Abstract.

Coarse mineral dust particles have been observed much further from the Sahara than expected based on theory. They have different impacts to finer particles on the Earth's radiative budget, and carbon and hydrological cycles, though tend to be under-represented in climate models. We use measurements of the full dust size distribution from aircraft campaigns over the Sahara, 5
Canaries, Cape Verde and Caribbean. We assess the observed and modelled dust size distribution over long-range transport at high vertical resolution using the Met Office Unified Model, which represents dust up to 63.2 μm diameter, greater than most climate models. In the observations, we find that the mass contribution of coarse particles ($d > 6.32 \mu\text{m}$) to total mass is independent of 0.55 μm aerosol optical depth. We show that the model generally replicates the vertical distribution of the total dust mass but transports larger dust particles too low in the atmosphere. Importantly, coarse particles in the model are deposited 10
too quickly, resulting in an underestimation of dust mass that is exacerbated with westwards transport; 20-63 μm dust mass contribution between 2-3.7 km altitude is underestimated by factors of up to 11 at the Sahara, 150 at the Canaries and 340 at Cape Verde. At the Caribbean, there is negligible modelled contribution of $d > 20 \mu\text{m}$ particles to total mass, compared to 15% in the observations. This work adds to the growing body of research that demonstrates the need for a process-based evaluation of climate model dust simulations to identify where improvements could be implemented.

15 1 Introduction

Every year, 400-2200 Mt of mineral dust is lifted from the Earth's surface and becomes suspended in the atmosphere (Huneeus et al., 2011). This lofted dust can alter the global radiation budget by directly reflecting and absorbing radiation (Kok et al., 2018), altering cloud properties (Lohmann and Feichter, 2005; Price et al., 2018) and precipitation patterns (Rosenfeld et al., 2008) by activating ice and droplet nucleation. Shao et al. (2011) estimate that 75 % of the uplifted dust is deposited on land, 20
providing important nutrients to locations such as the Amazon rainforest (Prospero et al., 2020) as well as altering the surface albedo upon deposition, for example on snow and ice (Dumont et al., 2020; Painter et al., 2007). The remaining dust supplies valuable nutrients to nutrient-poor oceans, potentially resulting in the formation of phytoplankton blooms (Jickells et al., 2005;

Dansie et al., 2022). Lofted dust also negatively impacts aviation (Nickovic et al., 2021), energy production, (Piedra et al., 2018) and human health (Kotsyfakis et al., 2019). Many of these processes are sensitive to particle size.

25

Coarse ($d > 2.5 \mu\text{m}$), super-coarse ($d > 10 \mu\text{m}$) and giant ($d > 62.5 \mu\text{m}$) dust particles (size ranges as reviewed and defined in Adebisi et al. (2023)) have vastly different impacts on the Earth system than fine ($d < 2.5 \mu\text{m}$) particles. The lifetime of dust in the atmosphere decreases exponentially with increasing particle diameter (Kok et al., 2017). Sedimentation varies strongly with particle size and dominantly affects super-coarse and giant particles (Foret et al., 2006). The larger particles are also more susceptible to wet deposition processes as they are efficient in-cloud nucleators of ice (Hoose and Möhler, 2012; Pruppacher and Klett, 2010; Sassen et al., 2003; Adebisi et al., 2023) and, after undergoing in-cloud chemical processing, liquid water (Nenes et al., 2014; Karydis et al., 2011). Coarser particles are also more likely to be removed by below-cloud scavenging (Jones et al., 2022). Coarser particles decrease the amount of outgoing longwave radiation at the Top-Of-the-Atmosphere (TOA) and increase shortwave absorption in the atmosphere, both of which cause a net warming effect at the TOA (Kok et al., 2018). Larger particles also contain a greater mass of the nutrients which provide vital sustenance for the biosphere (Barkley et al., 2021; Baker et al., 2006; Dansie et al., 2017). Simulating the lifetime and transport range of different sized dust particles in models is therefore both challenging and key to capturing their various effects and impacts.

