Short summary (only for submission/website)

Betula pendula is a widespread birch tree species containing ice nucleation agents that can trigger the freezing of cloud droplets, and thereby alter the evolution of clouds. Our study identifies three distinct ice-nucleating macromolecules (INMs) aggregates of varying size that can nucleate ice at temperatures up to -5.4°C. Our findings suggest that these vegetation-derived particles may influence atmospheric processes, weather, and climate stronger than previously thought.

Key figure
Abstract.

Various aerosols, including mineral dust, soot, and biological particles, can act as ice nuclei, initiating the freezing of supercooled cloud droplets. Cloud droplet freezing significantly impacts cloud properties and, consequently, weather and climate. Some biological ice nuclei exhibit exceptionally high nucleation temperatures close to 0°C. Ice Nucleating Macromolecules (INMs) found on pollen are typically not considered among the most active ice nuclei. Still, they can be highly abundant, especially for species such as *Betula pendula*, a widespread birch tree species in the boreal forest. Recent studies have shown that certain tree-derived INMs exhibit ice nucleation activity above -10°C, suggesting they could play a more significant role in atmospheric processes than previously understood. Our study reveals three distinct INM classes active at -8.7°C, -15.7°C, and -17.4°C are present in *B. pendula*. Freeze-drying and freeze-thaw cycles noticeably alter their ice nucleation capability, and the results of heat treatment, size, and chemical analysis indicate that INM classes correspond to

size-varying aggregates, with larger aggregates nucleating ice at higher temperatures in agreement with previous studies on fungal and bacterial ice nucleators. Our findings suggest that *B. pendula* INMs are potentially important for atmospheric ice nucleation because of their high prevalence and nucleation temperatures.

1 Introduction

35 Heterogeneous ice nucleation is a pivotal process in the Earth's atmosphere as it can influence the properties of clouds. Cloud droplets can be supercooled to −38°C until ice forms homogeneously, but ice-nucleating particles (INPs) can trigger freezing at much higher temperatures. Thereby, INPs influence clouds and their properties, such as lifetime and precipitation. More than half of precipitation initiates via the ice phase of mixed-phase clouds (Lau and Wu, 2003). Therefore, accurate data on INPs, such as composition, concentration, and initial freezing temperatures – many of these factors strongly depend on location

40 and time of year – is crucial to understanding and accurately modeling their influence on Earth's climate. Various aerosol particles can function as INPs, but the specific properties and prerequisites for nucleating ice are poorly understood. This is particularly true for ice-nucleating primary biological aerosol particles (PBAPs), with certain types active in ice nucleation at relatively high sub-zero temperatures (above −10°C).

Birch pollen is one of the most studied PBAPs and can induce heterogeneous ice nucleation around −15°C (Diehl et al., 2001).

45 In 2012, Pummer et al. found that extractable macromolecules outside the sporopollenin shell of birch pollen are the ice nucleation active substance (Pummer et al., 2012). Field and laboratory studies have shown that these ice-nucleating macromolecules (INMs) are highly abundant in alpine vegetation and originate not only from birch pollen but also from different surfaces of birch trees (Felgitsch et al., 2018; Seifried et al., 2020). During and after precipitation, these INMs were mobilized and aerosolized in high concentrations near mountain forests and above the canopy (Bieber et al., 2020; Seifried et

50 al., 2021). These studies suggest a high abundance of birch INMs but compared to other biological INPs, e.g., of bacterial or fungal origin, which can be active up to −2°C (Corotto et al., 1986; Fröhlich-Nowoisky et al., 2015; Pouleur et al., 1992), birch INMs have relatively low nucleation temperatures (−15°C). Birch INMs have been described as polysaccharides with a molecular weight of 100 and 300 kDa, starting heterogeneous ice nucleation at −15°C (Dreischmeier et al., 2017; Pummer et al., 2012, 2015). Later studies showed that they exhibit typical protein properties (Burkart et al., 2021; Felgitsch et al., 2018;

55 Tong et al., 2015), i.e., denaturation by heat and enzymes. It is still up for discussion whether pollen INMs are saccharides (Dreischmeier et al., 2017; Pummer et al., 2012), proteins (Felgitsch et al., 2018; Tong et al., 2015), or a combination of both. Spectroscopic results supported both findings, showing infrared bands representative of polysaccharides and amides and fluorescence signals associated with proteins (Burkart et al., 2021; Felgitsch et al., 2018; Pummer et al., 2013). Dreischmeier et al. (2017) verified the freezing activity of birch INMs at −15°C and their saccharide nature, but the publications' supplement

60 results show ice nucleation activity up to −6°C, which was later attributed to the pollen grains rather than to the INMs (Dreischmeier, 2019). Murray et al. (2022) also reported high freezing temperatures from birch pollen (up to −7.7°C) in large droplet volumes, attributed them to INMs, and hypothesized that freezing temperatures between −6° and −15°C are due to large aggregates of smaller INMs. Dreischmeier et al. (2017) reached a similar conclusion regarding aggregates but in a different context. They suggested that INMs could be aggregates of smaller antifreeze polysaccharides. They based their

65 conclusions on the findings of ice nucleation and antifreeze activity in boreal pollen, and both substances showed similar spectroscopic signals.

In this study, we focus on (i) the different subpopulations of pollen INM and their freezing temperatures, (ii) what influences the ice nucleation activity, and (iii) how aggregation might be responsible for this behavior of birch INMs. We used two complementary ice nucleation assays to investigate the different subpopulations and initial freezing temperature differences.

70 We show how simple and common laboratory sample-handling techniques can strongly influence the ice nucleation activity of pollen INMs. Combined with size measurements, we conclude that aggregation may be a critical property of birch INMs.

Finally, we place our results in the context of previous studies and try to contribute to a deeper understanding of birch INMs and a general knowledge of INMs produced by trees.

2 Materials & Methods

2.1 Sample preparation

Birch pollen from *Betula pendula* (silver birch) was obtained from Pharmallerga (CZ, Czech Republic). According to the distributor, the pollen was harvested by hand in March 2020 in České Budějovice, Czech Republic, hereafter referred to as pollen A, and in March 2019 in Galanta/Trnava/Senec, Slovakia, referred to as pollen B. The individual batches contained pollen from five growing sites (forest, park, land, roadside). All samples shown in the manuscript used Pollen A. Some experiments were replicated also with Pollen B, this data is in the supplement.

