub>2</sub> negative trends are in the  
 481 northern hemisphere between 30°N and 60°N. The decrease in NO<sub>2</sub> trends is consistent with the  
 482 successful measures to curb emissions of pollution criteria in the US and Europe. The increased  
 483 trends in TrC-O<sub>3</sub> but decreased trends in TrC-NO<sub>2</sub>, and TC-CO might indicate STE contribution  
 484 (Trickl et al., 2020; Li et al., 2024) in addition to the local chemistry.

485

486

487 Figure 11: Global and regional trends in O<sub>3</sub>, NO<sub>2</sub>, CO, and HCHO calculated from the GEOS-  
 488 GMI simulation for the tropospheric column (black), lower troposphere (purple), middle  
 489 troposphere (blue), and upper troposphere (green) from 2005 to 2019. The lower, middle, and  
 490 upper troposphere are defined as in [Figure 5](#).

491

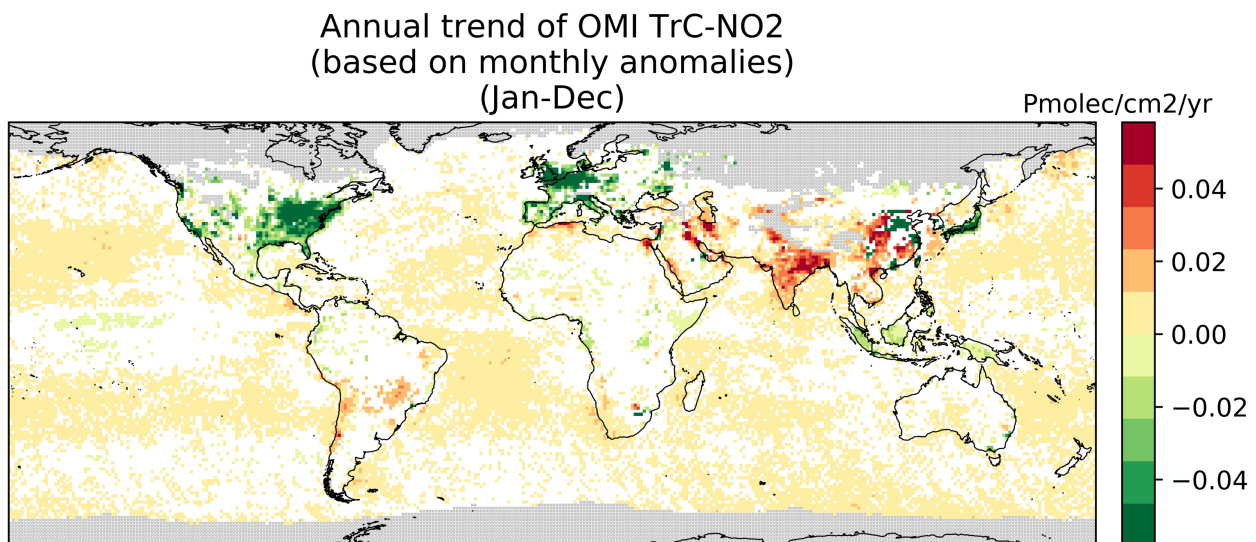

492 The GEOS-GMI simulation provides an estimate of the relative contribution from different  
 493 portions of the tropospheric column to the column trends and shows that this contribution varies  
 494 by region and constituent. The middle and upper troposphere make the largest contributions to

495 the simulated TrC-O<sub>3</sub> trend globally, with large contributions from the upper troposphere driving  
496 the simulated TrC-O<sub>3</sub> trend at 30°S-30°N (Figure 11). The middle and upper troposphere  
497 contribute most of the simulated positive TrC-O<sub>3</sub> trend over the eastern USA, while all three  
498 levels contribute over western Europe and East Asia. The upper troposphere makes the primary  
499 contribution to the simulated trend over Australia. Simulated TrC-O<sub>3</sub> trends are also quite  
500 comparable to those observed by OMI/MLS within the measurement model uncertainty (see  
501 Figure 10 and Figure 7). Over Australia, the OMI/MLS trend of  $1.05 \pm 1.44$  DU/decade is higher  
502 than the model trend of about  $0.18 \pm 0.308$  DU/decade (see Figure 11). However, since OMI/MLS  
503 trend has a calculated uncertainty ( $2\sigma$ ) of 1.44 DU/decade, both the model and OMI/MLS for  
504 Australia are not statistically different.

505 While the upper troposphere is a major driver of the simulated TrC-O<sub>3</sub> trends, the lower  
506 troposphere is the largest contributor to the simulated trends in the tropospheric NO<sub>2</sub>, CO, and  
507 HCHO globally and over many regions (Figure 11). Exceptions include the simulated NO<sub>2</sub> in the  
508 tropics (30°S-30°N), which is dominated by the upper troposphere, the simulated HCHO column  
509 over the eastern USA, which is driven by the middle and upper troposphere; an important role  
510 for upper tropospheric CO over East Asia; and the CO trend over Australia driven by the middle  
511 tropospheric contribution. Figure 11 also shows that in some regions, such as the eastern USA  
512 for all 3 precursors, the upper and lower tropospheric trends counteract each other, reducing the  
513 magnitude of the column trend. In the following sections, we investigate trends and variability in  
514 O<sub>3</sub> precursors, NO<sub>2</sub>, CO, and HCHO.

#### 515 3.4.4. NO<sub>2</sub> Trends

516 The TrC-NO<sub>2</sub> trends over 2005-2019 are shown in Figure 12 with a regional summary in Figure  
517 13. On a global scale, there is a strong spatial variability of the TrC-NO<sub>2</sub> trends. About a third of  
518 the oceans show HC increase of TrC-NO<sub>2</sub> trends (at 95% confidence level), especially at mid-  
519 latitude, with trends up to  $+0.01$  Pmolec/cm<sup>2</sup>/yr while only a few cells in the equatorial Pacific  
520 show an HC decrease.  
521

522  
523 Figure 12: Global trends of OMI NO<sub>2</sub> tropospheric column (TrC-NO<sub>2</sub>) over 2005-2019 (see text  
524 for details on the calculation of the trends). Grey areas correspond to areas without enough data,  
525 white areas correspond to regions where the trends remain at low confidence (at a 95%  
526 confidence level).

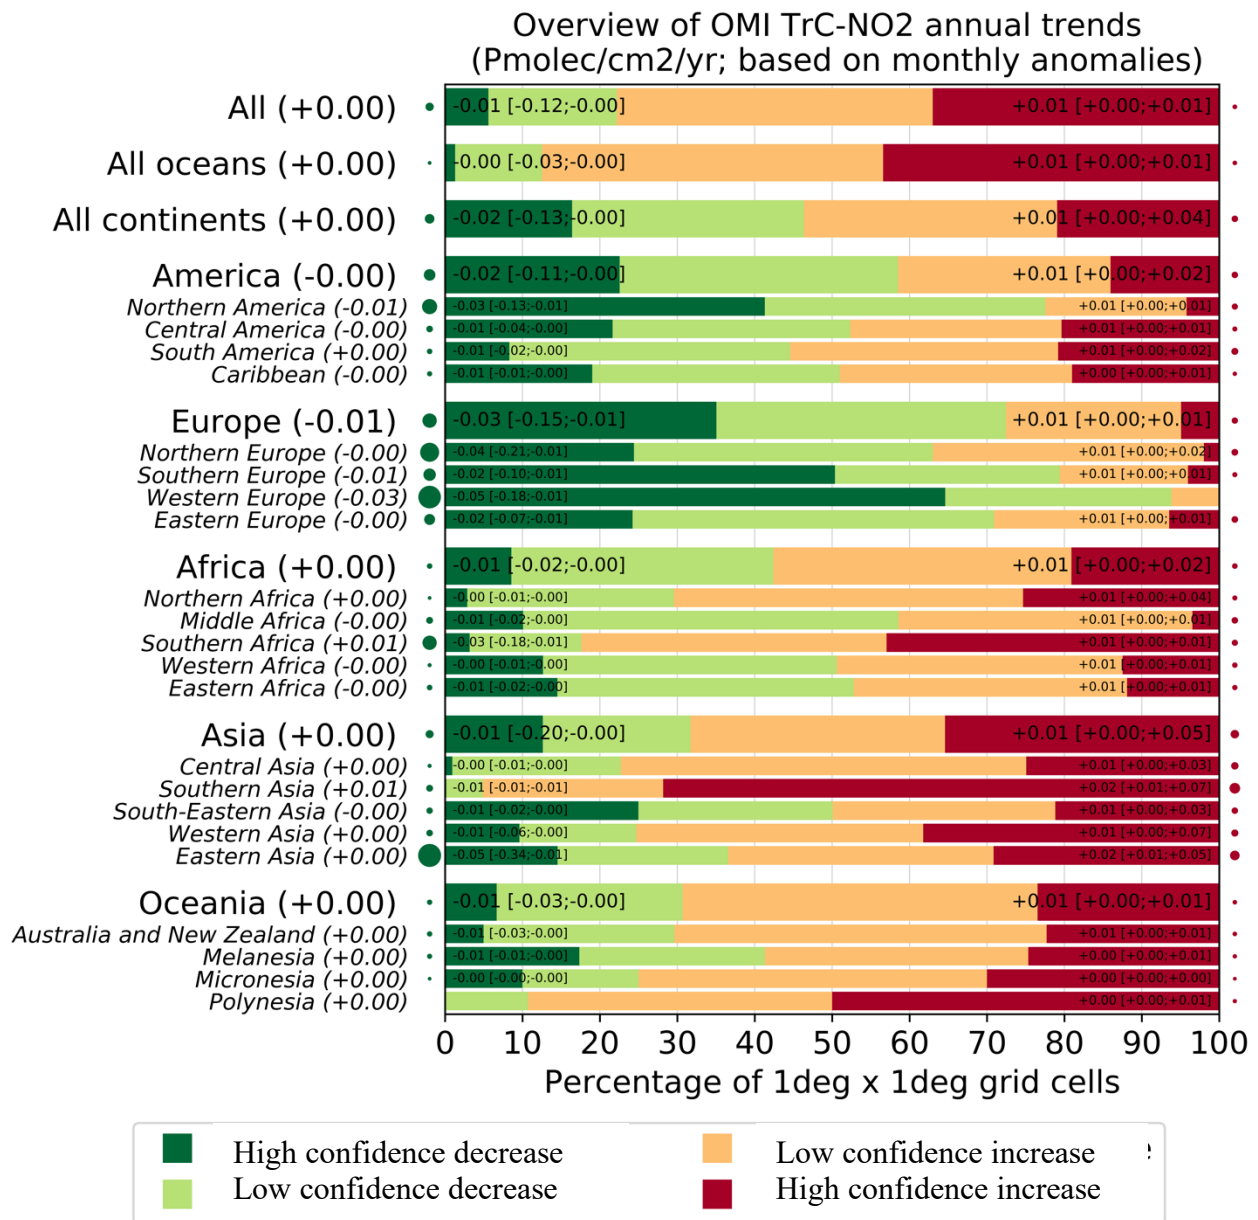

527 Regional trends are shown in [Figure 13](#). For high-confidence trends in a given region, the  
528 numbers correspond to the percentiles 5/50/95 of trends among the different cells of the region  
529 where trends are considered high-confidence. Each region is tagged with a circle whose size is  
530 proportional to the p50 of the high-confidence trends (red for positive and green for negative),  
531 which allows us to quickly see regions where the trend is strong. For instance, for Eastern Asia  
532 (this region includes 1442 1°x1° grid cells) about 15% of the grid cells (about 216 grid cells) in  
533 this region show a high-confidence decrease in TrC-NO<sub>2</sub>. Over these specific 216 cells with a  
534 high-confidence decrease of TrC-NO<sub>2</sub>, the 5th and 95th percentile of the trend is -0.34 and -0.01,  
535 respectively, Pmolec/cm<sup>2</sup>/yr. About 28% of the grid cells in this region show a high-confidence  
536 increase of TrC-NO<sub>2</sub> (which means about 403 grid cells). Over these specific 403 cells with a  
537 high-confidence increase of TrC-NO<sub>2</sub>, the 5th (resp 95th) percentile of the trend is +0.01 (resp  
538 0.05) Pmolec/cm<sup>2</sup>/yr. Therefore, the Eastern Asia region shows sub-regions with high-  
539 confidence decreasing TrC-NO<sub>2</sub>, others with high-confidence increasing TrC-NO<sub>2</sub>, and the rest  
540 with low-confidence (positive and negative) trends. This figure allows us to quickly understand  
541 the distribution of the trends within a given region while the overall regional trend is given by  
542 the 50<sup>th</sup> percentile and the circles tagging each region. It's a regional summary of what is shown  
543 in the trend global map. In Eastern Asia, the area where trends are with high-confidence positive  
544 is more extended than for the high-confidence decrease (28% versus 15%), but the trend values  
545 tend to be smaller (at least when comparing the 50<sup>th</sup> percentiles, -0.05 versus +0.01  
546 Pmolec/cm<sup>2</sup>/yr). The map of regions is included in the supplement. Canada is included in  
547 northern America but as shown in the trend map, most of Canada does not have OMI data

548 Over continental areas, high-confidence positive and negative trends are found in about  
549 15-20% of the grid cells each ([Figure 12](#)). Regions with predominantly decreasing TrC-NO<sub>2</sub>  
550 include western and southern Europe (where about 50-60% of cells with a high-confidence  
551 decrease), northern America (40% of cells with a high-confidence decrease, mostly located in the  
552 eastern United States), Japan, and Indonesia. In absolute terms, these negative trends reach  
553 values of about -0.03 Pmolec/cm<sup>2</sup>/yr. Specific eastern regions of China also show similar high-  
554 confidence TrC-NO<sub>2</sub> decreases but overall, a larger part of the country faces increasing trends up  
555 to +0.03 Pmolec/cm<sup>2</sup>/yr. Similar positive trends are observed over most of India, as well as in  
556 specific parts of south-eastern Asia (mainly Vietnam) and the Middle East (mainly Iran and  
557 Iraq). Conversely, TrC-NO<sub>2</sub> trends in Africa and South America remain mainly low-confidence ,  
558 except in a few specific regions with high-confidence increases (e.g. South Africa, Morocco,  
559 Chile, and parts of Brazil).