30

35

Recent field campaigns have revealed that coarse, super-coarse and giant particles are transported further across the Atlantic from the Sahara than expected, given their estimated deposition velocity and amount of time in transit (Ryder et al., 2018; Weinzierl et al., 2017; Ryder et al., 2019; van der Does et al., 2016; Denjean et al., 2016). The processes responsible for this unexpected long range transport are unclear. Additionally, many global climate models (GCMs) do not represent super-coarse or giant particles and fail to represent the mass concentration of coarse particles at any stage of transport (Adebisi and Kok, 2020; O'Sullivan et al., 2020; Huang et al., 2021; Ansmann et al., 2017). Ryder et al. (2019) estimate that by not representing these particles, dust mass over the Sahara in GCMs is underestimated by up to a factor of 5. The lack of representation of coarser dust particles in GCMs means that they may simulate a direct radiative effect (DRE) forcing that is too small in the longwave (positive DRE) and too negative in the shortwave (negative DRE) (Kok et al., 2017; Adebisi and Kok, 2020), and therefore are too negative in total forcing (shortwave plus longwave). By representing particles up to $20 \mu\text{m}$, Adebisi and Kok (2020) estimate that the dust DRE at the TOA in AeroCom models (currently in the range of -0.78 to -0.03 W m^{-2}) would be shifted to approximately -0.4 to $+0.3 \text{ W m}^{-2}$, meaning that dust could have a net warming or cooling impact on climate.

45

50

By comparing observations to model simulations, previous studies have been able to evaluate the representation of dust size distribution at various points throughout the dust life cycle. Ansmann et al. (2017) found that several dust numerical weather prediction (NWP) forecasts were accurate up to 2000 km west of the coast of Africa, but beyond this, rapid dust removal reduced the quality of the forecast in terms of the total dust mass concentration and 500-550 nm extinction coefficient. Dust-related processes in models are often tuned so that the modelled aerosol optical depth (AOD) matches observed AODs retrieved by satellite instruments. O'Sullivan et al. (2020) show that observations from a campaign obtaining in-situ and remote sensing

55

measurements over the Eastern Atlantic agreed with an NWP forecast and a reanalysis output in terms of the AOD, but struggled to show the correct vertical and horizontal distribution of coarser particles. By tuning models to AOD, a fine bias is often created in the dust size distribution to compensate for the under-represented (or absent) coarser particles.

Some studies have shown that altering certain fixed parameters in the model, such as settling velocity or particle density, can improve model agreement with observations. Drakaki et al. (2022) found that by decreasing the settling velocities of dust in the model by 40-80 % produced good agreement in the size distribution with in-situ aircraft observations over the Sahara and the Eastern Atlantic. By reducing the settling velocity (by 13 % in line with suggestions by Huang et al. (2020)) and lowering the dust particle density from 2500 kg m⁻³ to between 125-250 kg m⁻³, Meng et al. (2022) were able to improve model agreement with observations in terms of the super-coarse particle volume near the Sahara, though dust volume was still underestimated in dust outflow regions. These significant, order of magnitude changes to particles' density and settling velocity are not representative of realistic uncertainties in these variables or processes, and instead act as a proxy to representing poorly understood processes which can potentially impact particle lifetime, such as electric charging (van der Does et al., 2018; Toth III et al., 2020; Renard et al., 2018; Méndez Harper et al., 2022), asphericity (Huang et al., 2021, 2020; Mallios et al., 2020; Saxby et al., 2018; Colarco et al., 2014; Yang et al., 2013), turbulence (Denjean et al., 2016; Rodakovski et al., 2023), topography (Heisel et al., 2021; Rosenberg et al., 2014) and vertical mixing (Gasteiger et al., 2017; Cornwell et al., 2021).