Birch pollen washing water (BPWW), containing birch pollen INMs, was prepared with ultra-high quality (UHQ) water. The UHQ water was prepared by autoclaving MilliQ water for 20 min at 120°C, followed by filtration through a 0.1 µm sterile PES (polyether sulfone) vacuum filter (three times). Birch pollen and UHQ water were mixed to obtain a concentration of 50 mg birch pollen per mL of water. The pollen grains were extracted for 6 h, during which the mixture was occasionally shaken. The suspension was centrifuged at 3500 rpm for 5 min at room temperature, and the supernatant was filtered through a 0.2 µm syringe filter (VWR, Radnor, PA, USA) to remove any pollen grains and their fragments from the sample. The obtained BPWW now only contains (macro-)molecular components. The BPWW was stored at −20°C if not used immediately.

2.1.1 Sample treatment

BPWW was freeze-dried, freeze-thawed, and heat-treated. Before freeze-drying, BPWW was stored at -80°C for at least 15 minutes. BPWW was dried to a stable mass using an Alpha 2-4 LDplus (Christ, Germany), the duration of which varied according to the volume. Subsequently, water was added to obtain the same mass as before freeze-drying. Freeze-thaw cycles are subsequent measurements with the ice nucleation assay, where the next measurement was started after all droplets were completely thawed. For heat treatments, aliquots of BPWW (between 750 µL and 1500 µL) were placed in a microtube (1.5 or 2 mL, Eppendorf), sealed with parafilm, and incubated at 40°C, 78°C and 98°C for 1 h or 24 h respectively (Accublock™Mini, Labnet International Inc. USA). After the specified duration, the samples were cooled to room temperature and analyzed on the same day.

2.1.2 Filtration

For INM size characterization, BPWW was filtered through centrifugal molecular weight cut-off (MWCO) filters with nominal cut-offs at 10, 30, 50, 100, and 300 kDa (Vivaspin©15R/20, Sartorius). The filter material was polyether sulfone (PES) or Hydrosat©(HS) in the case of the 10 kDa filter. The BPWW was filtered at 3000 xg (times gravitational force) for 30 min at 4°C. The filters were rinsed with UHQ water four times before sample filtration to avoid contamination. MWCO filters, typically used for protein concentration, have nominal cut-off masses that rely on molecular density and shape assumptions. Therefore, we avoid drawing direct conclusions about the INM mass or size and instead focus on the observed size trend.

2.1.3 Purification

Before chemical analysis, the INMs from BPWW were purified by ice-slide ice affinity purification. Details of the purification method concept have been described elsewhere (Adar et al., 2018; Lukas et al., 2021; Marshall et al., 2016; Schwidetzky et al., 2023). In brief, the sample is continuously pumped to flow down a metal plate cooled by a cryostat to ~-3.5°C. As the sample slowly flows down, an ice layer forms. About 800 mL BPWW was prepared and diluted with about 2075 mL of UHQ water to obtain a sufficient volume. The plate was not pre-cooled to avoid immediate freezing of the first droplets. After 1 h,

110 the ice sheet was collected, frozen at –20°C and freeze-dried. The dry residue was used to prepare ice-affinity purified BPWW by adding UHQ to a final concentration of 7.2 mg residue mL^{-1}. Only one run was performed.

2.2 Measurements

2.2.1 Ice nucleation measurements

Two independent droplet-freezing assays were used to investigate the ice nucleation activity in immersion freezing mode.
115 First, the twin-plate ice nucleation assay (TINA) (Kunert et al., 2018) and second, the Vienna optical droplet crystallization analyzer (VODCA) (Felgitsch et al., 2018; Pummer et al., 2012). Procedures for both setups can be found in the respective publications. The main differences are that the droplets are on a PCR tray in TINA, and in VODCA, the droplets are emulsified in a paraffin-lanolin oil mixture. TINA uses an IR camera, which detects the latent heat to detect freezing, while VODCA uses a light microscope to detect the difference in optical density (frozen droplets appear darker).

120 TINA analyzes 98 droplets of 3 µL each and up to 8 samples simultaneously. In contrast, VODCA measures around 100 droplets ranging from 1.8 pL to 33.5 pL. As pL droplets are six orders of magnitude smaller than µL droplets, the probability of homogeneous and heterogeneous freezing events is much higher in µL droplets. Classical nucleation theory suggests smaller droplets, such as those in VODCA, freeze at lower temperatures. The background freezing temperature in VODCA is around -33°C, whereas with TINA, the background freezing of UHQ water has been measured between -20°C and -30°C, see
125 supplement Figure S1. In addition, larger droplets contain more INMs than small droplets. Therefore, the probability of ice nucleation by high-temperature active INMs (present only at low concentration) is increased in large droplets, as the most efficient INM nucleates the whole droplet. Consequently, VODCA and TINA can be considered complementary techniques: While TINA is better for low INM concentrations, VODCA allows measuring to characteristic freezing temperatures down to -34°C.

130 Both methods give a list of freezing points per droplet. In the first step, the fraction of frozen f_{ice} droplets is calculated. Subsequently, the number of INMs active above a specific temperature $N_m(T)$ can be estimated using Vali's formula (Vali, 1971). Detailed information on the evaluation of data for TINA (Kunert et al., 2018) and VODCA (Seifried et al., 2023) can be found elsewhere. TINA measurement uncertainty was calculated with Gaussian error propagation.

The two most significant differences are the cooling rate and the droplet size and shape. The cooling rates differ, 1 K min^{-1}
135 for TINA and 10 K min^{-1} for VODCA. An intercomparison study of various ice nucleation assays showed good agreement of our pL-assay with other ice nucleation assays (DeMott et al., 2018). But previous studies suggested that the cooling rate could influence the freezing temperature (Vali, 2014; Wright et al., 2013). For example, Vali (2014) suggests a difference of factor ten in cooling rate can approximately shift freezing temperatures by up to ~2°C.

Regarding differences in droplet size and shape, Miller *et al.* (2021) discuss these as potential reason for the high background
140 freezing temperature in µL-assays in detail. Looking at heterogeneous freezing we refer to Kunert *et al.* (2018), where extensive comparisons to other ice nucleation assays are reported showing similar freezing temperatures and ice nuclei concentrations. A recent study by Bieber *et al.* (2024) suggests *B. pendula* INMs trigger freezing within the bulk of the droplet rather than the surface, meaning these potential effects are most likely irrelevant to the investigated sample.