560 The trends in NO<sub>2</sub> have varying effects on the tropospheric ozone column, which is  
561 related to the different local chemistry in each region. The concomitant decrease in TrC-O<sub>3</sub> and  
562 TrC-NO<sub>2</sub> trends over some parts of the eastern US, and western Europe is consistent with the  
563 strict NO<sub>x</sub> control measures that were applied over the last two decades. STE can also contribute  
564 to increased TrC-O<sub>3</sub> trends, especially in the mid-latitudes. A decreasing trend of TrC-NO<sub>2</sub> but  
565 an increasing trend of TrC-O<sub>3</sub> is present in some other regions such as in the central US, which  
566 might be due to local chemistry and STE.

567

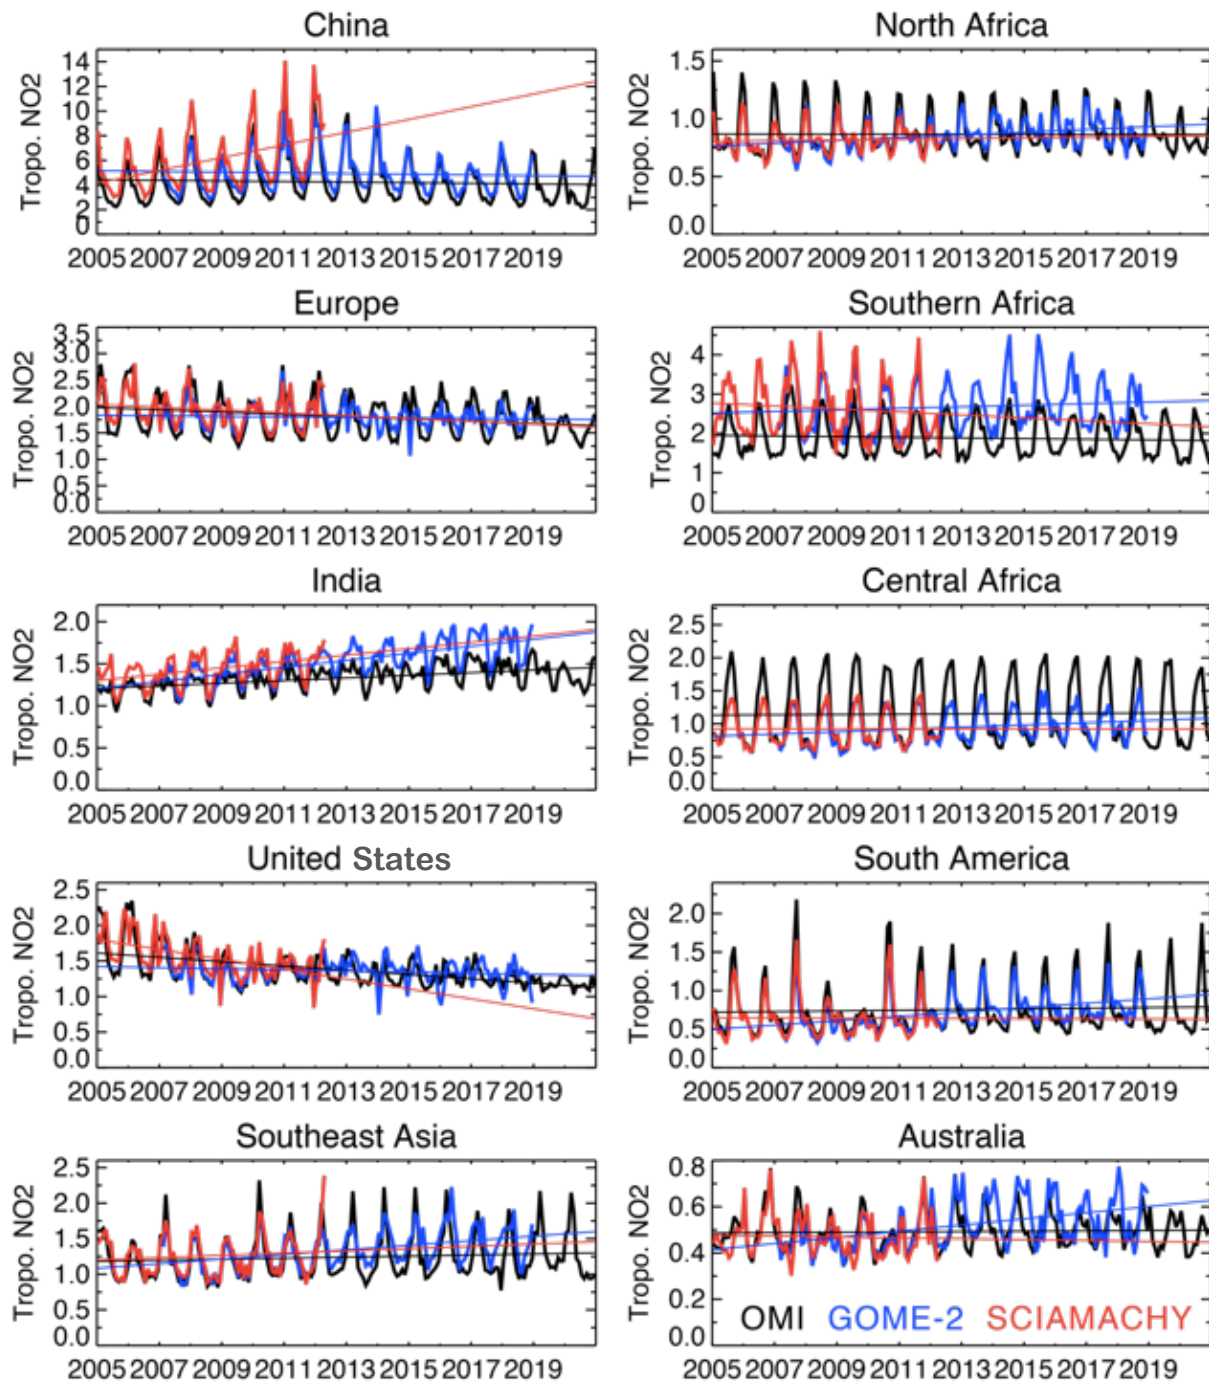

568

569 Figure 13: Summary of the high-and low-confidence regional trends of OMI NO<sub>2</sub> tropospheric  
 570 column (TrC-NO<sub>2</sub>) trends over 2005-2019, at a 95% confidence level (see text for details on the  
 571 calculation of the trends). For each region, the trend on the bars is in the format: p50 [p5; p95],  
 572 which represents the 50<sup>th</sup>[5<sup>th</sup>, and 95<sup>th</sup>] percentiles of the trends.

573

574 [Figure 14](#) shows the time series of regional mean tropospheric NO<sub>2</sub> concentrations from three  
 575 satellite instruments, OMI for 2005-2020, GOME-2 for 2007-2018, and SCIAMACHY for 2005-  
 576 2012. All the instruments exhibit common large seasonal and year-to-year variations over both  
 577 industrial regions and biomass-burning areas. Slight systematic differences among the instruments  
 578 can mainly be attributed to the different overpass times. The satellite observations show positive  
 579 trends over China by 2010, followed by a continued decrease. Over the USA and Europe, all the  
 580 retrievals show a downward trend over the analysis period. Over the US, the observed TrC-NO<sub>2</sub>  
 581 levels decreased rapidly during 2005–2009 and subsequently show weaker reductions, as

582 discussed by Jiang et al. (2018). A similar slowdown trend is found in Europe. Over India, the  
 583 OMI observations show positive trends over the 14 years ( $+1.6\% \text{ yr}^{-1}$ ). The seasonal and year-to-  
 584 year variations over Southeast Asia and northern and central Africa are associated with changes in  
 585 biomass-burning activity (Ghude et al., 2009).  
 586

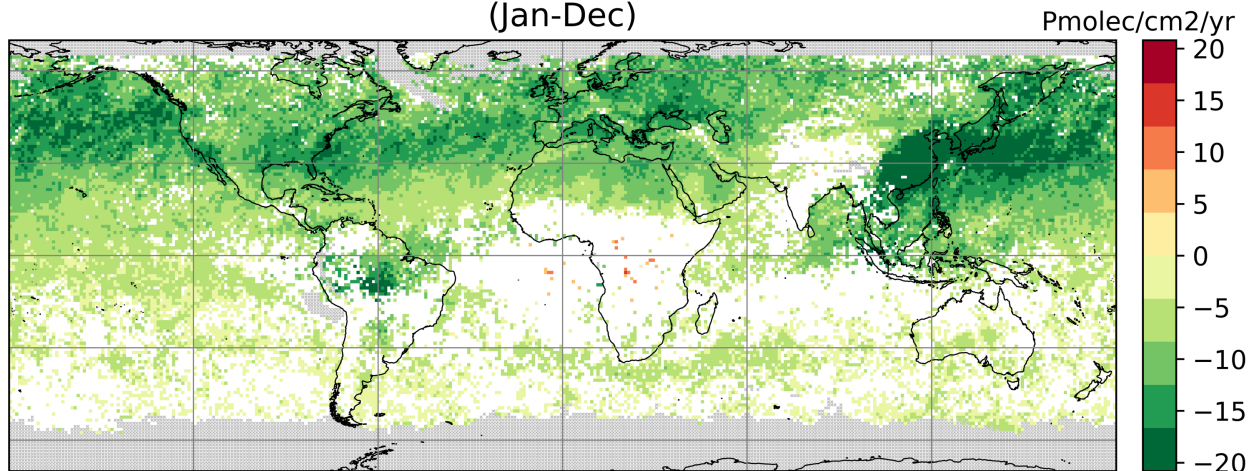

587  
 588 Figure 14: Time series of regional monthly mean tropospheric NO<sub>2</sub> columns (in 10<sup>15</sup> molecules  
 589 cm<sup>-2</sup>) averaged over China (110–123° E, 30–40° N), Europe (10° W–30° E, 35–60° N), the US  
 590 (70–125° W, 28–50° N), India (68–89° E, 8–33° N), South America (50–70° W, 20° S–Equator),  
 591 northern Africa (20° W–40° E, Equator–20° N), central Africa (10–40° E, Equator–20° S),

592 southern Africa (25–34° E, 22–31° S), southeastern Asia (96–105° E, 10–20° N), and Australia  
593 (113–155° E, 11–44° S) obtained from OMI (black), GOME-2 (blue), and SCIAMACHY (red).

### 594 3.4.5. CO Trends

595 CO trends are calculated based on MOPITT v9 products, see sec. 2.2.1. Observed CO trends  
596 below show a slowing in the trend compared to a previous analysis (Buchholz et al. (2021)). In  
597 the northern hemisphere, CO trends are largely negative over the US and Europe, which is  
598 consistent with improvements in combustion efficiency and policies implemented to reduce air  
599 pollution since 2004. Except for small sporadic positive trends, no HC trends can be calculated  
600 over Central Asia (India and China), while there is a strong negative trend in East China due to  
601 the recent strong focus on air quality improvement, and no HC trend in the SH.

Annual trend of MOPITT TC-CO  
(based on monthly anomalies)  
(Jan-Dec)