The Fennec (Ryder et al., 2013a, b, 2015), AERosol Properties - Dust (AER-D) (Ryder et al., 2018) and Saharan Aerosol Long-Range Transport and Aerosol-Cloud-Interaction Experiment (SALTRACE) (Weinzierl et al., 2017) airborne campaigns measured vertically resolved size distributions at four locations between the Sahara and Caribbean and thus represent observations at different stages in the long range trans-Atlantic transport of Saharan dust. These campaigns measured the full size range of lofted mineral dust particles using open-path wing probes, unlike many previous campaigns which assumed the transport of coarser particles to be minimal, and therefore did not measure substantially into the coarse, super-coarse or giant size range, or measurements of coarser particles were restricted by sampling constraints due to instrument inlets and pipework (Ryder et al., 2019; Rosenberg et al., 2014). This study is the first time that these three campaigns will have been analysed together, in particular taking the vertical distribution of dust size into account. In order to better understand the ability of models to simulate dust transport and deposition, these campaigns will be analysed and compared to a Met Office Unified Model (MetUM) climate simulation (HadGEM3A-GA7.1) (Walters et al., 2019). HadGEM3A-GA7.1 includes representation of coarse dust particles up to 63.2 μm in diameter; a notably larger upper size limit than other models which tend to cut off the represented dust size distribution at ~20 μm (Mahowald et al., 2014; Zhao et al., 2022; Huneus et al., 2011). The HadGEM3A-GA7.1 dust simulation has not yet been extensively compared with in-situ airborne observations. The campaigns and model have not had their vertically resolved dust size distribution evolution assessed in such detail before and over such a large spatial extent, representing the vertically resolved size distribution evolution over long range transport. O'Sullivan et al. (2020) suggest that the earlier MetUM NWP GA6.1 configuration (notably different with dust represented by two size bins) often places dust too

low in the atmosphere, over the Eastern Atlantic, which we investigate in this study.

This study aims to gain a more in-depth insight into the systematic biases between modelled and observed size distributions and how those biases evolve during transport. Such assessments of model performance are crucial in guiding improvements to model representation of mineral dust transport and deposition.

In Sect. 2, we introduce the aircraft campaigns, the model setup used in this study and our methodology for the analysis. In Sect. 3, we investigate the relationship between the coarser dust size distribution and the AOD in the aircraft observations. In Sect. 4, we present and discuss our results analysing the vertical dust structure, size distribution and concentration evolution across the Atlantic in the model and observations. In Sect. 5 we summarise and present conclusions.

2 Methods

2.1 Aircraft Observations

The vertically resolved in-situ aircraft observations used in this study were taken during scientific flights at the Sahara, Canary Islands, Cape Verde and Caribbean during the Fennec, AER-D and SALTRACE campaigns. Figure 1 shows the location (flight tracks) of the observations used in this study. All aircraft observations are presented at ambient conditions. The Fennec and AER-D campaigns made use of the BAe-146 Facility for Airborne Atmospheric Measurements (FAAM) aircraft and instruments (Ryder et al., 2013a, b, 2018), while the SALTRACE campaign used Falcon Deutsches Zentrum für Luft- und Raumfahrt (DLR) aircraft and instruments (Weinzierl et al., 2017). The following two sections describe these two different aircraft and instrumentation setups. Henceforth all aerosol sizes will be given in diameters.

2.1.1 FAAM BAe-146 aircraft setup

The Fennec campaign took place in June 2011, flying over a remote region of the Sahara Desert (Mauritania and Mali), as well as over the Canary Islands (Figure 1; Fennec Sahara and Fennec SAL, respectively). This campaign therefore provides data at two separate locations; over the desert close to dust sources (Fennec Sahara) (Ryder et al., 2013a) and as the SAL forms over the marine boundary layer (MBL) between the west coast of Africa and the Canary Islands (Fennec SAL) (Ryder et al., 2013b). In total, 41 vertical profiles were conducted during the Fennec campaign: 20 at the Canaries and 21 over the Sahara (Table 1). These profiles are conducted as the aircraft ascends/descends between the minimum safe altitude (around 160 m above ground level depending on visibility) and up to 8 km. The profiles at the Canaries were measured as the aircraft travelled to and from Fuerteventura airport (28.4° N 13.8° W) and the Sahara, so two profiles were usually measured per flight. The lowest portion of the profile was over the ocean, while the highest altitude of the profile lies just over the continent.