2.2.2 Dynamic light scattering

145

Dynamic light scattering (DLS) was measured to obtain information about the hydrodynamic radius of particles suspended in our sample. Particle sizes are measured with a Nicomp 380 submicron particle sizer (Entegris, USA) with a fixed scattering angle of 90° and a laser wavelength of $\lambda = 632.8$ nm. DLS measurements were performed on undiluted ice-affinity purified BPWW samples before and after heat treatment. More details can be found in Schwidetzky et al. (2020, 2021).

2.2.3 Circular dichroism spectroscopy

Circular dichroism (CD) determines information about chiral molecules in a sample, often used to investigate secondary structures of proteins found in BPWW. CD spectra were recorded using a J-1500 CD-Spectrometer (Jasco, USA). Samples were measured in a 350 µL quartz cuvette (Hellma Analytics, Germany) with a path length of 1 mm. Spectra were recorded at room temperature from 190 nm to 250 nm with a data pitch of 0.2 nm, a scan rate of 5 nm min^{-1}, and a data integration time of 2 s. Samples were diluted about 1:5 (1 part sample to 5 parts overall) with UHQ water. UHQ Water was measured as background. Spectra were background subtracted and processed using JASCO's Spectra Manager Analysis program.

2.2.4 Fluorescence spectroscopy

Fluorescence spectroscopy detects the autofluorescence of BPWW, which can be assigned to various biological molecules, such as various proteins containing aromatic amino acids. Fluorescence excitation-emission maps (FEEM) were recorded using an FSP920 spectrometer (Edinburgh Instruments, UK) with an Xe900 xenon arc lamp (450W) and an S900 single-photon photomultiplier. Samples were measured in a quartz glass cuvette (500 µL, Hellma Quartz (Suprasil©, Germany). Measurement parameters included a dwell time of 0.25 s and monochromator step widths of 5 nm (excitation and emission). First-and second order excitation was prevented using an offset of 10 nm and a 295 nm low-pass filter.

2.2.5 Infrared spectroscopy

Vibrational spectroscopy, including infrared spectroscopy, records inter- and intramolecular vibrations, leading to chemical information such as functional groups. Thus, the sort of biomolecules in our samples, e.g. proteins and saccharides, were assigned. Fourier-transform-infrared (FTIR) spectroscopic measurements were recorded using a Vertex 80v (Bruker, Germany) with a liquid nitrogen-cooled MCT (mercury cadmium telluride) detector. The spectrometer operates at a pressure of 2 mbar. The internal reflection element (IRE) in the attenuated total reflection (ATR) cell (GladiATR™, Pike Technologies, USA) was a diamond crystal. OPUS 6.5 software (Bruker, Germany) was used for evaluation and instrument control. The crystal surface was flushed with dry nitrogen. For each measurement, 128 scans were accumulated at a resolution of 0.5 cm^{-1}. The IRE was coated with a thin layer of soluble sample components for measurement. Approximately 30 µL of the sample were pipetted onto the IRE and dried with a steady stream of dry nitrogen. Post-processing of the spectra included normalization and removal of the IRE signal between 1900 cm^{-1} and 2350 cm^{-1}.

3 Results & discussion

3.1 Investigating *Betula pendula* INMs using two complementary ice nucleation assays.

Figure 1a shows the ice nucleation activity of BPWW after freeze-drying, measured with two complementary ice nucleation assays: (i) TINA, which measures 3 µL droplets (Kunert et al., 2018), hereafter referred to as µL-assay, and (ii) VODCA, which measures pL droplets, with an average volume of 8.2 pL (Pummer et al., 2012), hereafter referred to as pL-assay. The results in Figure 1a show the number of nucleation sites (N_m) per gram of pollen in BPWW. Three distinct INMs evolve in the N_m spectra, which can be recognized via the various rises and plateaus. Starting from the right, a sharp increase between -5.7°C and ~ -7°C highlights the first INM. After a plateau from ~ -7°C to ~ -14°C, the second INM appears between ~ -14°C and ~ -16°C. The third INM follows immediately, triggering freezing between ~ -16°C and ~ -19°C, followed by a plateau until ~ -34°C. Hence, we can derive three distinct INM subpopulations with different efficiencies, which, from now on, we term as INM *Classes A, B*, and *C*, in the order of decreasing freezing temperatures. The measurements of the two assays overlap between ~ -15°C and ~ -19°C, but the pL-assay results show only Class *B* and *C*, with *Class B* only being minimally visible. *Class B* is hard to distinguish from *Class C* INMs, as their activity overlaps. However, the distinct rise at ~-15°C (*Class*

B), prior to the rise at ~-19°C (*Class C*) in the cumulative spectrum is very reproducible in all our measurements, suggesting that *Class B* is not an artifact but indeed a separate Class of INM.

190 We used the heterogeneous underlying-based (HUB) stochastic optimization analysis (de Almeida Ribeiro et al., 2023) on the µL-assay data to better identify and characterize the underlying number of the INM subpopulations (classes). Figure 1b shows the differential spectrum predicted by HUB from the optimized distribution of nucleation temperatures. The three INM classes in the differential spectrum are centered at the average freezing temperatures of -8.7 °C for *Class A*, -15.7°C for *Class B*, and -17.4°C for *Class C*. In the differential spectrum of the freeze-dried BPWW, *Class C* INMs represent more than 99.9%

195 of the active nucleation sites in pollen. Freeze-drying of our sample increased the activity of *Class A*, an effect we show and discuss in section 3.2.