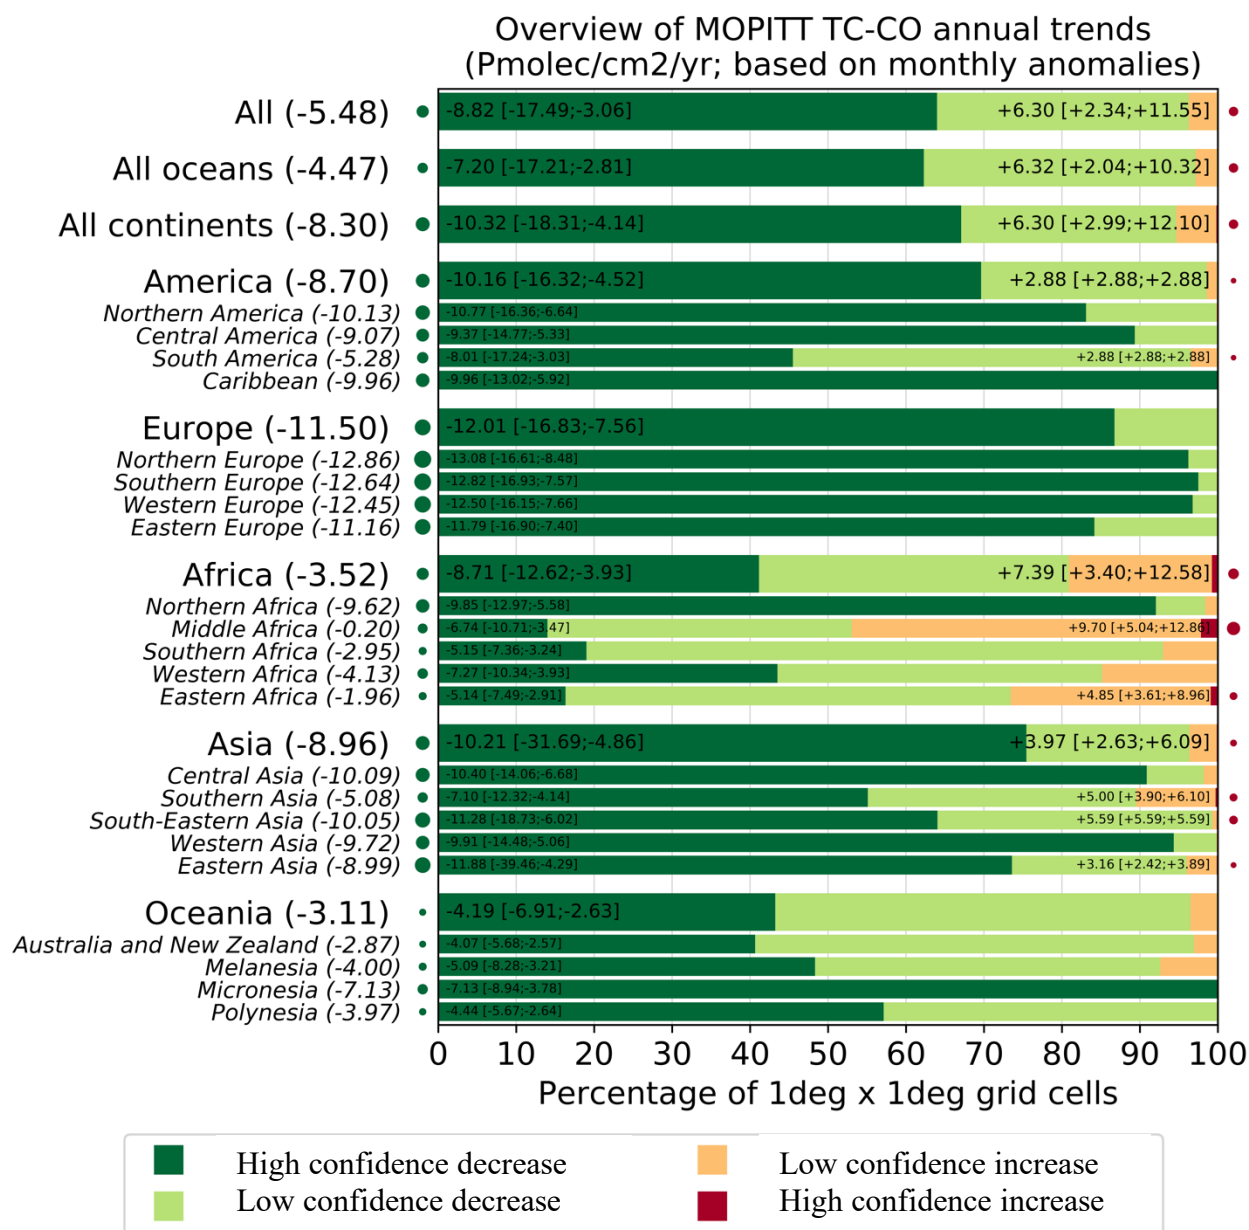

602  
603 Figure 15: Trends in TC-CO from MOPITT V9J data, 2005-2019 (see text for details on the  
604 calculation of the trends). Grey areas correspond to areas without enough data, white areas  
605 correspond to regions where the trends remain statistically low-confidence at a 95% confidence  
606 level.

607

608 A regional summary of the trends in the global map is shown in [Figure 16](#). CO trends are  
609 predominantly negative everywhere except for some sporadic positive trends over middle Africa.  
610 Decreasing TC-CO trends are highest in Europe, followed by Asia and America with about 86%,  
611 75%, and 69% of their cells being negative, respectively. The 50 percentiles of the trends in  
612 these cells are -12.01, -10.21, and -10.16 Pmolec/cm<sup>2</sup>/yr, respectively. Africa shows the lowest  
613 decreasing trends as the negative trends in North Africa are being offset by small increasing  
614 trends in middle Africa. Overall, about 41% of the cells in Africa show decreasing trends, and  
615 50% of the trends in these cells account for -8.71 Pmolec/cm<sup>2</sup>/yr. Thus, even though the NH  
616 accounts for most of CO emissions, decreasing trends of TC-CO are evident in these regions.

617

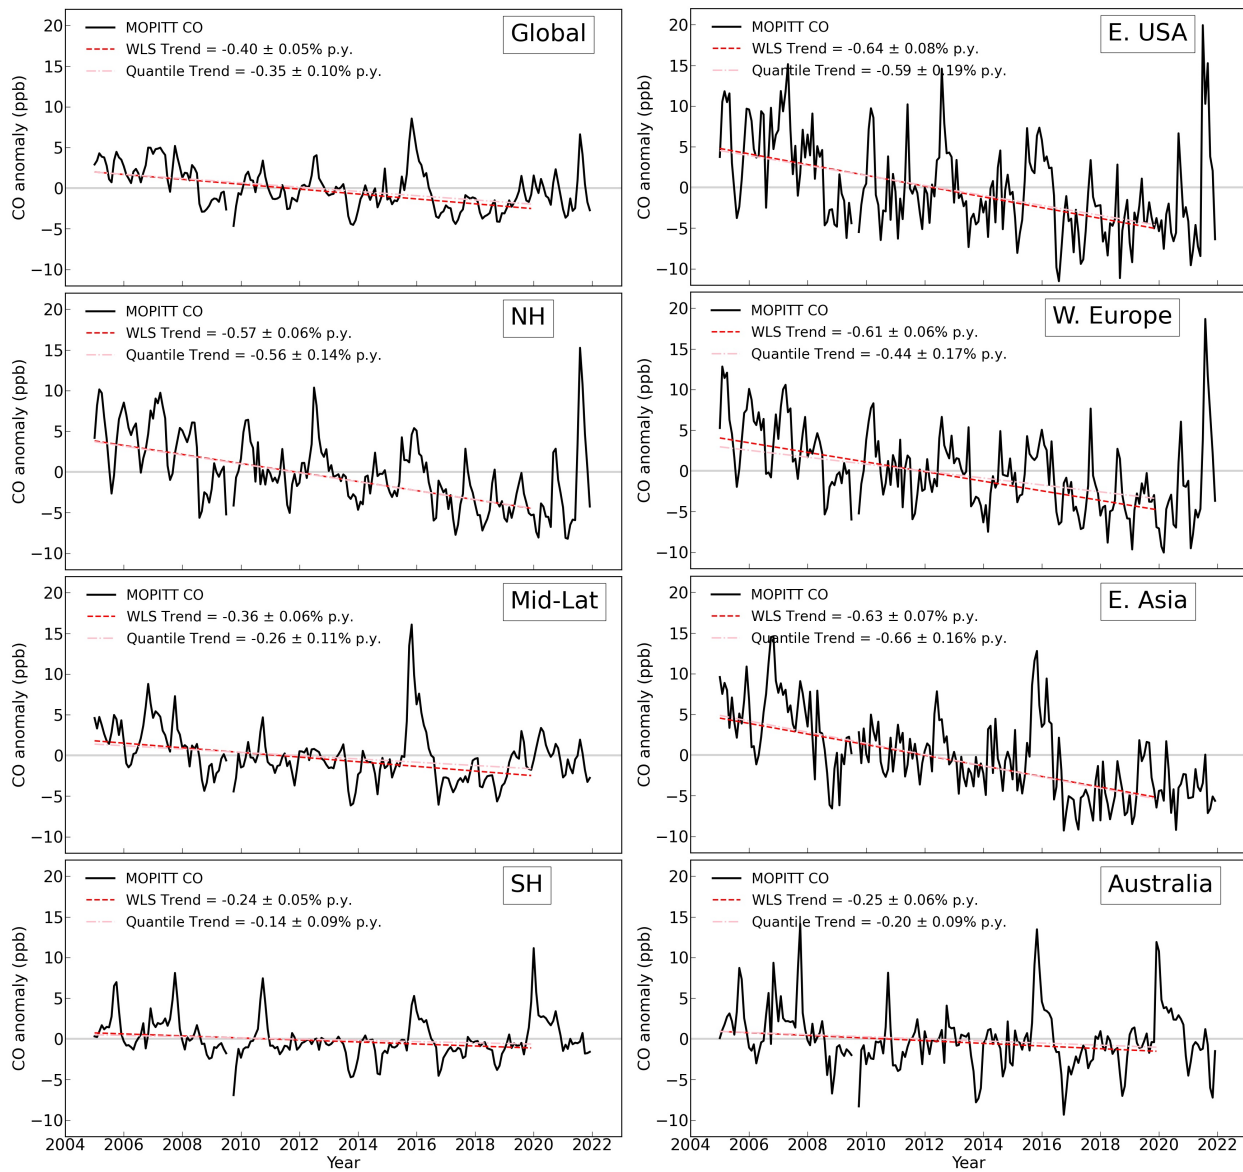

618  
 619 Figure 16: Summary of the statistically high- and low-confidence regional trends of MOPITT  
 620 TC-CO trends over 2005-2019, at a 95% confidence level (see text for details on the calculation  
 621 of the trends). For each region, the trends reported on the left (resp. right) represent the 50<sup>th</sup>[5<sup>th</sup>,  
 622 and 95<sup>th</sup>] percentiles of the trends calculated over the different grid cells showing a high-  
 623 confidence TC-CO increase or decrease.

624  
 625 Shown below are also the trends in the MOPITT column average volume mixing ratio (VMR)  
 626 anomalies from 2005 to 2019 (Figure 17) using QR as well as Weighted least squares (WLS)) as  
 627 Buchholz et al. (2021). The region boundaries are the same as used in Fig. 10 and 11. Results  
 628 show a HC decreasing trend in the NH (-0.35 ± 0.1% annually), a smaller decreasing trend in the  
 629 Mid-latitudes (-0.26 ± 0.1% annually), and LC trend in the SH (-0.14 ± 0.1% annually). The three  
 630 anthropogenic regions investigated in the NH all show strong decreases in CO. The larger  
 631 negative trend over Australia (-0.2 ± 0.1% annually) than the average SH, suggests sources from

632 the other two land regions (Southern Africa and South America) may be counteracting negative  
 633 trends in CO for the SH.  
 634

635  
 636 Figure 17: MOPITT monthly average CO anomalies in column average volume mixing ratio  
 637 (VMR, ppb), 2005-2021 (black). Updated dataset based on Buchholz et al. (2021). Data is Level  
 638 3, monthly average daytime observations, using version 9 joint NIR/TIR retrievals (V9J).  
 639 Regions are defined in [Figure 10](#) and [Figure 11](#). Trends are calculated on anomalies 2005-2019.  
 640 The weighted Least Squares trend (red) is weighted by the monthly regional standard deviation.  
 641 The quantile regression trend is also shown (pink). Grey dashed lines indicate a zero trend.

642  
 643 We also compare CO trends with Community Earth System Model (CESM) simulations  
 644 (Supplement Fig S1). While the magnitude of modeled CO tends to be underestimated relative to  
 645 observations, the anomalies between the model and measurements are comparable, indicating the  
 646 model reproduces interannual variability well. The negative trends in the NH are also reproduced

647 by CESM, although to a smaller degree than observations, suggesting that the trends in sources  
 648 or loss processes (such as OH oxidation) are underestimated in the model. These processes will  
 649 impact the feedback into modeled ozone and the resulting interpretation of driving factors for  
 650 ozone abundance and variability. Interestingly, CESM correctly represents a negative trend in  
 651 CO for the NH and East Asia while GEOS-GMI has a positive CO trend in those regions (Fig.  
 652 11), likely due to the well-known misrepresentation of East Asia air quality improvements in  
 653 emission inventories (Yin et al, 2015; Strode et al., 2016; Zheng et al, 2019). In the SH, CESM  
 654 does not predict HC trends.

655

### 656 3.4.6. HCHO Trends

657 HCHO, mainly a photochemical product results from hydrocarbon oxidation. HCHO is itself a  
 658 source of OH and ozone through its photolysis producing HO<sub>2</sub>, which can be recycled back to  
 659 OH if sufficient NO levels are present.

664 Unlike higher aldehydes, the OH reaction with HCHO leads also to the formation of a formyl  
 665 radical (HCO), which ultimately forms HO<sub>2</sub> ([R 3.4-3](#)).

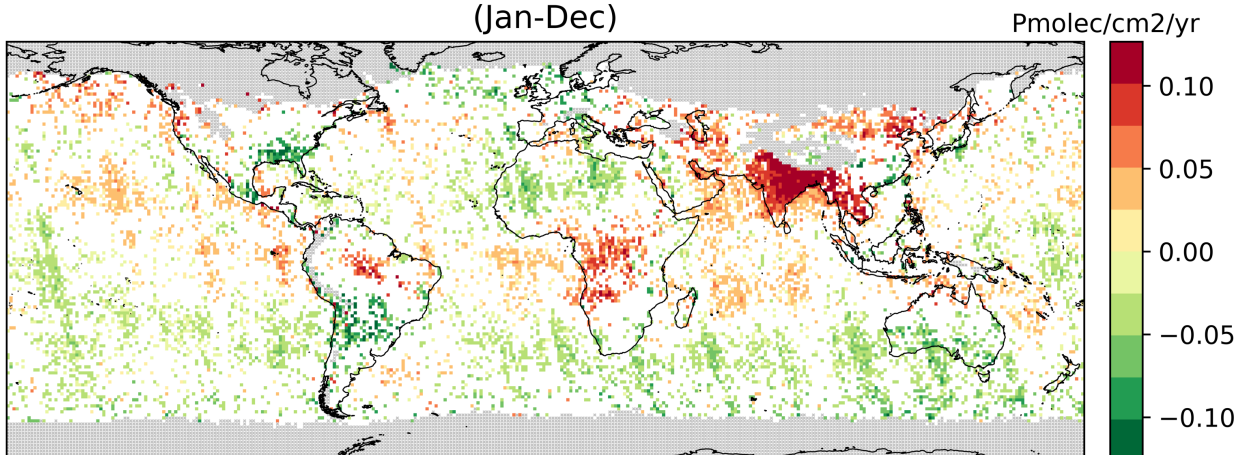

667 Due to its solubility, the variability of HCHO also depends on the presence of clouds, and wet  
 668 deposition ultimately represents another important sink for HCHO (Lelieveld and Crutzen, 1991).  
 669 Overall, HCHO plays a key role in the O<sub>3</sub> budget, both in polluted and remote regions.