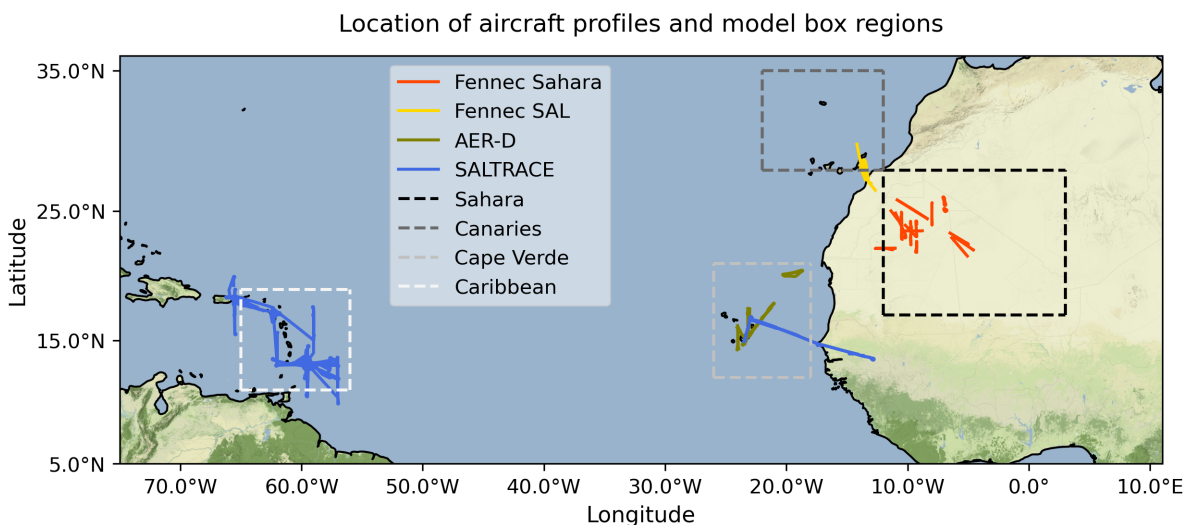

Figure 1. Location of the vertical profiles measured during the Fennec and AER-D campaigns, as well as the flight paths followed during the SALTRACE campaign (solid lines), and box regions used for analysis of the model data (dashed lines).

Flight number	Date	Time of flights (UTC)	Number of profiles
b600	17 June 2011	10:00-12:30	1C 1Ma 1Mu
b601	17 June 2011	15:00-19:30	2C 1Ma 1Mu
b602	18 June 2011	08:30-12:30	2C 1Ma 1Mu
b604	20 June 2011	13:00-17:30	2C 2Mu
b605	21 June 2011	10:00-12:00	1C 2Mu
b606	21 June 2011	14:00-19:00	2C 1Mu
b609	24 June 2011	11:30-16:30	2C 1Mu
b610	25 June 2011	07:30-12:00	2C 2Mu
b611	25 June 2011	14:30-19:00	2C 2Mu
b612	26 June 2011	07:30-12:00	2C 2Mu
b613	26 June 2011	14:00-18:00	2C 3Mu

Table 1. Details of the Fennec flights used in this study including date and time of flights. Time is given to nearest 30 minutes. The number of profiles are described by the number taken from the Canaries (C) and the number at North Mali (Ma) and North Mauritania (Mu). Data taken from: Ryder et al. (2013a, b).

The AER-D campaign took place in August 2015, conducting 26 vertical profiles in the Cape Verde region. The flights from which these profiles are taken are described in Table 2.

Flight number	Date	Time of flights (UTC)	Number of profiles
b920	7 Aug 2015	15:00-17:00	7
b924	12 Aug 2015	15:30-16:30	1
b928	16 Aug 2015	15:30-16:30	6
b932	20 Aug 2015	11:00-12:00	6
b934	25 Aug 2015	15:00-17:45	6

Table 2. Details of the AER-D flights used in this study.

Instrument	Abbreviation	Size range (μm)	Fennec	AER-D	SALTRACE
Passive cavity aerosol spectrometer probe 100-X	PCASP	0.13-3.83	Y	Y	N
Cloud Droplet Probe	CDP	2.86-20	Y	Y	N
Two-dimensional stereo probe	2DS	10-63.2	N	Y	N
TSI Integrating Nephelometer 3563	Nephelometer	n/a	Y	Y	N
Radiance Research Particle Soot Absorption Photometer	PSAP	n/a	Y	Y	N
Ultra High Sensitivity Aerosol Spectrometer	UHSAS-A	0.08-3	N	N	Y
Grimm Sky OPC	SkyOPC	0.3-3	N	N	Y
Cloud and Aerosol Spectrometer with Depolarization Detection	CAS-DPOL	0.5-50	N	N	Y

Table 3. Size distribution instruments and scattering and absorption instruments used during the Fennec and/or AER-D campaign, where Y/N indicates instrument operation/not-operational. Sizes are given as geometric diameter. Size ranges correspond to data selected for model intercomparisons (as opposed to the full range measured by the instruments). Data taken from: Ryder et al. (2013a, 2018, 2015), Walser (2017) and Weinzierl et al. (2017).