From six independent BPWW samples, three each from pollen A and pollen B (see section 2.1), we derive the concentration of the INM classes in untreated BPWW (see Figure S2). *Class A* occurs with a concentration of $N_m < 10^3$ g^{-1} (only detectable with the µL-assay), *Class B* with a concentration of $N_m \sim 10^2$ to $\sim 10^7$ g^{-1}, and *Class C* with a concentration of $N_m \sim 10^5$ to $\sim$

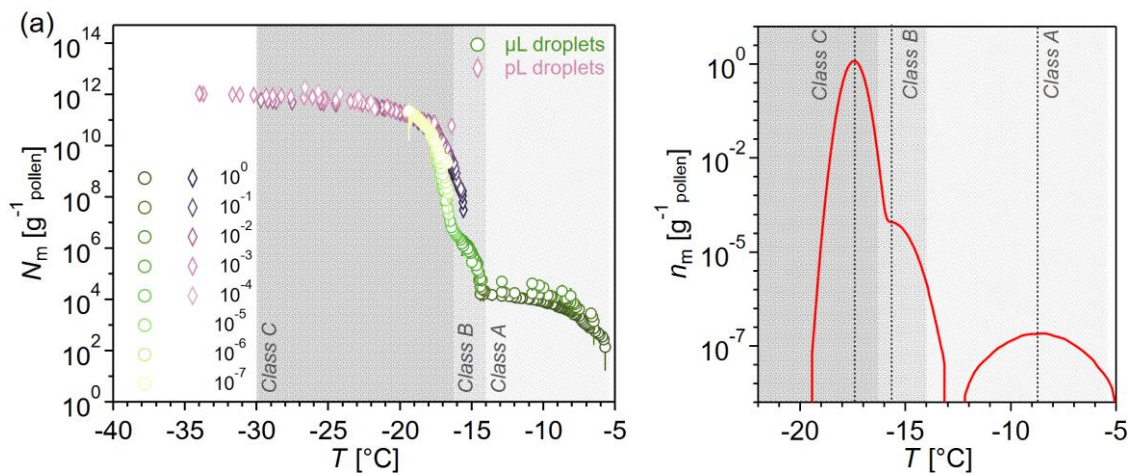
200 10^{11} g^{-1}. This underscores that the overwhelming majority are *Class C* INMs. Several factors, such as the extraction process and the natural variability of biological samples, can cause these variations.


Figure 1. Freezing spectrum of birch pollen washing water (BPWW) with 50 mg pollen mL⁻¹ measured with two complementary ice nucleation assays. (a) Cumulative number $N_m(T)$ of INMs per gram *Betula pendula* pollen (Pollen A, after freeze-drying). Green circles

205 show the measurement with the µL-droplet-assay. Pink diamonds represent the measurement with the pL-droplet-assay. The legend on the left shows the dilutions of the sample, e.g., 10^{-1}, which corresponds to a 1:10 dilution. The graph shows three distinct average freezing temperatures at -8.7°C, -15.7°C, and -17.4°C marked by the steep increase of the N_m spectra. The first hump (-5.4°C to -14°C) is only measurable with the µL-droplet assay. The measurements overlap between -15°C and -20°C. **(b)** Number of INMs $n_m(T)$ analyzed with the heterogeneous underlying-based (HUB) stochastic optimization analysis of de Almeida Riberio et al. (2023) to better identify and

210 characterize the underlying number of INM subpopulations in pollen, performed on the µL-assay data from (a).

The combination of two ice nucleation assays is beneficial for two reasons: (1) low-concentrated ice nuclei can be detected, and (2) measurement down to about -34°C. Due to the low concentration, *Class A* INMs are only detectable with the µL-droplet assay, while the pL-assay allows us to conclude that no further classes of nucleators are present in the sample.

The ice nucleation activity is in agreement with previous studies. From the first study on the ice nucleation activity of *B.*

215 *pendula* (Diehl et al., 2001) to the discovery of the INMs (Pummer et al., 2012), the freezing temperature was reported between -15°C and -18°C, which was also supported by other studies (Augustin et al., 2013; Burkart et al., 2021), some even find the two distinct species at -15°C and -18°C (Dreischmeier et al., 2017; O'Sullivan et al., 2015), which we now refer to as *Class B* and *C*.

Ice nucleation activity at higher temperature has already been measured by Dreischmeier et al. (2017), who showed these

220 highly efficient INMs in the supplement to their manuscript; however, they did not discuss them, and only later in Dreischmeier's Ph.D. thesis they were assigned to whole pollen grains rather than being INMs (Dreischmeier, 2019). More recently, *Class A* was mentioned in the context of cryopreservation in 100 µL volumes (Murray et al., 2022). The data presented here, for the first time, clearly shows the complete N_m spectrum of *B. pendula* with three distinct INM classes with average

freezing temperatures at -8.7°C, -15.4°C, and -17.4°C. In addition, the fitting results (Figure 1b) are in agreement with the assignment of the pollen INMs with the experimental data from Dreischmeier et al. (2017) and performed by de Almeida Ribeiro et al. (2023).

B. pendula INMs are often overlooked in terms of atmospheric relevance due to their low nucleation temperatures between -15°C and -18°C. Inorganic ice nuclei, e.g., mineral dust, are much more prevalent in this temperature range due to their high mass concentrations above the land surface. Naturally occurring ice nuclei with nucleation temperatures >-10°C are rare and dominated mainly by fungal and bacterial ice nuclei, which appear in low natural concentrations. We show that *B. pendula* pollen can contain highly efficient ice nuclei (*Class A* INMs) but at very low concentrations compared to the more common *Class B* and *C* INMs. However, studies have shown that INMs found on *B. pendula* pollen are across the whole tree (Felgitsch et al., 2018; Seifried et al., 2020). Considering the wide distribution of *B. pendula* in the boreal forest, we speculate that *B. pendula* INMs might influence the total population of ice nuclei above -10°C near boreal forests. Understanding the emission, transmission, and nucleation mechanisms of ice nuclei active in this high-temperature regime is crucial because of their substantial influence on cloud micro-processes and subsequent impacts on weather and climate.

3.2 Effects of freeze drying, freeze-thaw cycles, and heat on ice nucleation activity

Upon establishing the presence of three distinct INM classes in *B. pendula* pollen, we explored their stability and response to various conditions: (a) freeze-drying with subsequent hydration of the residue, (b) repeated freeze-thaw cycles, and (c) heat treatments. All experiments in this section were conducted with the sample from Figure 1a. Replicates with other pollen can be found in the supplement if indicated.

While Figure 1a shows a freeze-dried sample to better identify the three INM classes, Figure 2 compares the freeze-dried sample to the untreated sample to illustrate how freeze-drying elevated *Class A* INMs. Freeze-drying and subsequently hydrating the residue - while retaining the initial concentration of the INM sample - increases the concentration of *Class A* INM, where N_m increased by factors between 10 and 400 within five replicates of this experiment (see Figure S3). In contrast, *Class B* and *C* concentrations remained constant or decreased slightly by a factor of up to five.