670 Trends of the OMI HCHO tropospheric columns (hereafter referred to as TrC-HCHO) are  
 671 computed as described for OMI TrC-NO<sub>2</sub>. TrC-HCHO trends over 2005-2019 are shown in  
 672 [Figure 18](#) with a regional summary in [Figure 19](#). The first global feature to highlight on the  
 673 global trends map is the presence of stripes along the OMI orbits. The number of rows affected  
 674 by the OMI row anomaly has increased over the years (Boersma et al., 2018). The affected rows  
 675 are filtered out in the HCHO data, but the change in the sampling and the related increase in the  
 676 noise impact the trend analysis. Along orbit stripes in the trend analysis should be ignored but  
 677 zonal trends are still valid ([Figure 18](#)).

678

Annual trend of OMI TrC-HCHO  
(based on monthly anomalies)  
(Jan-Dec)

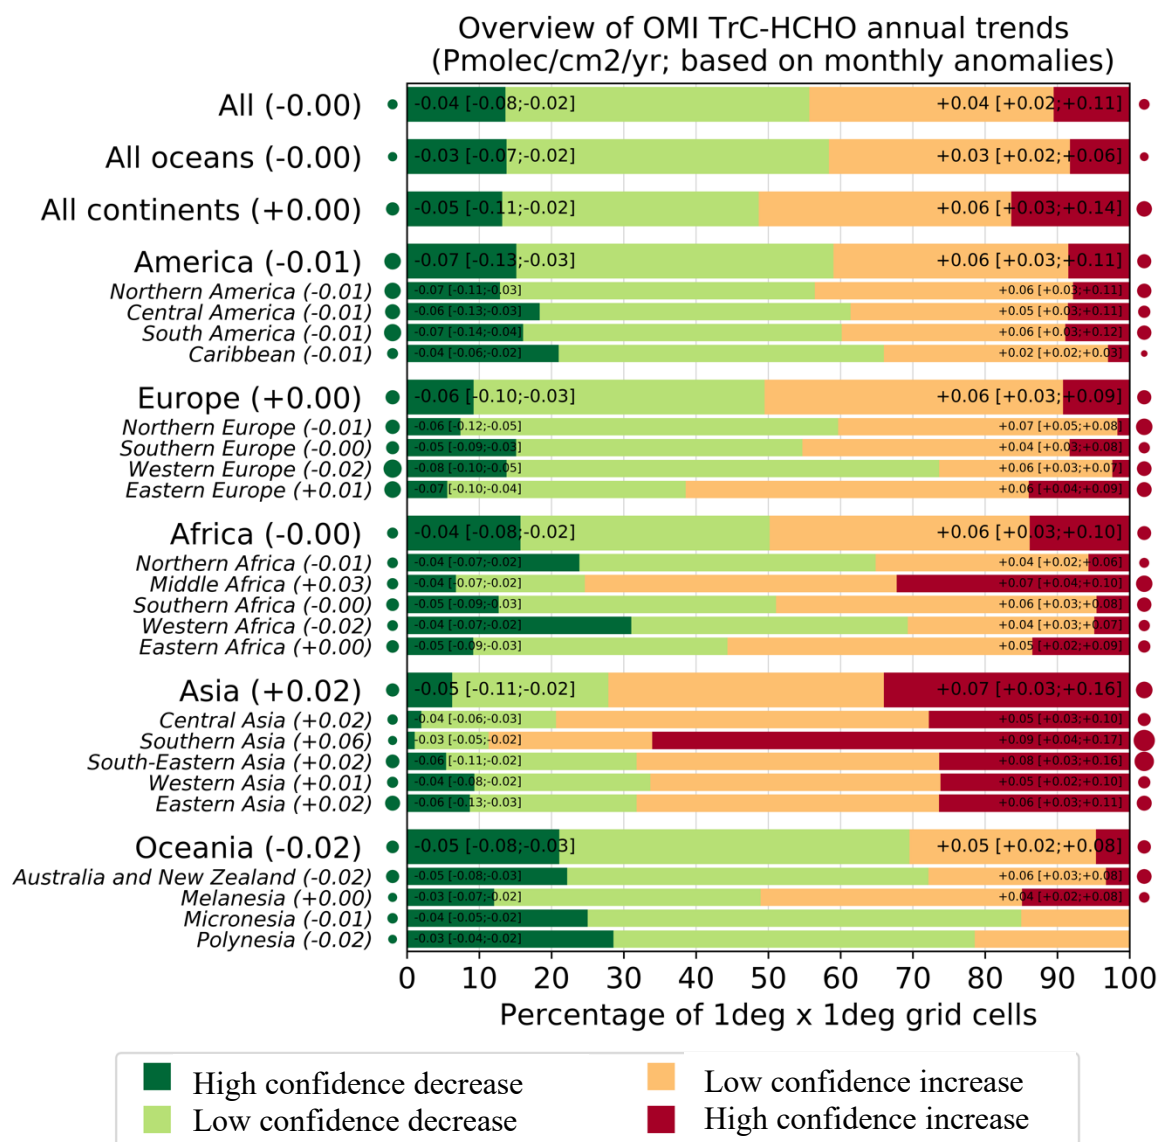

679

680 Figure 18: Global trends of OMI HCHO tropospheric column (TrC-HCHO) over 2005-2019 (see  
681 text for details on the calculation of the trends). Grey areas correspond to areas without enough  
682 data, white areas correspond to regions where the trends remain statistically low-confidence at a  
683 95% confidence level.

684 Despite the fact that TrC-HCHO trends remain LC over a large part of the globe, specific regions  
685 do highlight clear trends. The region with clearest changes is unambiguously southern Asia  
686 where about 65% of the cells show increasing trends with a median of +0.09 Pmolec/cm<sup>2</sup>/yr. The  
687 other regions with a large portion (25-30% of the cells) of increasing trends include the rest of  
688 Asia and central Africa, with median TrC-HCHO trends ranging between +0.05 and +0.08  
689 Pmolec/cm<sup>2</sup>/yr, as well as some parts of central Brazil (Amazonians). Conversely, some HC  
690 decreases of TrC-HCHO are observed in the south-eastern US, the southern half of Southern  
691 America, North and western Africa, and southern Australia, although part of them overlap with  
692 the aforementioned stripes and might thus not be real.

693

694

695 Figure 19: Summary of the statistically high- and low-confidence regional trends of OMI HCHO  
 696 tropospheric column (TrC-HCHO) trends over 2005-2019, at a 95% confidence level (see text  
 697 for details on the calculation of the trends). For each region, the trends reported on the left (resp.  
 698 right) represent the 50<sup>th</sup> [5<sup>th</sup>, and 95<sup>th</sup>] percentiles of the trends calculated over the different grid  
 699 cells showing a HC TrC-HCHO increase or decrease.

700

701 HCHO trends varies with that of O<sub>3</sub> (sec. 3.4.1) which might be due to several factors, such as  
 702 their different sensitivity to NO<sub>x</sub> and hydrocarbons (Luecken et al., 2018) but also possible STE  
 703 contribution to tropospheric ozone levels, especially in midlatitudes (Willimas et al., 2019; Li et  
 704 al., 2024). For example, while TrC-O<sub>3</sub> is increasing in the southeastern US, TrC-NO<sub>2</sub>, TC-CO,  
 705 and TrC-HCHO are decreasing, which, in addition to the local chemistry, might indicate a STE  
 706 signal. TrC-NO<sub>2</sub> trends are decreasing over the northern coast of Australia while those of TrC-O<sub>3</sub>  
 707 and TrC-HCHO are increasing. While the increase of HCHO/NO<sub>2</sub> might indicate a trend toward  
 708 NO-limited conditions (see below), the increase of TrC-O<sub>3</sub> trends in this region might also  
 709 indicate increasing trends of STE contribution (Li et al., 2024). However, TrC-HCHO trends are

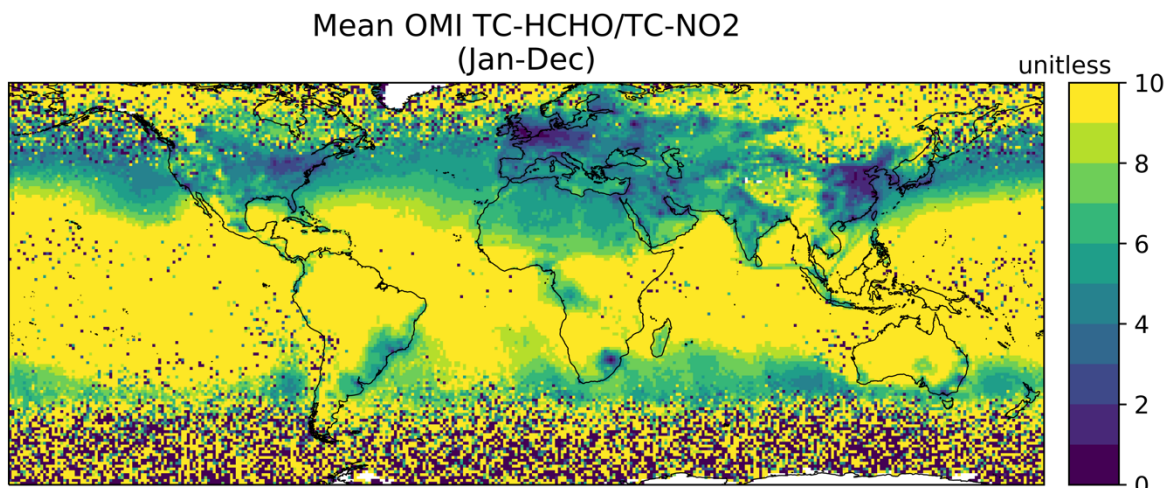

710 consistent with that of TrC-O<sub>3</sub> in other regions, e.g., over the northeastern US and Europe.  
711 Similarly, while NO<sub>2</sub> trends are slightly increasing over central and southern Australia, trends of  
712 TrC-O<sub>3</sub> and TrC-HCHO are decreasing, which indicates a trend toward VOC-limited conditions  
713 (see below).

714

### 715 3.4.7. HCHO/NO<sub>2</sub>

716 The ratio of TrC-HCHO/TrC-NO<sub>2</sub> observed from space (e.g., Martin et al., 2004) has been used  
717 in a number of studies to give insights on the O<sub>3</sub> chemical regime, higher (resp. lower) TrC-  
718 HCHO/TrC-NO<sub>2</sub> ratios indicate NO<sub>x</sub>-limited (resp. RO<sub>x</sub>-limited) regimes. Although imperfect  
719 (e.g. Sourì et al., 2023), this indicator yet provides some qualitative information on the evolution  
720 of the O<sub>3</sub> regime over the last years (Nussbaumer et al., 2023). We note that this analysis does not  
721 consider variations in the ratios and their trends with respect to season or altitude. The mean TrC-  
722 HCHO/TrC-NO<sub>2</sub> over 2005-2019 are shown in Figure 20, and the trend results are in Figure 21  
723 with a regional summary in Figure 22. The highest ratios are observed in the tropical regions due  
724 to strong TrC-HCHO from biogenic sources and fire NMVOC emissions in tropical South America  
725 and Africa combined with relatively low TrC-NO<sub>2</sub>. Conversely, lower TrC-HCHO/TrC-NO<sub>2</sub> ratios  
726 are observed across western Europe and north-eastern Asia, and to a lesser extent, the northeastern  
727 US.  
728

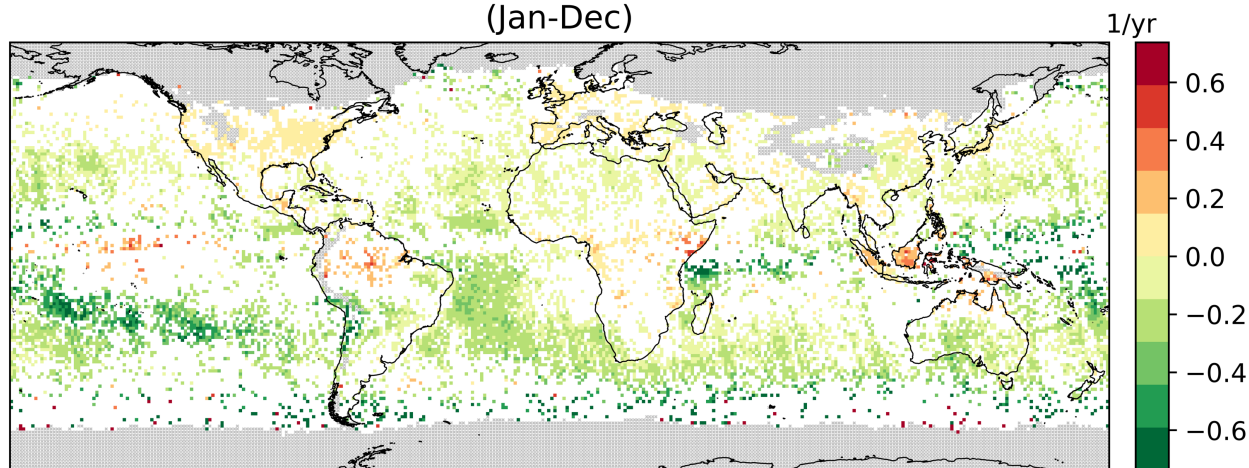

729  
730 Figure 20: Global mean OMI HCHO/NO<sub>2</sub> tropospheric column ratio over 2005-2019.  
731