125 Both the Fennec and AER-D campaigns measured particles up to 300 μm diameter. Table 3 shows the instruments operated
in each campaign and the size range applied from each instrument, adjusted from geometric to optical diameter (see Ryder
et al. (2013b, 2018) for details).

During Fennec, wing-mounted (i.e. with no fuselage inlet) optical particle counter (OPC) probes were operated to mea-
130 sure the accumulation mode and coarse to super-coarse mode size distributions (passive cavity aerosol spectrometer probe
(PCASP) and Cloud Droplet Probe (CDP), respectively), while measurements from an optical array probe (OAP), are used for
the super-coarse and giant modes. The OPCs use light scattering measurement techniques, and therefore the size bins applied
are adjusted for a dust refractive index of 1.53-0.001i, based on scattering and absorption measurements (Ryder et al., 2013b).
Errors due to uncertainties and oscillations in the Mie scattering curve for the OPCs, in addition to systematic error for the
135 PCASP and random (counting) errors for all probes were propagated through to size distribution uncertainties. Full details of

Fennec instrument processing are given in Ryder et al. (2013a, b).

During AER-D, the same wing-mounted OPCs were operated (PCASP and CDP), while measurements from the OAP two-dimensional stereo probe (2DS) are used for the super-coarse to giant mode. As with Fennec, the size bins applied to the OPC data are adjusted for a dust refractive index of 1.53-0.001i based on scattering and absorption measurements (Ryder et al., 2018). Sizing for the 2DS is performed using the mean of the x and y dimensions of each particle image, in order to be consistent with Fennec data processing, and is also curtailed at 300 μm for this reason, though no particles approaching this size were detected during AER-D. We propagate errors in size and number distribution due to uncertainties and oscillations in the Mie scattering curve for the OPCs, in addition to random errors (from counting and discretization error) and systematic errors (from sample area) for all instruments. Full details of AER-D instrument processing are given in Ryder et al. (2018).

During both Fennec and AER-D, the aircraft measured scattering coefficient with a TSI integrating nephelometer 3563 and absorption coefficient with a Radiance Research particle soot absorption photometer (PSAP) (Ryder et al., 2015). These have been integrated vertically to provide AOD at 550 nm.

Due to dust-induced visibility reductions impacting the minimum safe altitude for flying, the minimum height of observational data at the Sahara varies by flight, from around 100-500 m above ground. Therefore, we impose a minimum altitude threshold of 500 m here for the Fennec Sahara profile analysis to avoid sampling bias across different flights, weather and dust conditions. Data collected in the MBL may contain contaminated dust and non-dust aerosols, such as sea salt and anthropogenic pollution. Compositional analysis carried out by Ryder et al. (2018) on the aerosols measured during the AER-D campaign, showed that particles $d > 0.5 \mu\text{m}$ were dominated by alumino-silicates and quartz, while between 0.1-0.5 μm , the dominant particles were sulphates and salts. As we are most interested in the coarser dust particles in this study, these fine-sized contaminants should not impact our analysis. Therefore, profiles over the Canary Islands and during AER-D are analysed to their minimum sampling altitude (either ~ 16 m or to landing at Fuerteventura airport). Finally, filtering of the data removed noise based on a signal to noise ratio as a function of diameter.

2.1.2 Falcon DLR aircraft setup

The SALTRACE campaign took place in June and July 2013, conducting flights in the East Atlantic in the Cape Verde region (SALTRACE-E) and in the West Atlantic around the Caribbean (SALTRACE-W) (Figure 1 and Table 4).

During SALTRACE, the Falcon DLR took measurements using a combination of OPCs: Grimm Sky OPC (SkyOPC), Ultra High Sensitivity Aerosol Spectrometer (UHSAS-A) and the Cloud and Aerosol Spectrometer with Depolarization Detection (CAS-DPOL). Some details of these instruments are shown in Table 3. Full details can be found in Walser (2017) and Weinzierl