To the best of our knowledge, the impact of freeze-drying on the ice nucleation activity has not been deliberately studied for biological ice nuclei. However, previous studies have regularly freeze-dried samples before ice nucleation measurements (Forbes et al., 2022; Lukas et al., 2021; O'Sullivan et al., 2015; Rangel-Alvarado et al., 2015; Schwidetzky et al., 2023; Zhang et al., 2016). In particular, the widely studied Snomax® consists of freeze-dried fragments of *Pseudomonas syringae*.
Figure 2. Freeze-drying increases the ice nucleation activity of birch pollen washing water (BPWW). Cumulative number $N_m(T)$ of INMs per gram of *Betula pendula* pollen after freeze-drying BPWW, dissolving in ultra-high quality (UHQ) water, and retaining the initial BPWW concentration (Pollen A). The freeze-dried sample (solid circles) increased in ice nucleation activity compared to the untreated sample (hollow circles). Ice nucleation activity consistently increased in the four independent experiments (see supplement), but the increase varied. The legend on the left shows the dilutions of the sample, e.g., 10^{-1} corresponds to a 1:10 dilution.

Figure 3 shows that the N_m spectrum remained stable throughout fourteen freeze-thaw cycles. Interestingly, at temperatures below -15°C, there is a shift to higher concentrations of *Class B* INMs and an inverse effect on *Class C* INMs, both by a factor of ~5.

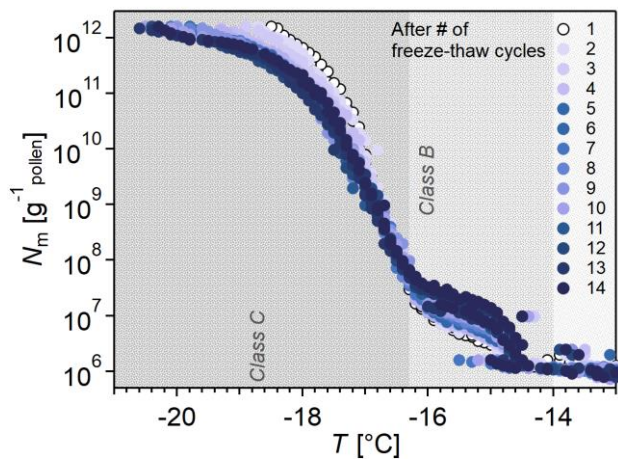
Experiments of this type have been performed with different biological INMs, resulting in significant shifts in the freezing efficiency of bacterial ice nuclei (Polen et al., 2016) and much smaller effects on fungal and lichen INMs (Eufemio et al., 2023; Schwidetzky et al., 2023). While the ice nucleation active component of bacteria and fungi are proteins (Green and Warren, 1985; Schwidetzky et al., 2023), it is unknown for lichens and *B. pendula*. The contrasting responses of biological ice nucleators to freeze-thaw cycles highlight the complexity of their ice nucleation mechanisms and underline the importance of further studies.


Figure 3. Freeze-thaw cycles alter the ice nucleation activity of birch pollen washing water (BPWW) in lower-temperature regions.
Cumulative number $N_m(T)$ of INMs per gram pollen after fourteen freeze-thaw cycles (Pollen A, after ice affinity purification, e.g. sample was also freeze-dried). The color gradient indicates the number of freeze-thaw cycles, with the colors increasing in darkness with each cycle, as indicated in the legend on the right. The figure shows the temperature range where the repeated freeze-thaw cycles have affected the ice nucleation activity. Each cycle increases ice nucleation activity at -15°C and decreases at -18°C.

Figure 4 shows the N_m spectra of heat-treated samples. Heat treatment at 40°C for one hour had a minor effect on *Class A* INMs, decreasing the concentration by about ten, while *Classes B* and *C* were unaffected. A one-hour heat treatment at 78°C deactivates *Class A*, while *B* and *C* are slightly reduced. This effect is more pronounced when the temperature is increased to 98°C and even more pronounced when the heat treatment duration is increased from one to 24 hours. Heat treatment at 98°C also increases ice nucleation activity to a slightly lower temperature.

Although heat treatments at high temperatures are not relevant for ambient atmospheric processes, they provide valuable insight. Firstly, these treatments reveal a diverging response of the INM classes to heat, which raises further questions about possibly varying chemistry. Secondly, they are often used on field samples to determine whether the ice nuclei are of biological origin, as many biological molecules, particularly proteins, are heat-sensitive and can denature at high temperatures, losing their activity. Our data suggests a simple heat treatment is insufficient to classify whether ice nuclei are of biological origin.

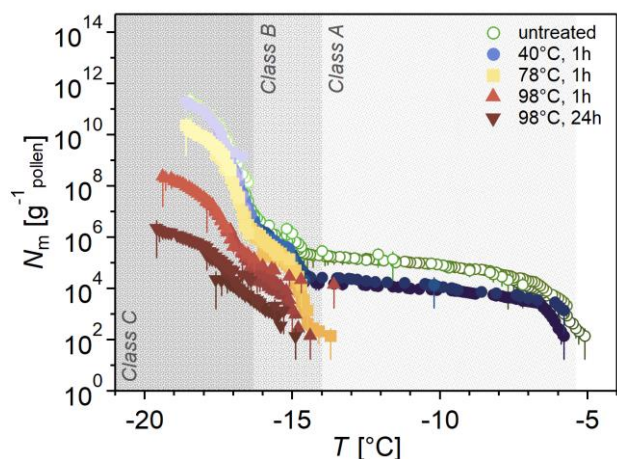
Previous studies on the thermal stability of birch INMs showed mixed results. Pummer et al. (2012) reported no change in ice nucleation activity after dry heating up to 111°C for 1 h, but a complete loss of activity after heating to 202°C for 1 h (Pummer et al., 2012), but in their work the sample was dried before the heat treatment. Daily et al. (2022) also reported a loss of activity after dry heating to 250°C for 4 h and no loss after a wet heat treatment at 100°C for 30 min. Dreischmeier et al. (2017) also used a wet heat treatment (as in our study) and showed a concentration-dependent effect. Heat treatment of 90°C for 3 h resulted in a complete loss of activity in a less concentrated sample but had no impact on a thousandfold more concentrated sample (Dreischmeier, 2019). This is consistent with our results from a dilution series, for which higher treatment temperature and duration, fewer dilutions had to be measured until the sample froze homogeneously. Dreischmeier (2019) and Pummer *et al.* (2012) used pL-assays, which did not allow them to measure *Class A* INMs. The measurement of a dilution series allowed us to obtain a more comprehensive understanding of the thermal degradation process.