732 At a global scale, the HC changes in TrC-HCHO/TrC-NO<sub>2</sub> trends ([Figure 21-Figure 22](#)) mostly  
733 go in the direction of a reduction, with about 25% of the grid cells showing a median trend of -  
734 0.52 yr<sup>-1</sup>. (while only 5% of the cells show an HC increase of +0.03 yr<sup>-1</sup>) as shown in [Figure 22](#).  
735 This suggests that these areas are evolving toward VOC-sensitive conditions (which does not  
736 necessarily imply that they are already in this regime). This situation is observed over a large part  
737 of Oceania (especially Polynesia) and specific parts of Africa, Asia, and South America. The  
738 opposite HC trends, toward more NO-sensitive conditions, are mainly observed over Europe and  
739 northern America, as well as South Asia. We note that the mean TrC-HCHO/TrC-NO<sub>2</sub> indicates  
740 the mean status of the chemical regime over this period of time (2005-2019). However, the trends  
741 of the TrC-HCHO/TrC-NO<sub>2</sub> ratio show the changing sensitivity of the chemical regime over this

742 period of time. For example, while the ratio in the Eastern US indicates VOC-sensitive conditions,  
743 the trends of TrC-HCHO/TrC-NO<sub>2</sub> indicate a direction toward NO-sensitive conditions.  
744

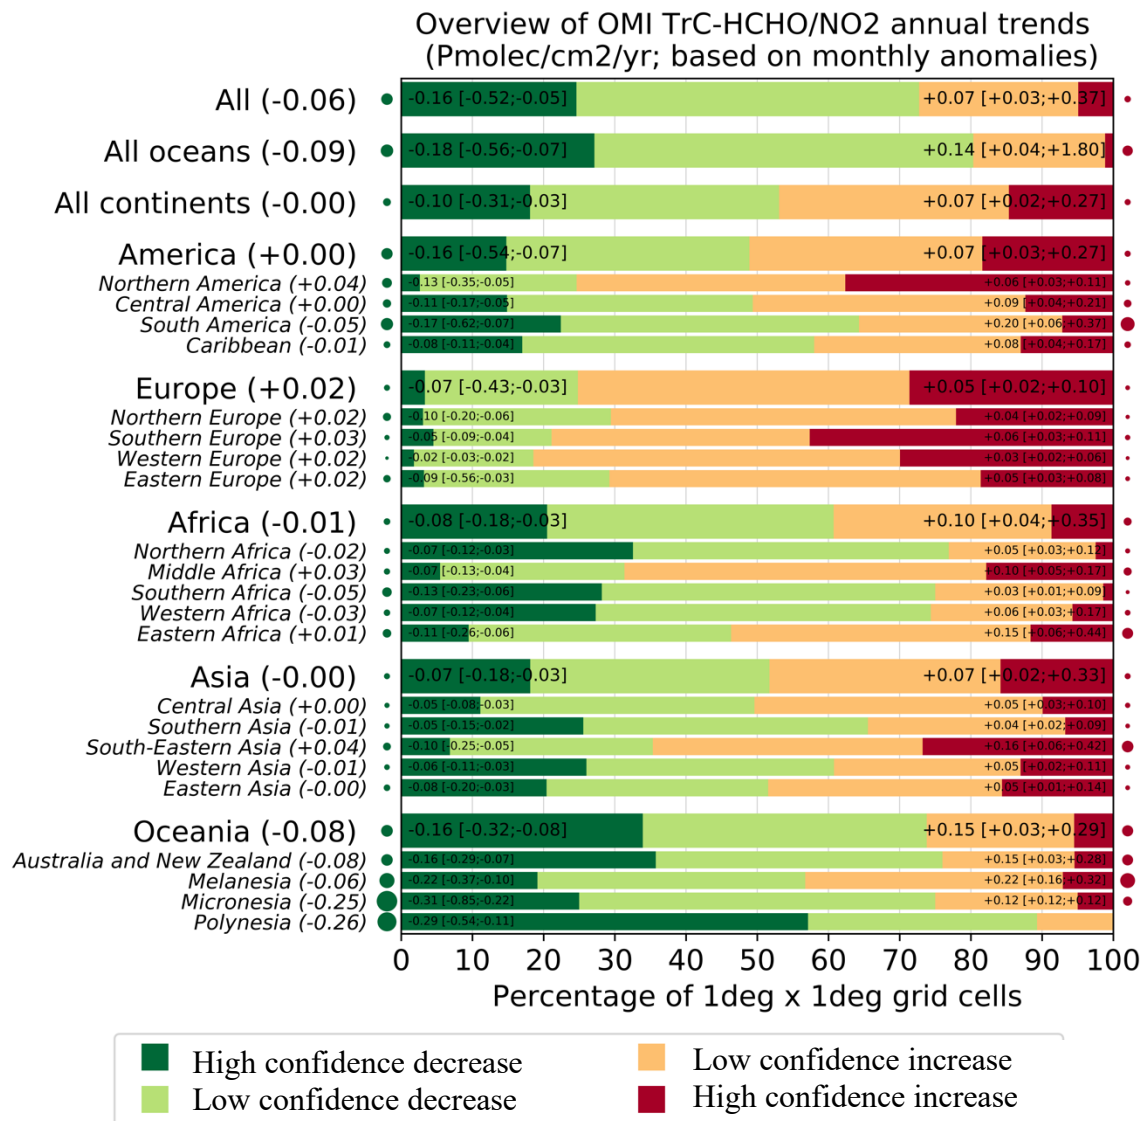

Annual trend of OMI TrC-HCHO/NO<sub>2</sub>  
(based on monthly anomalies)  
(Jan-Dec)

745  
746 Figure 21: Global trends of OMI HCHO/NO<sub>2</sub> tropospheric column ratio over 2005-2019 (see  
747 text for details on the calculation of the trends). Grey areas correspond to areas without enough  
748 data, white areas correspond to regions where the trends remain statistically low-confidence at a  
749 95% confidence level.

750  
751 The trends on the TrC-HCHO/TrC-NO<sub>2</sub> ratio is mainly driven by specific trends on TrC-HCHO  
752 and/or TrC-NO<sub>2</sub>, depending on the region. The ratio increase in southern and western Europe and  
753 southeast Asia appears primarily due to decreasing TrC-NO<sub>2</sub>, since TrC-HCHO does not change  
754 with HC. Over North America, observed TrC-HCHO values decrease but less than TrC-NO<sub>2</sub>,  
755 which thus drives the ratio toward an increase. Conversely, the increase of TrC-HCHO/TrC-NO<sub>2</sub>  
756 in equatorial Africa and Amazonians appears mainly driven by increasing TrC-HCHO. The  
757 regions with HC decreasing TrC-HCHO/TrC-NO<sub>2</sub> ratio include Chile and Australia, due to both  
758 decreasing TrC-HCHO and increasing TrC-NO<sub>2</sub> (Figure 22), indicating a trend towards a VOC-  
759 limited regime. Note that over the US, Jin et al. (2020) demonstrated the reasonable ability of the  
760 OMI-based TrC-HCHO/TrC-NO<sub>2</sub> trends to capture the transition from RO<sub>x</sub>-limited to NO<sub>x</sub>-limited  
761 regimes over main US cities and found a relatively good consistency between observed changes  
762 of the surface O<sub>3</sub> and space-based HCHO/NO<sub>2</sub> increasing trends.

763  
764

765  
 766 Figure 22: Summary of the statistically high- and low-confidence regional trends of OMI TrC-  
 767 HCHO/TrC-NO<sub>2</sub> tropospheric column ratio trends over 2005-2019, at a 95% confidence level (see  
 768 text for details on the calculation of the trends). For each region, the trends reported on the left  
 769 (resp. right) represent the 50<sup>th</sup>[5<sup>th</sup>, and 95<sup>th</sup>] percentiles of the trends calculated over the different  
 770 grid cells showing a high confidence TrC-HCHO/TrC-NO<sub>2</sub> increase or decrease.

771  
 772

### 774 3.5. Lightning NO<sub>x</sub> and Its Effects on Tropospheric NO<sub>x</sub> and O<sub>3</sub>

775 Nitric oxide (NO) is produced in lightning flash channels and quickly comes into equilibrium with  
776 NO<sub>2</sub>. Cloud-scale simulations of thunderstorms indicate that 55-75% of lightning NO<sub>x</sub> (LNO<sub>x</sub>) is  
777 detrained above 8 km (Pickering et al., 1998) where it enhances upper tropospheric NO<sub>y</sub>, OH, and  
778 O<sub>3</sub> (Labrador et al., 2005; Allen et al., 2010; Liaskos et al., 2015) and contributes to enhanced  
779 longwave radiative absorption by O<sub>3</sub> (Lacis et al., 1990; Finney et al., 2018). Enhanced OH leads  
780 to a decrease in CH<sub>4</sub> lifetime and decreased longwave radiative absorption (Fiore et al., 2006;  
781 Finney et al., 2018). The lifetime of NO<sub>x</sub> in the upper troposphere is controlled by the chemical  
782 cycling of NO<sub>x</sub> with reservoir species and is 10-20 days away from deep convection (Prather and  
783 Jacob, 1997) but only 2-12 hours in the vicinity of convection (Nault et al., 2016, 2017). This  
784 chemical recycling provides a source of NO<sub>x</sub> downwind of thunderstorms, which causes the ozone  
785 production efficiency of emitted NO<sub>x</sub> to be 4-20 times higher in the upper troposphere than at the  
786 surface. Thus, LNO<sub>x</sub> has a disproportionate impact on the tropospheric O<sub>3</sub> budget (Pickering et al.,  
787 1990; Grewe et al., 2001; Sauvage et al., 2007).

788 The distribution of lightning is fairly well known over much of the Earth due to remote  
789 sensing observations and an increase in the number and capability of ground-based lightning  
790 networks. However, the LNO<sub>x</sub> production efficiency (PE, mol fl<sup>-1</sup>) is a continued source of  
791 uncertainty. Schumann and Huntrieser (2007) reviewed the literature on LNO<sub>x</sub> production, finding  
792 a best estimate of 250 moles per flash, with uncertainty factors ranging from 0.13 to 2.7. The PE  
793 can be estimated from theoretical and laboratory considerations (Price et al., 1997; Koshak et al.,  
794 2014), using thunderstorm anvil observations by aircraft (Ridley et al., 2004; Huntrieser et al.,  
795 2008, 2011; Pollack et al., 2016; Nault et al., 2017; Allen et al., 2021a), based on satellite data  
796 (Bucsela et al., 2010; Beirle et al., 2010; Pickering et al., 2016; Bucsela et al., 2019; Lapierre et  
797 al., 2020; Zhang et al., 2020; Allen et al., 2019, 2021b), or using cloud-resolved (e.g., DeCaria et  
798 al., 2000; 2005; Fehr et al., 2004; Ott et al., 2007, 2010; Cummings et al., 2013; Pickering et al.,  
799 2023) or global model simulations with chemistry (e.g. Martin, et al., 2007; Murray et al., 2012;  
800 Miyazaki et al., 2014; Marais et al., 2018). These various techniques have yielded PE estimates  
801 ranging from <50 to >1000 mol fl<sup>-1</sup>, with most estimates in the 100-400 mol fl<sup>-1</sup> range. Miyazaki  
802 et al. (2014) assimilated OMI NO<sub>2</sub>, MLS and TES O<sub>3</sub>, and MOPITT CO into a chemical transport  
803 model to provide comprehensive constraints on the global LNO<sub>x</sub> source, resulting in an estimate  
804 of mean PE of 310 moles per flash. Marais et al. (2018) used cloud-sliced upper tropospheric NO<sub>2</sub>  
805 from OMI together with the GEOS-Chem model to estimate a mean LNO<sub>x</sub> PE of 280 moles per  
806 flash. Lightning is the dominant source of NO<sub>x</sub> in the tropical upper troposphere year-round and  
807 in the northern mid-latitudes in summer. Lightning is responsible for 10-15% of NO<sub>x</sub> emissions  
808 globally. Assuming 100-400 mol fl<sup>-1</sup>, the global LNO<sub>x</sub> production is likely 2 – 8 Tg N a<sup>-1</sup>  
809 (Schumann and Huntrieser, 2007; Verma et al., 2021). LNO<sub>x</sub> impacts air quality and deposition  
810 (Kaynak et al., 2008; Allen et al., 2012). On average LNO<sub>x</sub> adds 1-2 ppbv to surface O<sub>3</sub> (Kang et  
811 al., 2019b), although contributions as large as 18 ppbv have been seen for individual events  
812 (Murray et al., 2016). Allen et al. found that the addition of LNO<sub>x</sub> to the Community Multiscale  
813 Air Quality (CMAQ) model increased wet deposition of oxidized nitrogen at National  
814 Atmospheric Deposition Program (NADP) sites by 43%, reducing low biases from 33% to near-  
815 zero. Kang et al. (2019b) found similar improvements for wet deposition and also found that  
816 including LNO<sub>x</sub> resulted in smaller biases with respect to ozonesondes and aircraft profiles taken  
817 during the NASA DISCOVER-AQ field campaign (Flynn et al., 2016). Thus, to accurately assess  
818 its impacts on air quality, it is critical that LNO<sub>x</sub>-producing deep convection is accurately  
819 simulated.

820 Only in recent years with the advent of satellite observations of lightning flashes and improved  
821 coverage by ground-based lightning networks has there been sufficient data to make estimates of  
822 trends in the occurrence of lightning. However, it is unknown whether trends in LNO<sub>x</sub> production  
823 are similar to those of lightning itself. Lightning characteristics such as the ratio of intracloud (IC)  
824 flashes to cloud-to-ground (CG) flashes, the multiplicity (i.e., the number of strokes per flash), and  
825 the peak current or energy associated with flashes may vary over time. All of these lightning  
826 characteristics may have effects on the magnitude of LNO<sub>x</sub> production. We have insufficient data  
827 to take into account these possible effects on LNO<sub>x</sub> production over large spatial domains or over  
828 sufficiently long periods of time.