Flight number	Date	Location	Time of measurements (UTC)	Number of segments / full profiles
130611b	11 Jun 2013	La Palma (ES) to Sal (CV)	12:51-16:25	17 / 2
130612a	12 Jun 2013	Sal to Dakar (SN)	08:52-12:08	19 / 2
130612b	12 Jun 2013	Dakar to Sal	13:12-16:10	13 / 2
130614a	14 Jun 2013	Sal to Dakar	09:06-12:37	29 / 2
130614b	14 Jun 2013	Dakar to Sal	13:47-15:54	27 / 2
130617a	17 Jun 2013	Sal to Praia (CV)	11:06-12:27	17 / 2
130620a	20 Jun 2013	Barbados	12:01-15:55	32 / 2

130711a	11 Jul 2013	Barbados	12:37-15:03	10 / 2
130711b	11 Jul 2013	Barbados to San Juan	18:04-21:05	24 / 2
130712a	12 Jul 2013	San Juan to Fort Lauderdale	14:09-17:52	8 / 1

Table 4. Details of the SALTRACE flights, including location, and the time (UTC) of flights. Where ES is Spain, CV is Cape Verde, SN is Senegal and PR is Puerto Rico. The number of horizontal segments and vertical profiles measured during each flight are shown; each horizontal segment is measured over 150 seconds. Data taken from: Weinzierl et al. (2017) supplementary material.

et al. (2017) supplementary material.

170

We use data from both vertical profiles and horizontal segments in our analysis of the SALTRACE data. SALTRACE data from horizontal flight legs are broken down into 338 flight segments, each lasting for 150 seconds. These have been inverted and represented using lognormal modes in order to consistently propagate measurement uncertainties (e.g. optical particle counter response and properties, correction for refractive index) (Walser, 2017). These horizontal segments provide size distributions at a high resolution in diameter space. Additionally, in order to provide a vertically continuous description of dust mass and size variation with altitude, we use SALTRACE profile observations. The profile data has not undergone such extensive processing as the horizontal segments, and instead adjustments to the instrument bin sizes were applied to account for refractive index. Comparisons between the detailed size distributions from horizontal segments and those from profiles shows good agreement (not shown). This allowed 39 size-resolved vertical profiles from SALTRACE to be analysed.

175

180

2.1.3 Manipulation of aircraft data

For all campaigns, profile data was aggregated across instrument size bins to match the six size bins of the model (Table 5), assuming homogeneous distributions across instrument size bins and proportioning number concentration across instrumental size bins where model and instrument size bins did not match up perfectly. This provides measured number concentrations corresponding to each model size bin as a function of time for the aircraft data. Assuming the density of dust to be 2.65 g cm^{-3} (Hess et al., 1998) and that the particles are spherical, we calculate mass concentrations for each of these size bins using standard volumetric and mass equations. These size and time resolved mass concentrations can then be manipulated as follows to provide mass concentration profiles and size distributions.

Profiles are either measured as one single 'deep' profile, or several smaller profile segments combined together. Quasi-vertical profile data are averaged over 50 m intervals for high resolution analysis and model evaluation, for both FAAM and DLR measurements. For size distribution analysis, FAAM (i.e. Fennec, AER-D) aircraft profiles were averaged over 500 m altitude intervals. DLR (i.e. SALTRACE) size distributions were taken from horizontal flight segments, and measurements performed within 500 m altitude bands were averaged. The data is regionally averaged for each campaign. In some portions of our analysis, we do not analyse data below 1 km or above 6 km in order to avoid the observed data becoming skewed by non-dust particles in the MBL or at the top of/above the SAL.

A caveat of our analysis is that this removes any measured particles outside the model limits ($0.063 < d < 63.2 \mu\text{m}$). Particles larger than $63.2 \mu\text{m}$ accounted for 10-40 % of the total dust mass measured at the Sahara below 5 km, but at the Canaries and Cape Verde, these particles accounted for less than 10 % of the dust mass and only occurred below 2 km (not shown). Hence, these giant particles were not included in this study as we focus our comparison on the size range transported in the model's atmosphere. Particularly over the Sahara, giant dust particles are likely to be omitted by model simulations and the extent of this should be addressed in the future but is not in the scope of this study.