Figure 4. Heat treatment diminishes ice nucleation activity in birch pollen washing water (BPWW), especially at T > -15°C. Cumulative number $N_m(T)$ of INMs per gram *Betula pendula* pollen (Pollen A, after freeze-drying). INMs were ice-affinity purified and then heated (40°C – blue circles, 78°C – yellow squares, 98°C – red triangles) for 1 h (also 24 h for 98°C, downward triangles), the color gradients indicate dilutions. Heat effects depend on treatment temperature, duration, and freezing temperature. Ice nucleation activity > -15°C is reduced by a temperature of 40°C, while ice nucleation activity < -15°C is only altered at temperatures of 98°C.

To summarize, this section investigated how ice nucleation activity of birch INMs can be influenced: (i) freeze-drying increases *Class A* INM concentration, (ii) freeze-thaw cycles increase *Class B* and decrease *Class C* INM concentration, and (iii) heat treatments decrease INM concentration overall.

The data shows how subtle changes in sample treatment can significantly alter the ice nucleation activity of birch INMs. While heat treatment is intended to change the activity of a sample, repeated freezing or freeze-drying are usually (un)intended steps for or during sample preparation that can significantly impact the results. We suggest that in further studies, the steps of sample preparation, both in the lab and field studies, are documented in detail. Understanding how ice nucleation activity is affected can provide important insight into the stability and mechanisms of ice nuclei.

As introduced above, Murray et al. (2022) proposed that highly efficient birch INMs are likely to be large aggregates of smaller subunits. Aggregation could be the process interconnecting the three INM classes reported in our study, if they are aggregates of varying sizes. The following section explores this hypothesis by examining size-selective filtrations and DLS measurements focusing on the size of the INM.

3.3 Investigations on INM Size

INM sizes were assessed by (a) using size-selective filters and subsequently measuring ice nucleation activity and (b) measuring particle sizes by dynamic light scattering (DLS) of the heat-treated samples, which differed in INM concentration and freezing temperatures.

Figure 5 shows the N_m spectra of the filtrates from one filtration series out of four independent series (for simplicity). The full dataset is shown in Figure S5. Generally, all samples showed low concentrations of *Class A* INMs, but we can still see that the 300 kDa filter does not affect the sample, whereas the 100 kDa removes all of *Class A* INMs and decreases the concentration of *Class B* and *C* INMs. The < 50 and < 30 kDa fractions almost show no *Class B* INMs. Individual droplets in the < 50 kDa fractions froze above -15°C due to this experiment's uncertainty. The <10 kDa fraction shows almost exclusively *Class C* INMs, with single freezing events at higher temperatures. Hence, we confidently conclude that the ice nucleation activity in terms of N_m and freezing temperature decreased with decreasing pore sizes. This suggests the three INM classes are different in size, with *Class A* being the largest and *Class C* being the smallest.

Previous studies by Pummer et al. (2012) and Dreischmeier et al. (2017) employed MWCO filtrations and concluded that the INMs must be > 100 kDa, which is directly contradicted by our results. The discrepancy is due to the different droplet volumes since both studies used pL-assays, which have a lower sensitivity than the μL-assay used in this study. The data shows birch INMs are smaller than previously assumed.
Figure 5. Investigation of INM sizes by size-selective filtrates of birch pollen washing water (BPWW). (a) Cumulative number $N_m(T)$ of INMs per gram of *Betula pendula* pollen of the unfiltered sample (Pollen A, untreated). BPWW was size-selectively filtered with nominal filter sizes of 300, 100, 50, 30, and 10 kDa. The ice nucleation activity decreases with smaller filter sizes in concentration and initial freezing temperature. The colors increase in brightness with smaller cutoff sizes. Four independent experiments were performed (see supplement). Unfiltered sample refers to BPWW, which, during preparation, is filtered with a 220 nm filter.

Figure 6 shows the hydrodynamic radius (R_h) of ice-affinity purified (i.e. also freeze-dried) BPWW before and after heat treatment as measured by DLS. The radii range from ~240 nm (non-heat-treated) to ~280 nm (40°C) down to ~115 nm (98°C, 1 h).

Correlating the radii to the freezing onset temperature (as measured with the µL-assay shown in Figure 4) shows the non-heat-treated and 40°C treated samples have larger radii and higher freezing onset temperatures of around ~-6°C. In contrast, the 78°C and 98°C treated samples have smaller radii and lower freezing onset temperatures of around ~-15°C. The freezing spectra in Figure 4 show the non-heat-treated and 40°C treated samples contain *Class A* INMs, while the 78°C and 98°C only contain small concentrations of *Class B* and mostly *Class C* INMs. The data evidently shows that the higher the heat treatment temperature, the smaller the radii, directly correlating to lower freezing onset temperatures and INM classes.

One might note that DLS gives only a single particle size, while it is highly likely that there are different particle sizes within the sample. The largest particles are preferentially observed, as the intensity of light scattering is disproportionately affected by larger particles. Hence, the untreated sample has a similar radius to the sample treated at 40°C but with a much larger uncertainty (calculated from 4 independent samples). The larger uncertainty is explained by the measurement principle of DLS, where the scattering signal is proportional to the sixth power of particle diameter d^6. Hence, the measurement uncertainty drastically increases in polydisperse systems containing a multitude of larger particles.
Figure 6. INM sizes determined by dynamic light scattering (DLS) of heat treated BPWW compared to freezing onset temperature T_{on}. The hydrodynamic radius R_h (nm) of particles in ice-affinity purified BPWW (Pollen A, after freeze-drying), measured by DLS, shows

a decline in the size of the largest particles with increasing heat treatment temperature. Along with it the freezing onset temperature of the undiluted sample decreased (freezing onset temperatures were determined from Figure 4). Error bars were calculated using error propagation combining the measurement errors from multiple measurements. Untreated BPWW was plotted as heat treated at 20°C for practical purposes. Replication of the 40°C heat treatment was not possible, and only one measurement has been acquired for which a 10% error was assumed.

355

Figures 5 and 6 show that the larger INMs in our sample have higher freezing temperatures. In Figure 5, filtering off larger particles results in lower nucleation temperatures. Whereas in Figure 6 larger particles directly correlate with higher freezing onset temperatures, derived from the loss of activity by heat treatment. While both measurements do not necessarily represent INM sizes, both experiments show the same trend: larger sizes correlate with higher freezing onset temperatures.