### 829 **3.5.1. Global Historical Trends of Lightning**

830 The first attempts at an examination of trends in thunderstorm activity were conducted in terms of  
831 thunder-days (in Japan by Kitagawa et al., 1989; in Brazil by Pinto et al., 2013). A more recent  
832 global analysis was conducted by Lavigne et al. (2019), who analyzed trends in thunder-days  
833 (number of days with audible thunder at weather observation stations) over 43 years and in flashes  
834 recorded by the Lightning Imaging Sensor (LIS) on the Tropical Rainfall Measuring Mission  
835 (TRMM) for 16 years. Thunder-days increased since the 1970s in the Amazon Basin, the Maritime  
836 Continent, India, Congo, Central America, and Argentina. Decreases in thunder-days were found  
837 in China, Australia, and the Sahel region of Africa. Lavigne et al. (2019) do not provide a global  
838 trend in thunder days, but an average trend computed over the nine primary lightning regions that  
839 they considered, weighted by the mean annual thunder days in each region, yields a near global  
840 estimate of +3.8% per decade. How well do thunder-days represent lightning flash rate? Lavigne  
841 et al. found a positive correlation between thunder-days and LIS flash rates in China, the Maritime  
842 Continent, South Africa and Argentina, but disagreement on the trend in India and West Africa.

843 Large-scale ( $\pm 38^\circ$  latitude) trends in lightning flashes have been examined in the data collected by  
844 the LIS on the TRMM satellite (January 1998 – December 2014) and on the International Space  
845 Station (February 2017 – December 2021). Füllekrug et al. (2022; see Figure SB2.1b) demonstrate  
846 that the annual mean deviations from the 1998 – 2021 mean are no more than ~5% except for ~-  
847 10% in 2020 and ~-8% in 2021. However, no long-term trend is evident from the LIS data. The  
848 possibility that these larger negative deviations in 2020 and 2021 are due to Covid-19 lockdowns  
849 and general declines in economic activity has been speculated. The link may be provided by  
850 changes in Aerosol Optical Depth (AOD) as suggested by Liu et al. (2021) who demonstrated 10-  
851 20% flash reductions in March – May 2020 relative to the 2018 – 2021 mean for those months  
852 from the GLD360 and WWLLN ground-based lightning networks. Regional lightning reductions  
853 were consistent with AOD reductions noted by Sanap (2021). Larger reductions in lightning were  
854 noted over Africa/Europe and Asia/Maritime Continent and lesser reductions over the Americas.

### 855 **3.5.2. Regional Historical Trends of Lightning**

856 Widely varying trends in lightning over China have been reported in the literature. To some extent,  
857 whether the trend in lightning is upward or downward depends on the particular region studied and  
858 on the period of time considered. Yang and Li (2014) were the first to report on lightning trends  
859 in China. They used lightning data from the TRMM/LIS sensor and human-observed thunderstorm  
860 day occurrence over the period 1990 to 2012 in southeastern China. Thunderstorms and lightning  
861 occurrence increased over the period as well as LIS precipitation radar echo tops heights. These  
862 increases were accompanied by decreases in visibility, indicating increases in pollution aerosol.  
863 Detailed work on lightning trends in China has been performed in relation to aerosols. Shi et al.  
864 (2020) correlated flashes from the TRMM/LIS Low-Resolution Monthly Time Series (2.5 deg.  
865 resolution) with AOD from MODIS-Terra V6.1 Level 3 over the period 2001 to 2014. For AOD

866 < 1.0,  $r = 0.64$ , indicating a likely microphysical effect on lightning flash rate. For  $AOD > 1.0$ ,  $r =$   
867  $-0.06$ , which could indicate that with higher aerosol concentration there is a radiation effect  
868 stabilizing the atmosphere and/or a decrease in the number of graupel particles in the mixed-phase  
869 region of the storms that is important for charging. Flashes were also correlated with surface  
870 relative humidity and Convective Available Potential Energy (CAPE). As AOD generally  
871 increased over much of the early portion of this time period and then decreased, lightning flash  
872 rates followed similar trends. Wang et al. (2021) examined a 9-year record (2010- 2018) of CG  
873 lightning from the China Lightning Detection Network in three polluted urban areas of China  
874 (Chengdu, Wuhan, and Jinan). They found decreasing trends (see Wang et al., 2021) in CG  
875 lightning and total AOD (from the MERRA-2 reanalysis). Annual mean lightning density in these  
876 three regions decreased by 50 – 75% as annual mean AOD fell from 0.70 – 0.75 to 0.53 to 0.62.

877 Qie et al. (2022) analyzed the OTD/LIS record from 1996 through 2013, and found that lightning  
878 increased over the eastern Tibetan Plateau by  $0.072 \pm .069$  fl  $\text{km}^2 \text{ yr}^{-1}$ . Over the 18 years, this  
879 increase amounted to a total of  $1.3$  fl  $\text{km}^2 \text{ yr}^{-1}$ , compared with a climatological value of  $7.7$  fl  $\text{km}^2$   
880  $\text{yr}^{-1}$ , thereby indicating a HC increase. The ground-based World Wide Lightning Location Network  
881 (WWLLN) also showed increased strokes in this region. The increase in lightning frequency in  
882 this region was found to be due to an increase in thunderstorm frequency, not increased storm  
883 intensity.

884 Koshak et al. (2015) analyzed National Lightning Detection Network (NLDN) CG flashes over  
885 the contiguous United States (CONUS) from 2003 to 2012. The five-year mean flashes over 2008  
886 to 2012 decreased by 12.8% from the five-year mean for 2003 to 2007 (Table 1). The CONUS  
887 average wet bulb temperature also trended downward during this period, which may have led to  
888 lesser or weaker storms. However, US Environmental Protection Agency air quality trends show  
889 an 18% decrease in PM<sub>2.5</sub> concentrations over CONUS between the two subperiods, which also  
890 could have had an influence on the flash rates. A recent effort to update the Koshak et al. (2015)  
891 analysis is underway. NLDN flashes have been reprocessed (Kenneth Cummins, personal  
892 communication) from 2015 through 2021 to ensure that the classification of IC and CG flashes is  
893 done consistently with data prior to 2015. Trend analysis of NLDN CG flashes from 2003 (a major  
894 upgrade of the NLDN network hardware) through 2022 (William Koshak, personal  
895 communication) shows a HC reduction in CG flashes over CONUS, comparing the mean CG  
896 flashes over 2003-2004 with the mean over 2021 -2022. Within this period a major decrease  
897 (~25%) in CONUS CG flashes occurred from 2011 to 2012. Flashes in 2013 remained low, but  
898 recovered by 2014-2015. A major decrease (~27%) occurred from 2019 to 2020, with a small  
899 increase in 2021. These results have been obtained from ongoing efforts by Dr. William Koshak  
900 of the NASA Marshall Space Flight Center, and are presently part of a draft manuscript by lead  
901 author Koshak that extends and refines the earlier work in Koshak et al. (2015). Details concerning  
902 these trends will be contained in that manuscript.

903 A possible contributing factor to the CONUS decline in CG flashes over 2003 to 2021 is the  
904 substantial decrease in aerosol. Surface annual average PM<sub>2.5</sub> concentrations averaged over  
905 CONUS decreased by 37% from 2000 to 2021 according to the EPA National Air Quality Trends  
906 Report (<https://www.epa.gov/air-trends/air-quality-national-summary>). However, no decrease in  
907 CONUS annual average PM<sub>2.5</sub> was seen from 2019 to 2020. As mentioned previously, AOD may  
908 be a better indicator of the aerosol amount that may become incorporated into thunderstorm clouds.  
909 Sanap (2021) showed negative anomalies of AOD of ~0.1 in portions of CONUS in March and  
910 April 2020 and 0.1 to 0.2 in May 2020. The major decrease in CONUS CG flashes from 2011 to  
911 2012 has been related to drought conditions during Summer 2012 over the South Central and  
912 Southeastern US (Koshak et al., 2015). The reason for the number of CONUS flashes remaining

913 lower in 2013 is uncertain. Koehler (2020) analyzed 26 years (1993 – 2018) of NLDN CG  
914 lightning data to construct a thunder-day climatology for CONUS. Positive anomalies from the  
915 26-year mean were found from Texas to Colorado during 2003 to 2007, and negative anomalies  
916 in this region during 2008 to 2012. These anomalies were consistent with precipitation anomalies  
917 associated with ENSO.

918  
919 Holzworth et al. (2021) analyzed primarily CG lightning data from WWLLN for June, July, and  
920 August for the years 2010 through 2020. The ratio of lightning strokes north of 65° N latitude to  
921 the total global strokes increased by a factor of three over this period. This increase occurred as  
922 the surface temperature anomaly in this region increased by 0.3°C (see Holzworth et al., 2021).  
923 These results suggest a substantial increase in upper tropospheric NO<sub>x</sub> and subsequent ozone  
924 production at high northern latitudes.

### 925 926 **3.5.3. Future Lightning Trends**

927 Parameterizations in global chemistry and climate models have been developed for  
928 lightning flash rate. These schemes typically use kinematic, thermodynamic or microphysical  
929 variables from the model as predictors. In some studies such predictors have simply been applied  
930 to output from multiple climate models. This is the case with the Romps et al. (2014) work, which  
931 showed that when a lightning parameterization scheme using CAPE x Precipitation Rate is applied  
932 to 11 climate models an increase in CG lightning by 12 +/- 5% per degree Celsius of climate  
933 warming was computed. This work simply used the 12-hour resolution time series of spatial means  
934 of these variables over CONUS as input. Changes in IC lightning flashes were not considered. IC  
935 flashes typically outnumber CG flashes by a factor of 3 averaged over CONUS. Therefore, the  
936 result of this work is unknown with respect to the amount of change in LNO<sub>x</sub> emission. Romps et  
937 al. (2018) updated their analysis using CAPE from 3-hourly North American Regional Reanalysis  
938 (NARR) data and hourly precipitation from NOAA River Forecast Centers, finding that CAPE x  
939 Precipitation Rate captures the spatial, seasonal, and diurnal variations of NLDN CG flash rate  
940 over land, but does not predict the pronounced land-ocean contrast in flash rates. Therefore, these  
941 analyses are of limited value in estimating trends of LNO<sub>x</sub> over broader-scale regions. Romps et  
942 al (2019) tested four lightning proxies in a cloud-resolved 4-km resolution simulation over  
943 CONUS with the Weather Research and Forecasting (WRF) model, and over the tropical oceans  
944 with a Radiative Convective Equilibrium model. The proxies were CAPE x Precipitation Rate,  
945 precipitation with vertical velocity > 10 m/s, vertical ice flux at the 260K isotherm, and vertical  
946 integral of cloud ice and graupel product. The fractional change in proxy values per 1 degree  
947 Celsius of warming over CONUS was +8 to +16%. Over the tropical oceans the changes in proxy  
948 values per degree ranged from +12% for CAPE x Precipitation Rate to -1% for ice flux and -3%  
949 for the cloud ice and graupel product. Therefore, over broad regions of the Earth, there is great  
950 uncertainty on future trends in lightning.

951 Finney et al. (2016; 2018) compared lightning projections for 2100 using vertical ice flux  
952 (Finney et al., 2014) and cloud-top height parameterizations for flash rate in the UK Chemistry  
953 and Aerosols Model. They obtained -15% global change in total flash rate with ice flux under a  
954 strong global warming scenario (see Finney et al., 2018), which was composed of a greater  
955 decrease in the tropics and small increases in mid-latitudes. In terms of LNO<sub>x</sub> emissions this work  
956 using the ice flux scheme produced -0.15 TgN K<sup>-1</sup> change over the years from 2000 to 2100,  
957 implying less O<sub>3</sub> production. With the cloud-top height scheme they obtained +0.44 TgN K<sup>-1</sup> LNO<sub>x</sub>  
958 change, implying increased O<sub>3</sub> production. However, the ice flux scheme provided a more realistic