2.2 Model setup

The GA7.1 atmosphere-only version of the Hadley Centre Global Environment Model 3 (HadGEM3A-GA7.1) (Walters et al., 2019) configuration of the MetUM is used to model, among other variables, global mineral dust concentrations and aerosol optical depths. This setup is identical to those used in the HadGEM3 CMIP6 (Coupled Model Intercomparison Project phase 6) AMIP simulations which is configured to use observed sea surface temperatures and CMIP6 historical inventories (Eyring et al., 2016). The model has 85 height levels, 50 of which are concentrated below 18 km, and a horizontal grid resolution of $1.875^\circ \times 1.25^\circ$ (N96). Mineral dust is represented by the Coupled Large-scale Aerosol Simulator for Studies in Climate (CLASSIC) scheme, described in Woodward et al. (2022), Woodward (2001) and Johnson et al. (2019). The CLASSIC dust emission scheme calculates horizontal flux in nine size bins between 0.0632 and $2000 \mu\text{m}$ diameter, and uses this to derive

vertical flux in six size bins up to $63.2 \mu\text{m}$. A fraction of the coarsest particles are re-deposited to the surface within the same
215 timestep as they are emitted, and these never enter the model atmosphere. The remaining particles are lofted into the atmosphere
and are transported as independent tracers corresponding to the six size bins shown in Table 5. The dust scheme is called at
every model time step, using the driving fields calculated directly from HadGEM3A-GA7.1 and Joint UK Land Environment
Simulator (JULES) (Woodward et al., 2022). The dust is mixed externally with other aerosols, which are simulated by the
United Kingdom Chemistry and Aerosols (UKCA) Global Model of Aerosol Processes (GLOMAP-mode) scheme (Bellouin
220 et al., 2013). The dust cannot act as cloud condensation nuclei or ice nucleating particles or chemically interact with the model.
The dust interacts with the rest of the model through radiative interactions with the atmosphere and ocean biogeochemistry via
the Model of Ecosystem Dynamics, nutrient Utilisation, Sequestration and Acidification (MEDUSA). The dust particles are
also assumed to be spherical.

Table 5. Size range of the modelled transported mineral dust size bins in the CLASSIC aerosol scheme described in Woodward (2001) and Johnson et al. (2019).

Bin number	Bin diameter range (μm)
1	$0.0632 \leq d < 0.2$
2	$0.2 \leq d < 0.632$
3	$0.632 \leq d < 2$
4	$2 \leq d < 6.32$
5	$6.32 \leq d < 20$
6	$20 \leq d < 63.2$

225 The dust emission scheme is described in detail in Woodward et al. (2022). The method of calculating horizontal and vertical
flux is derived from the work of Marticorena and Bergametti (1995), using dry threshold friction velocities from Bagnold (1941)
with correction for soil moisture, based on the method of Fecan et al. (1998), and clay fraction. The particles are then trans-
ported as six independent tracers and are subject to deposition by below-cloud scavenging, gravitational settling and turbulent
mixing in the boundary layer (BL). Dry deposition in the BL is calculated using a resistance analogue method where the par-
230 ticle deposition velocity is treated as an inverse resistance based on gravitational settling and turbulent mixing (Seinfeld, 1986).

The model is tuned to improve agreement between the dust simulation and observations. To do this, three dimensionless
parameters are altered: a global emissions multiplier, a friction velocity multiplier, and a soil moisture multiplier. The purpose
of tuning is to represent processes not included in the model, such as gustiness of wind at the source and the relationship of soil
235 moisture in the model's top level and at the soil surface (Woodward et al., 2022). The dust was not specifically tuned during
this study, or for GA7.1, and an improved dust simulation would almost certainly be achievable if tuning were undertaken.
However, we chose to use this configuration of settings as it is the same as those used in the HadGEM3 CMIP6 AMIP simula-

tions (Eyring et al., 2016) and has been widely used.

240 The model simulates five June months, 2010-2014, which outputs vertically resolved daily mean dust mass mixing ratios for each size bin. The averaged five Junes provide a 'June climatology'. We found minimal variability in Moderate Resolution Imaging Spectroradiometer (MODIS) Terra AOD in the two adjacent five year periods (2005-2009 and 2015-2019), suggesting that this five year period captures relatively average conditions and is of sufficient length for this study. The data is averaged over boxes representative of the campaign locations (Figure 1). Careful consideration was taken to make sure that the boxes
245 were suitably located so as to represent the locations measured during the observations. The Sahara, Canary and Cape Verde boxes do not overlap with the African coast as this was found to alter the distribution and magnitude of the vertical dust profile.