360 This supports the proposed idea that aggregation of INMs leads to higher nucleation temperatures (Murray et al., 2022) and correlates it with INM classes. Former studies have investigated bacterial (Qiu et al., 2019) and fungal (Schwidetzky et al., 2023) ice nuclei, showing that aggregation of ice nuclei leads to higher ice nucleation temperatures. In our experiments, *Class C* exhibits the smallest size, *Class B* is larger, and *Class A* is the largest-sized INM subpopulation. In principle, aggregation ability should connect with the chemical nature of the ice nucleators. To investigate the molecular signature of the INMs, CD,

365 fluorescence, and IR spectroscopy were utilized.

3.4 Chemical analysis of birch INMs

Initially, we employed fluorescence and infrared spectroscopy to analyze ice affinity purified BPWW, methods previously used by Pummer et al. (2013), Dreischmeier et al. (2017), and Burkart et al. (2021). First, fluorescence spectroscopy showed signals typical for aromatic amino acids, proving the presence of proteins (see Figure S6). Second, infrared spectroscopy

370 showed typical protein bands (amide I, II, III bands) and typical polysaccharide bands (sugar skeletal vibration and COC glycosidic vibration); the entire spectrum can be seen in the supplement Figure S7. These findings are consistent with existing literature and show proteinaceous and polysaccharidic signals.

Figure 7 shows the CD spectra of ice-affinity purified BPWW before and after heat treatment. The maximum is at ~185 nm, the minimum is at about 210 nm, and the signal increases until 250 nm. The signal of the heat-treated sample differs between

375 185 and 210 nm, suggesting a structural change from the proteins within the sample. With the CD spectrum of BPWW, the BeStSel tool is used to estimate the ratios of secondary structures to each other based on the CD spectra. The database comparison shows BPWW has about 30% beta-sheets and 5% alpha-helix structures. This is noteworthy since many of the highest active (in terms of freezing temperature) biological ice-nucleating proteins have considerable beta-sheet structures (Garnham et al., 2011; Kajava and Lindow, 1993; Lukas et al., 2021). However, other proteins are present in our sample, such

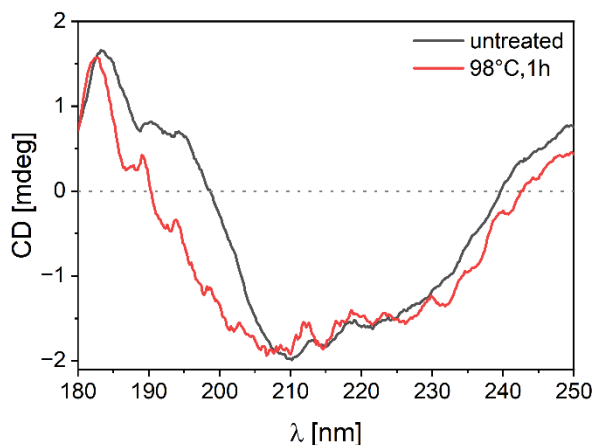
380 as the *Bet v* allergens, which show varying amounts of beta-sheet structures (Gajhede et al., 1996; Kofler et al., 2012; Neudecker et al., 2004; Soh et al., 2017).


Figure 7. Circular dichroism spectrum of birch pollen washing water (BPWW), untreated and heat treated. The spectrum shows the signal of ice-affinity purified BPWW (Pollen A) non-heat-treated (black) and heat-treated (red), with a minimum molar ellipticity at ~ 205 nm and a local maximum at ~ 195 nm. The heat-treated signal differs mainly in the 185 to 210 nm region, indicating a structural change.

Birch INMs were initially suggested to be composed of polysaccharides based on their high-temperature stability and various chemical and enzymatic experiments (Dreischmeier et al., 2017; Pummer et al., 2012, 2015). In contrast, studies focusing on specifically denaturing proteins and fluorescence spectroscopy suggest that proteins are at least involved in the ice nucleation activity of birch INMs (Burkart et al., 2021; Felgitsch, 2019; Tong et al., 2015). Burkart et al. (2021) also speculate that highly glycosylated proteins might be the ice nucleation active component. While our findings add weight to the theory of proteinaceous involvement in birch INMs, they also highlight the inherent complexity in deciphering the exact composition of birch INMs. This uncertainty presents a challenge for future research.

4. Conclusions

Our study re-examines the INMs of *Betula pendula* pollen, shedding new light on their complex ice nucleation capabilities. We identified three classes of INMs with average freezing temperatures of -8.7°C (*Class A*), -15.4°C (*Class B*), and -17.4°C (*Class C*). The concentrations from *Class A* to *C* increase by multiple orders of magnitude. Combining two ice nucleation assays with different droplet sizes (3 µL – TINA and pL-droplets – VODCA) allowed us to measure with high sensitivity and at temperatures down to -34°C.

We evaluated physical influences on the ice nucleation activity of our samples. First, our results show that freeze-drying increases the concentration of *Class A* INMs, allowing us to better identify this class, while the concentration of *Classes B* and *C* remains the same or decreases slightly. Second, repeated freeze-thaw cycles led to an increase in *Class B* and a decrease in *Class C* concentrations, both by a factor of five, while *Class A* was unaffected. Third, heat reduces the concentration of all INMs. *Class A* INMs were completely inactivated after 1 h at 78°C. *Class B* and *C* INMs decreased after 1h at 98°C, and after 24 h at 98°C, only *Class C* INMs remained. This demonstrates how subtle (unintended) differences in sample treatment can significantly alter the ice nucleation activity of birch INMs.

At last, we focused on investigating the size and chemistry. Size-selective filtrations showed that the smaller the INMs, the lower the freezing temperature. DLS measurements of non-heat-treated and heat-treated INMs show a decrease in size with increasing heat treatment temperature, which correlates with a lower freezing onset temperature of the sample. Chemical analysis, including CD-, fluorescence- and infrared spectroscopy, show proteinaceous and polysaccharidic signals.

Most previous studies on birch INMs have only reported activity at -15°C and -18°C (Augustin et al., 2013; Diehl et al., 2001; Dreischmeier et al., 2017; O'Sullivan et al., 2015; Pummer et al., 2012), with one study reporting up to -6°C (Murray et al., 2022). Our results confirm that INMs from *B. pendula* can induce heterogeneous freezing at temperatures at high subzero temperatures (up to -5.4°C) and allow us to estimate the concentration of these highly efficient INMs. Furthermore, it allows field measurements to search for birch INMs in the atmosphere actively. Tree-based INMs are often overlooked as a source of atmospherically relevant ice nuclei of biological origin. However, studies on *B. pendula* and *Pinus sylvestris*, another tree species with pollen that contains INMs, have shown an abundance of INMs on trees' surfaces (Felgitsch et al., 2018; Seifried et al., 2020, 2023). These tree species are widespread in the boreal forest, making them an important reservoir of INMs, and could potentially be large emitters of INMs.