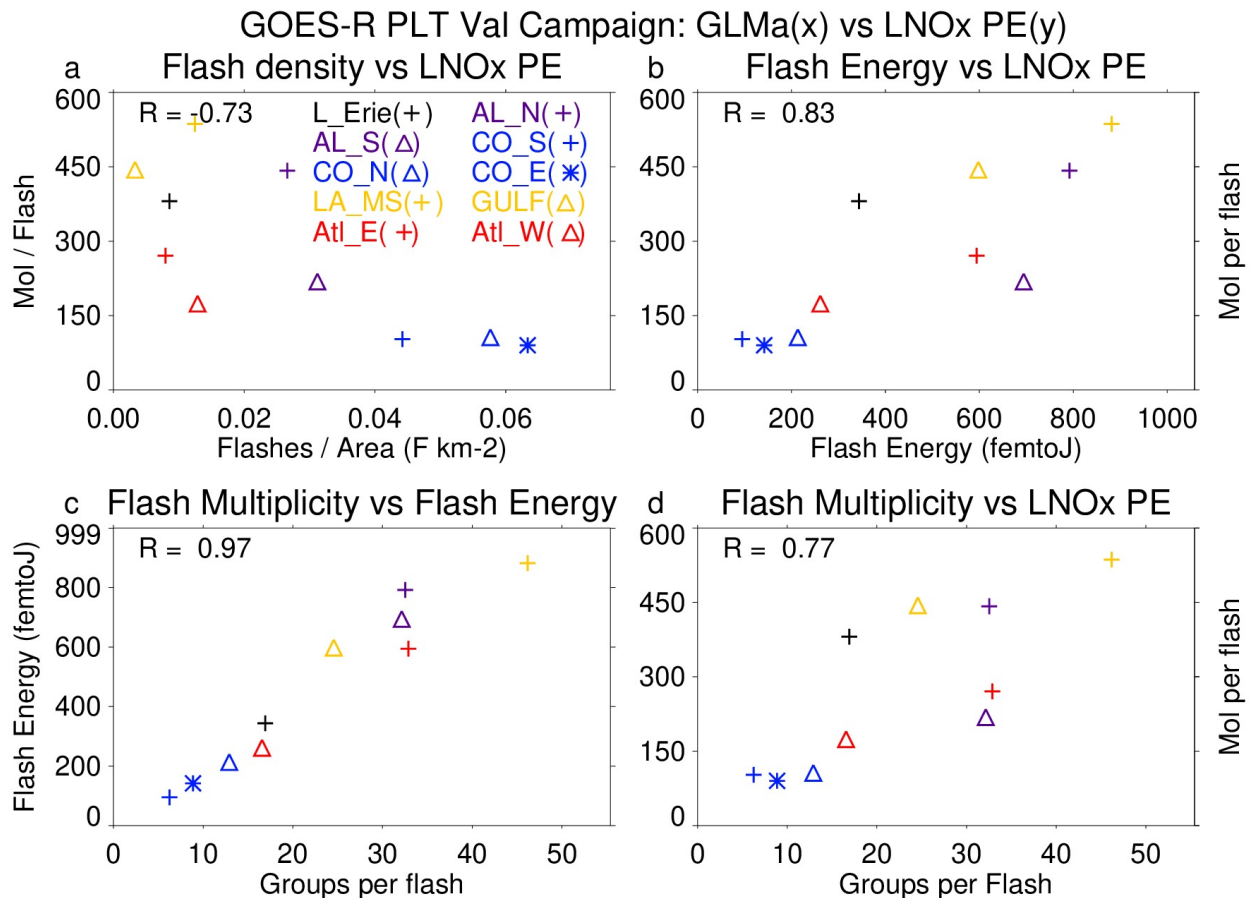

959 representation of global lightning for present day. Therefore, the negative LNO<sub>x</sub> emissions change  
 960 from this scheme may be more realistic. If indeed the ice flux scheme better represents the current  
 961 distribution of lightning, both the Romps and Finney results suggest LC increase in LNO<sub>x</sub>  
 962 emission in future climate, and possibly a small global decrease. Murray (2018) points out that the  
 963 ice flux scheme is a closer representation of the underlying charging mechanism, but this scheme  
 964 needs to be tested in multiple global chemistry and climate models.

965

### 966 3.5.4. Recent findings concerning LNO<sub>x</sub> PE

967 Recent satellite-based estimates of LNO<sub>x</sub> production (Figure 23) have suggested a possible flash  
 968 rate dependence of LNO<sub>x</sub> production per flash (Bucsela et al., 2019; Allen et al., 2019; 2021).  
 969 Smaller values of LNO<sub>x</sub> PE in these studies were found to be associated with high flash rates,  
 970 likely due to smaller flashes in these conditions (Bruning and Thomas, 2015). Allen et al. (2021a)  
 971 noted positive correlations (Figure 23) of LNO<sub>x</sub> PE with flash energy and with flash multiplicity  
 972 (number of strokes per flash). Laboratory studies by Wang et al. (1998) found a positive correlation  
 973 between peak current and LNO<sub>x</sub> production. Koshak et al. (2015) found an 8% increase in peak  
 974 current from the 2003-2007 period to the 2008-2012 period that accompanied the 12.8% decrease  
 975 in CG flashes. These findings make it difficult to project future LNO<sub>x</sub> production given only a  
 976 prediction of future lightning flashes.

977

978

979 Figure 23. Scatterplots showing the GLMa-derived relationship between (a) LNO<sub>x</sub> PE (mol per  
 980 flash) and flash density (flashes km<sup>-2</sup>), (b) LNO<sub>x</sub> PE and flash energy (fJ), (c) flash energy and

981 flash multiplicity, and (d) LNO<sub>x</sub> PE and flash multiplicity. Colors are used to separate flight days  
982 while symbols are used to separate system within each flight day. Correlations are shown in the  
983 upper right. LNO<sub>x</sub> PE derived from airborne remote sensor, the Geo-CAPE Airborne Simulator  
984 (GCAS) during the GOES-R Post-launch Test field campaign. GLMa indicates Geostationary  
985 Lightning Mapper data adjusted for missing data. From Allen et al. (2021a).

986

### 987 **3.5.5. Impacts of LNO<sub>x</sub> on upper tropospheric O<sub>3</sub>**

988 The literature concerning the effects of lightning NO<sub>x</sub> production on upper tropospheric ozone  
989 focuses on photochemical ozone production in storm outflow. The STERAO-A storm simulation  
990 by DeCaria et al. (2005) indicated that additional ozone production attributable to lightning NO  
991 within the storm cloud during the lifetime of the storm was very small (~2 ppbv). However,  
992 simulation of the photochemistry over the 24 hours following the storm showed that an additional  
993 10 ppbv of ozone production in the upper troposphere can be attributed to lightning NO production.  
994 Convective transport of HO<sub>x</sub> precursors led to the generation of a HO<sub>x</sub> plume, which substantially  
995 aided the downstream ozone production. Ott et al. (2007) simulated the July 21, 1998 EULINOX  
996 thunderstorm. During the storm, the inclusion of lightning NO<sub>x</sub> in the model combined with  
997 convectively-transported boundary layer NO<sub>x</sub> from the Munich, Germany region resulted in  
998 sufficiently large NO<sub>x</sub> mixing ratios to cause a small titration loss of ozone (on average less than  
999 4 ppbv) at all model levels. Simulations of the chemical environment in the 24 hours following the  
1000 storm show on average a small increase in the net production of ozone at most levels resulting  
1001 from lightning NO<sub>x</sub>, maximizing at approximately 5 ppbv per day at 5.5 km. Between 8 and 10.5  
1002 km, lightning NO<sub>x</sub> caused decreased net ozone production. Ren et al. (2008) found that net  
1003 tropospheric ozone production proceeded at a median rate of ~11 ppbv per day above 9 km in the  
1004 Intercontinental Transport Experiment (INTEX-A) in which the effects of frequent deep  
1005 convection over the United States dominated the upper troposphere. Apel et al. (2012) noted that  
1006 a box model calculation indicated a net ozone increase of ~10 ppbv over a few hours following  
1007 observed convection with lightning over Canada in the Arctic Research of the Composition of the  
1008 Troposphere from Aircraft and Satellite (ARCTAS) experiment. Apel et al. (2015) performed box  
1009 modeling of the chemistry downwind of two DC3 storms in northeast Colorado on June 22, 2012  
1010 finding greater ozone production over 2 days (14 ppbv) in the southern storm with more LNO<sub>x</sub>  
1011 than in the northern storm (11 ppbv). Brune et al. (2018) studied ozone production in the outflow  
1012 of the June 21, 2012 DC3 mesoscale convective system. Their Box model calculations yielded a  
1013 13 ppbv increase in ozone over 5 hours, similar to the observed 14 ppbv increase. This rate of  
1014 increase is larger than others in the literature, perhaps because for a portion of the 5 hours the  
1015 outflow was in cirrus cloud, in which photolysis rates may have been larger than clear-sky values  
1016 due to multiple scattering. Using a regional chemistry model, Pickering et al. (2023) estimated that  
1017 net ozone production in the upper tropospheric outflow of a severe high flash rate storm observed  
1018 over Oklahoma proceeded at a rate of 10-11 ppbv day<sup>-1</sup> during the first 24 hours of downwind  
1019 transport. Downwind photochemical production of ozone due to LNO<sub>x</sub> accounted for much of the  
1020 recovery of upper tropospheric ozone following large reductions due to convective transport of  
1021 lower ozone boundary layer air.

### 1022 **3.5.6. Summary of LNO<sub>x</sub>**

1023 LNO<sub>x</sub> is responsible for the largest fraction of upper tropospheric ozone in the tropics year-round  
1024 and in the mid-latitudes in summer. Effects on longwave radiation due to ozone are most sensitive  
1025 due to the ozone near the tropopause. Therefore, it is of great importance to have knowledge of  
1026 the trends in ozone in this region that are due to changes in frequency and characteristics of

1027 lightning flashes. Considerable uncertainty remains concerning trends in global thunder days. No  
1028 long-term trend in global flash rates has been found. However, regionally important trends have  
1029 been noted in CONUS and in China, which tend to be correlated to the decreasing atmospheric  
1030 aerosol content. An increasing trend at Arctic latitudes has been noted, as that region rapidly  
1031 warms. Future trends in flash rate also are uncertain, with conflicting predictions coming from  
1032 models with differing flash rate parameterizations. Flash characteristics (e.g., flash rate, flash  
1033 extent, flash energy or peak current, intracloud fraction) have been found to have important  
1034 implications for LNO<sub>x</sub> production per flash. Insufficient knowledge of these characteristics on a  
1035 global scale makes it highly uncertain to estimate changes in LNO<sub>x</sub> production, even with  
1036 knowledge of flash rate trends.

1037

### 1038 **3.6. Soil NO and HONO emissions and their impacts on O<sub>3</sub>**

1039 Nitrous acid (HONO) is produced from microbial activity in soils with a similar mechanism and  
1040 strength as NO (Oswald et al., 2013). This emission source may partially account for the current  
1041 mismatch between observed and simulated HONO levels in the lower troposphere (Su et al.,  
1042 2011; Yang et al., 2020). Zhang et al. (2016) estimate a 29 % contribution of soil-HONO to the  
1043 HONO sources in China. This may also contribute substantially to OH production with important  
1044 implications for the HO<sub>x</sub> and O<sub>3</sub> budget. To account for this emission source and assess the  
1045 global potential for atmospheric pollution soil-HONO emissions have been parameterized based  
1046 on the HONO/NO emission ratio measured at multiple field samples (taken from different  
1047 regions of the world) and up-scale it to the 4 major land cover types applied to the whole globe.  
1048 The study estimates a global emission source of 7 TgN/yr from soil-HONO in 2009 (Emmerichs  
1049 et al., 2023). This is at the lower end of the estimated range of 7.4-12 TgN/yr presented by Wu et  
1050 al. (2022) for 2017 who employ an empirical and statistical model in combination with  
1051 observations. Due to the importance of NO and HONO soil emissions for the O<sub>3</sub> budget their  
1052 variability and historical and future trends are described here and linked to O<sub>3</sub>. Additionally, we  
1053 discuss a modification of the soil NO emission scheme.

#### 1054 **3.6.1. Global modeling of reactive nitrogen emissions from soil**

1055 In this section, we present a short overview of the soil-NO emission algorithms and estimates for  
1056 regional and global emissions. The emission of nitrogen oxides (NO) from the soil is the major  
1057 source of NO<sub>x</sub> in unpolluted regions accounting for 15-25 % of global emissions (Weng et al.,  
1058 2020, Vinken et al., 2014). Thereby, NO is produced from the nitrification in soil (microbial  
1059 activity) and depends non-linearly on soil properties like pH, carbon and nutrient content,  
1060 temperature, and soil moisture (Gödde and Conrad 2000, Oswald et al. 2013). Model algorithms  
1061 estimate soil-NO emissions with a function dependent on biological and meteorological drivers.  
1062 The common empirical approach by Yienger and Levy (1995), which is used in the current  
1063 CMIP6 simulations (Szopa et al. 2022), is based on a biome-specific emission factor, soil  
1064 temperature, precipitation, and the canopy uptake reduction factor. The resulting global estimate  
1065 is in the range of 3.3-7.7 TgN/yr which is, however, only at the lower end of the more recent  
1066 model and observation-based estimates. The Yienger and Levy (1995) approach generally  
1067 underestimates soil NO for all landcover types except in the tundra and rainforest due to the  
1068 pulsing parameterization, which describes a large NO<sub>x</sub> release at the wetting of very dry soil and  
1069 the subsequent rapid decay (Steinkamp et al., 2009). This is accounted for in the more  
1070 mechanistic approach by Hudman et al. (2012) representing pulsing of the emissions following  
1071 dry spells and N-inputs from chemical fertilizer and atmospheric N-deposition. This approach  
1072 calculates spatial and temporal patterns of soil moisture, temperature, pulsing, fertilizer, manure

1073 and atmospheric N deposition and biome overall replacing the emission factors by Yienger and  
 1074 Levy (1995) which yields in comparison 34 % more annual global soil emissions of nitrogen  
 1075 oxide (10.7 TgN/yr). Satellite top-down estimates range from 7.9 TgN/yr (Miyazaki et al., 2017:  
 1076 2005-2014, assimilation of satellite data sets) to 16.7 TgN/yr (Vinken et al., 2014; GEOS-Chem  
 1077 and OMI). The emission of soil-NO varies regionally with small sources in Australia (~0.5  
 1078 TgN/yr), Europe, Russia and Southern Hemisphere (SH) Africa (0.7 TgN/yr, 0.8 TgN/yr),  
 1079 America (0.9-1 TgN/yr) and high values in S.E. Asia and Northern Hemisphere (NH) Africa (2-  
 1080 2.1 TgN/yr). The emission estimates (here for  $0.25^\circ$  lat.  $\times$   $0.3125^\circ$  lon.) increase with resolution  
 1081 in some regions like Europe by 38 % (Weng et al., 2020).

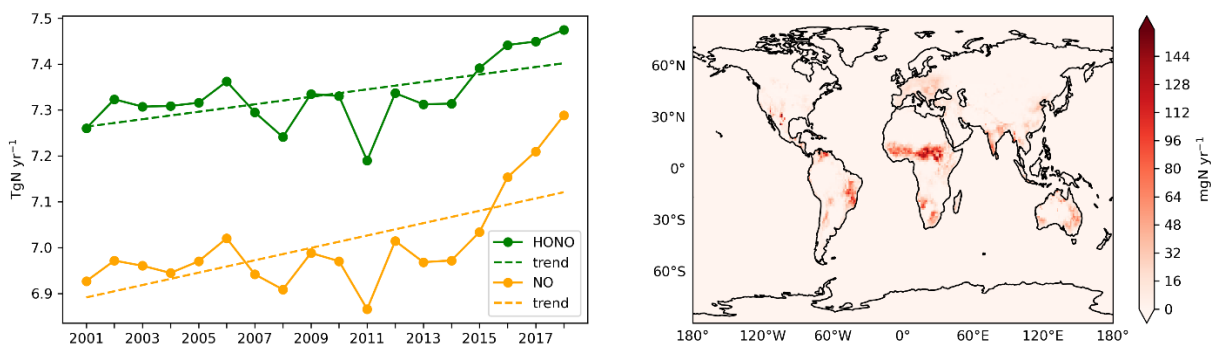

1082 Nitrous acid (HONO), a major OH source, is also produced from microbial activity in soils with  
 1083 a similar mechanism and strength as NO (Oswald et al., 2013). This additional emission source  
 1084 may account for the current mismatch between models and measurements representing HONO  
 1085 levels in the lower troposphere (Su et al., 2011; Yang et al., 2020). Soil emissions of HONO play  
 1086 a major role in the daytime-HONO concentrations in rural areas (in the lowest layers) where  
 1087 traffic emissions and NO<sub>2</sub> heterogeneous reactions occur less than in urban areas (Wu et al.  
 1088 2022). HONO photolysis is a main OH source and impacts the oxidation capacity of the  
 1089 atmosphere (Zhang 2016, 2019). Therefore, this may also contribute significantly to OH  
 1090 production with important implications for the HO<sub>x</sub> and O<sub>3</sub> budget.

### 1091 3.6.2. Variability and trends of soil emissions of NO and HONO in the last 15 years

1092 The magnitude of soil emissions varies strongly with season where the emissions rise from  
 1093 January and July by a factor of 2.5 (Weng et al., 2020). This follows the meteorological  
 1094 variability as for instance, heavy rainfall over dry grasslands/forests causes a pulse of soil NO  
 1095 emissions coupled with the usage of fertilizer (Hudman et al., 2012). According to the CCM1  
 1096 simulations by Jöckel et al. (2016) (following the future ('medium high') climate scenario  
 1097 RCP6.0 the soil NO emissions show a positive trend since pre-industrial times with a steeper  
 1098 increase of up to 0.3 TgN/decade from the year 2000. As soil emissions of HONO rely on the  
 1099 same biogeochemical process with similar dependencies on temperature and water content as NO  
 1100 also increased from 2000 to 2019.

1101 For soil-HONO, however, the trend over 2005-2019 is much smaller, most pronounced in  
 1102 Central Africa (Figure 25). Thereby, the highest positive monthly anomalies occur mainly in the  
 1103 5 most recent years which is likely due to the more frequent heat wave occurrence, e.g. in Europe  
 1104 and North America. Overall, Africa relates the most (~30%) to the global anomaly (Figure 24 -  
 1105 Figure 25).

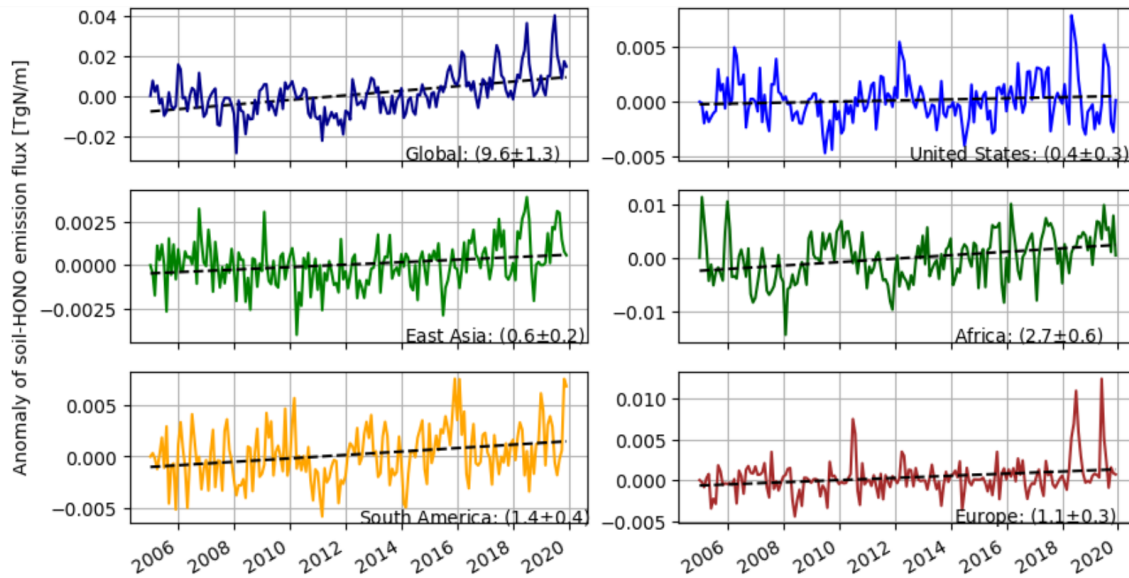

1106

1114  
 1115 Figure 25: Monthly anomalies of HONO emissions from soil (de-seasonalized). The trend is  
 1116 given in  $10^{-5}$ , including the uncertainty estimate ( $2 \times$  standard deviation).

### 1117 3.6.3. Canopy Reduction Factor

1118 Most NO soil emission models (Yienger and Levy, 1995; Hudman et al., 2012) rely on an  
 1119 empirical canopy reduction scheme which represents loss processes in plants as the diffusion of  
 1120  $\text{NO}_2$  through the stomata and direct deposition to the cuticle. In particular, a large fraction of  
 1121  $\text{NO}_x$  (and peroxyacyl nitrate) loss during the night may be only explainable by non-stomatal  
 1122 processes (Delaria et al., 2020b). Mechanistically, the canopy reduction can be described by an  
 1123 efficient  $\text{NO}_x$  deposition to plants. Thus, Delaria et al. (2020a) points out that models already  
 1124 represent the uptake by vegetation and do not need to use a canopy reduction scheme. The  
 1125 potential change of NO soil emissions is shown by employing the global model  
 1126 ECHAM/MESSy ( $1^\circ \times 1^\circ$ ) with an explicit trace gas uptake at stomata and cuticle (Emmerichs et  
 1127 al., 2021) for two different seasons in 2005 and 2006. Removing the canopy reduction factor in  
 1128 the model leads to a HC increase of soil NO emissions highest over tropical forests (Figure 26).  
 1129 The temporal variation follows the vegetational growth as in the Northern Hemisphere summer  
 1130 50% higher emissions occur. These findings are reasonable as Hudman et al. (2012) estimated  
 1131 that the canopy reduction scheme overall lowers the NO emissions by 10-15% in grasslands and  
 1132 up to 85% over forests (GEOS-Chem at  $2^\circ \times 2.5^\circ$  in 2006). Consequently, improper accounting  
 1133 for the canopy reduction factor may imply a strong underestimation of the soil-N in densely  
 1134 forested regions and globally by about 31% (2005-2006).

1135

1136  
1137  
1138

Figure 26: Relative difference Canopy Reduction soil HONO

### 1139 3.6.4. Projections of soil NO and variability in different climates

1140 The future land use is predicted to change as a consequence of the growing demand for  
1141 nutrition and biofuels which implies an increasing use of fertilizer. Consequently, NO soil  
1142 emissions are estimated to rise by ~28% during the century to 11.5 TgN/yr at the end of 2100  
1143 (Fowler et al., 2015). Similarly, Liu et al. (2021) estimate an increasing soil NO emission of 8.9  
1144 TgN/yr by the year 2050 due to intensive nitrification processes.

1145 An increase of LAI by 10 %, in contrast, would lead to 1% lower emissions. In addition, several  
1146 responses are expected from the changing climate. In fact, the 1°C higher temperature would  
1147 cause ~5% increase in emissions (Weng et al., 2020). Following the future ('medium high')  
1148 climate scenario RCP6.0 (Representative Concentration Pathway, 6 W/m<sup>2</sup> radiative forcing) until  
1149 2500, stabilization after 2150) used for the CMIP5 (Climate Model Intercomparison Project)  
1150 simulations. Jöckel et al. (2016) suggest an increase of ~15 % in soil NO emissions due to  
1151 increasing soil temperature (an increase of soil microbes) from present-day (2010) until 2100.  
1152 However, the most significant implications for large-scale denitrification activity are changing  
1153 rainfall and the regional hydrological cycles (Fowler et al., 2015). In general, soil NO<sub>x</sub> will play  
1154 a more important role in the global budget in the troposphere due to the decreasing  
1155 anthropogenic emissions in the future. Therefore, increasing NO<sub>x</sub>-soil emissions may slow down  
1156 the decrease of O<sub>3</sub> in response to declining anthropogenic emissions (Wu et al. 2022).

1157

### 1158 3.6.5. Next steps with biogeochemical models implemented in ESMs

1159 Uncertainties of modeling soil nitrogen emissions are associated with the model input and  
1160 parameters (Wang and Chen 2012). Process-based biogeochemical models which also consider  
1161 the complexity of soil emission processes as DNDC (Denitrification–Decomposition) are needed  
1162 (Li et al., 2011). The capability to represent interactive biogeochemical cycles allows for  
1163 instance for the online calculation of crop nutrition from soil. Also, a model like CLM5  
1164 distinguishes between natural and agricultural soils which more accurately predicts the fertilizer

1165 usage (Fung et al., 2022). Resolving the soil and litter biogeochemical dynamics vertically, in  
1166 addition, lead to a more efficient retainment and recycling of N by the ecosystem (Koven et al.,  
1167 2013). However, these models should be calibrated to multiple sites (Wang et al., 2019) which is  
1168 limited by the availability of measurement data, especially when it comes to global modeling.

1169

#### 1170 4. Conclusion

1171 In this article, we investigate temporal and spatial trends and variability of tropospheric ozone in  
1172 relation to its precursors using satellite products, ozonesonde measurements, and model  
1173 simulations. Our results show that ozone has positive trends at all latitudes and column depths  
1174 regardless of the tropopause height within  $\pm 100$  hPa. The positive trends in the 30-60°N band are  
1175 due to increasing trends over Canada and Alaska and are slightly offset by the small negative  
1176 trends over the northeastern US and Europe. The lower trends in the bands 30-60°N and 30-60°S  
1177 are due to the offsetting impact of negative trends over Eastern US and Europe in the north, and  
1178 Australia and South Africa in the south, respectively. The decreasing trends of TrC-O<sub>3</sub> over parts  
1179 of the northeastern US and Europe are likely due to the decreasing trend of TrC-NO<sub>2</sub>, which is  
1180 due to the effective measures applied over the last two decades to mitigate air pollution in these  
1181 regions. TrC-HCHO trends are decreasing in the Eastern US, some parts of northern and western  
1182 Africa, and western and northern Europe, and increasing in South Asia, central Africa, northern  
1183 Australia, and Brazil. TrC-HCHO trends are consistent with that of TrC-O<sub>3</sub> over northeastern US  
1184 and Europe. Simulated O<sub>3</sub> and its precursors are in good agreement with satellite measurements.  
1185 Considering different latitude bands, the TrC-O<sub>3</sub> highest trends are simulated between 30° S and  
1186 60° N, consistent with calculated trends based on satellite observations. The middle and upper  
1187 troposphere make the largest contributions to the simulated TrC-O<sub>3</sub> trend globally, with large  
1188 contributions from the upper troposphere driving the simulated TrC-O<sub>3</sub> trend at 30°S-30°N and  
1189 counteracting the negative TrC-O<sub>3</sub> trend in the southern midlatitudes.

1190 We have also shed light on NO<sub>x</sub> lightning and its relation to ozone trends. LNO<sub>x</sub> is responsible  
1191 for the largest fraction of upper tropospheric ozone in the tropics year-round and in the mid-  
1192 latitudes in summer. Ozone Radiative forcing is due to the ozone near the tropopause. An  
1193 increasing trend of LNO<sub>x</sub> at Arctic latitudes has been noted, as that region rapidly warms.  
1194 However, future trends in flash rate are uncertain, with conflicting predictions coming from  
1195 models with differing flash rate parameterizations. Soil HONO emissions had their highest  
1196 positive monthly anomalies mainly in the 5 most recent years which is likely due to the more  
1197 frequent heat wave occurrence, e.g. in Europe and North America. Soil HONO trends are highest  
1198 in Africa accounting for ~30% of the global anomaly. Soil NO<sub>x</sub> emissions could play an  
1199 important role in the tropospheric NO<sub>x</sub> global budget due to the decreasing anthropogenic  
1200 emissions in the future. Therefore, the expected increase in NO<sub>x</sub>-soil emissions may slow down  
1201 the decrease of O<sub>3</sub> in response to declining anthropogenic emissions. Overall, this study  
1202 presented a comprehensive overview of tropospheric ozone trends in relation to its precursors in  
1203 different spatial and temporal scales.

1204 Competing interests: At least one of the (co-)authors is a member of the editorial board of  
1205 Atmospheric Chemistry and Physics

1206 Author contribution: YE led the conceptualization, writing, and review of the article, JZ led the  
1207 OMI ozone satellite product and data analysis, SS led the GEOS 5 GMI data analysis, HP led the  
1208 sections on HCHO, NO<sub>2</sub>, HCHO/NO<sub>2</sub> data analysis and contributed to the CO analyses, KM led  
1209 the comparison of different satellite products, KP lead the lightning NO<sub>x</sub> section, HW and RB

1210 contributed to the CO analysis, DT and TE led the section on HONO soil emission, all authors  
1211 contribute to the writing and review of the article.