Based on our results, we hypothesize that the three found INM classes are aggregates of varying size, where the larger INMs have higher nucleation temperatures but, in turn, also occur in much smaller numbers. In terms of size, we show *Class A* is bigger than *Class B*, which is bigger than *Class C*. We suggest *Class C* INMs are the smallest aggregates or single units. A certain stable aggregate size of the subunits forms the *Class B* INMs, and *Class A* INMs are even larger. *Class A* INMs require specific prerequisites to form, and our results suggest that freeze-drying can induce this process. At the same time, repeated

freeze-thaw cycles seem to induce only minor aggregation of *Class B*. Heat leads to disassembly of the aggregates, and our results suggest that the larger the aggregates, the lower the temperature required for disassembly.

The current idea is that aggregation is essential for ice-nucleating molecules (especially of biological origin) and has been discussed in the context of ice-binding proteins (IBPs) from bacteria and insects (Burke and Lindow, 1990; Govindarajan and Lindow, 1988; Gurian-Sherman and Lindow, 1995; Kozloff et al., 1991). These proteins encompass antifreeze proteins (AFPs) and ice-nucleating proteins, each playing distinct roles in ice formation (Bar Dolev et al., 2016; DeVries and Wohlschlag, 1969). IBPs are characterized by motifs such as anchored clathrates and ice-like structures, typically found in β-sheet formations (Graether and Jia, 2001; Hakim et al., 2013; Leinala et al., 2002; Liou et al., 2000). These motifs confer a high affinity for ice. AFPs utilize these motifs to inhibit ice growth by binding to ice crystals (Raymond and DeVries, 1977). In contrast, INPs, primarily studied in bacterial contexts, form larger aggregates (Burke and Lindow, 1990; Ling et al., 2018). These aggregates enhance the proteins' ice-nucleating capabilities, with larger aggregates correlating with higher nucleation temperatures (Qiu et al., 2019). The aggregation in bacterial ice nuclei is facilitated by specific protein sequences that enable aggregation (Burke and Lindow, 1990; Govindarajan and Lindow, 1988; Gurian-Sherman and Lindow, 1995; Lukas et al., 2022). A similar idea is proposed for fungal ice nuclei, which are also proteinaceous (Schwidetzky et al., 2023). For birch INMs, aggregation has initially been suggested by Dreischmeier et al. (2017) and Murray et al. (2022). Our results also provide evidence that aggregation can cause higher nucleation temperatures, which correlates with the three separate INM classes we present. All previous studies linking aggregation and nucleation temperature are based on proteinaceous ice nucleators. However, the exact molecular composition of birch INMs remains elusive. Therefore, findings from bacterial or fungal ice nuclei cannot be directly transferred to pollen ice nuclei.

Nonetheless, our results indicate that aggregation leads to higher ice nucleation temperatures and is the link between the three INM classes, which opens further questions: a) about the reason for the discrete sizes of the aggregates, b) the chemical composition of their subunits, and c) how and why aggregates foster ice nucleation.

In all our results, we find three discrete INM classes that differ in size, the reason for which is not entirely clear. Still, the discreteness, rather than a continuous increase in size or nucleation temperature, is an intriguing effect that needs further investigation. A simple increase in INM surface leading to an increased number of nucleation sites on that aggregate could also explain the higher nucleation temperatures but not the observed discreteness unless the aggregates only form in discrete sizes. Another possible explanation could be a different nucleation mechanism enabled by an aggregate reaching a certain size. Up to our understanding, there are four central physical and chemical reasons for enhanced ice nucleation activity related to aggregates:

i) Water activity is a thermodynamic predictor of kinetic ice nucleation. It reveals a direct relationship to the water structure at the INM surface, allowing interpretation of the interaction between INM and critical ice nuclei. (Knopf and Alpert, 2023)

ii) Water in nano-sized confined geometries at the surface of INM aggregates can serve as the origin of ice formation, leading to stacking disordered ice (Knopf and Alpert, 2023; Nandy et al., 2023)

iii) Amino acid *TxT* motifs, where *T* is threonine, and *x* is a non-conserved amino acid, can order water molecules into a stacking disordered ice structure attributed to chemical functional groups capable of hydrogen bonding to water molecules composed of hydrophilic-hydrophobic patterns. (Alsante et al., 2024; Qiu et al., 2019)

iv) The ice nucleation process releases latent heat, which is the kinetic energy of the water molecules of the liquid transformed into infrared radiation. Aggregates exhibit an enhanced number of degrees of freedom, allowing a more efficient uptake of kinetic energy and a broader emission of IR radiation.

Elucidating the chemistry and physics of the INM will help further understand how they nucleate ice (Felgitsch et al., 2018; Seifried et al., 2020, 2023). In summary, our research contributes significant new insights into the nature and behavior of *B. pendula* INMs and underscores their potential as critical players in atmospheric ice nucleation processes. This understanding

is crucial for refining weather and climate models, where the role of biological ice nucleators has been historically underappreciated.

Data availability

All data are available from the corresponding author upon request.

Author contributions

HG, JFN, KM and TMS conceptualized the project. HG, JFN and KM supervised FR. FR performed the experiments with the support of NB and RS. All authors discussed the results. FR prepared the manuscript with input and revisions from all co-authors.

Competing interest

The authors declare no conflict of interest.

Acknowledgements

The authors would like to thank Ellen H.G. Backus, Clara M. Saak and Friederike Strahl from the Department of Physical Chemistry of the University of Vienna for valuable discussions and input. The authors also thank Rosemary Eufemio from Boise State University for her support with the HUB-backward fitting of the ice nucleation data.

Financial support

The authors acknowledge TU Wien Bibliothek for financial support through its Open Access Funding Programme. We gratefully acknowledge support by the FFG (Austrian Research Promotion Agency) for funding as part of project no. 888109 (Lab on a Drone). K.M. acknowledges the support by the NSF under Grant No. (NSF 2308172, 2116528).