The daily mean dust mixing ratio, temperature and pressure on model levels are used to calculate the air density, and the mass, number, volume and surface area concentration per size bin. The calculations of the size distributions and normalisations
250 were carried out in the same way as with the aircraft data.

3 Confirming representivity of the aircraft observations

As shown in Tables 1, 2 and 4, the aircraft campaigns cover limited periods of time, often only taking measurements for two to three weeks. The data collected during these campaigns can be biased towards certain types of events, for example, an effort
255 may be made to schedule and direct flights through forecasted high concentration dust events. Assuming that there may have been a scheduling bias towards high concentration dust events during the campaigns, it is important to understand if the dust size distribution, especially at the coarser size range, is at all dependent on the AOD, which we are using to represent the magnitude of the dust event. In this section, we show that any bias in data collection is not found to impact the findings from this study.

260 3.1 Spatial AOD comparisons

In order to ascertain whether the dust conditions measured during the campaigns are representative of average conditions spatially and in terms of AOD, combined MODIS dark target and deep blue AOD retrievals for land and ocean (Levy et al., 2013; Hsu et al., 2013) from the Terra satellite are used. A monthly mean AOD at 550 nm during the campaigns (June 2011 for Fennec, June 2013 for SALTRACE and August 2015 for AER-D) at the campaign locations (i.e. regional boxes shown in
265 Figure 1) was compared to a 5 year (2010-2014) and 20 year (2000-2019) average of AOD in June (or August for AER-D).

The monthly mean AOD at 550 nm recorded in June 2011 (Fennec), June 2013 (SALTRACE) and August 2015 (AER-D) by MODIS-Terra is comparable, in terms of spatial distribution at the campaign locations, to 5 and 20 year mean June (or August) AOD (not shown), except for at the Canaries. Here we see some dust transported northwestwards from the African continent,

270 increasing the June 2011 AOD at the Canary Islands slightly in comparison to the longer term June averages. However, the
change is relatively small (~ 0.1), suggesting that the observation periods, including at the Canaries, show relatively average
spatial distribution of AOD.

Next, we compare the mean MODIS AOD magnitude during the campaign months. During the Fennec campaign in June
275 2011, the spatial variability of the AOD at the Sahara was comparable to the longer term June averages, whereas at the Ca-
naries, the AOD during the Fennec campaign in June 2011 was greater (AOD between 0.4-0.6) than the 5 and 20 year averages
(0.2-0.4), seemingly due to a slightly more northerly plume of dust during June 2011. At Cape Verde during the AER-D cam-
paign, the mean August AOD was comparable to the longer August averages. However, in June 2013, during the SALTRACE
280 periods (0.5-0.6 and 0.3-0.4, respectively). This suggests that the campaigns observed conditions similar to or dustier than
average. Next, we analyse whether greater AOD impacts the shape of the measured coarse size distribution.

3.2 Relationship between AOD and size distribution

As AOD is the vertical integral of extinction caused by aerosols, which partially depends on number concentration, as well
285 as size-varying optical properties, we expect a greater concentration of dust to coincide with a higher AOD value. We aim to
test this hypothesis with our observational data and additionally, we want to understand the dependence of size distribution on
AOD; do high AOD events contain a different proportion of coarser particles to fine particles than low AOD events?

Here we show the impact of AOD on size distribution by splitting campaign flights into low, medium and high magnitude
290 AOD events based on in-situ AOD measurements taken during the Fennec and AER-D campaigns. This data is not available for
the SALTRACE campaign. The AOD thresholds used to split up each campaign is given in the Table 6 caption; these thresh-
olds were chosen as they approximately split the number of profiles from each campaign into thirds and are different for each
campaign. We use the Student's t-test to test the statistical significance of our proposed hypotheses. The smaller the returned
p-value, the greater the statistical significance of the observed difference. For the first test, we propose the null hypothesis
295 states that there is no difference between the total dust mass concentration measured and the AOD. We found a statistically
significant difference (to 95 % confidence interval) between the total dust mass concentration and the AOD measured at the
Sahara, Canaries and Cape Verde during low, medium and high events (Table 6 indicated by small p-values); hence, we reject
our null hypothesis. Thus, low AOD events measured during the two campaigns, for example, had a significantly different
concentration magnitude to medium or high AOD events.

300

Table 6. P-values resulting from a Student’s t-test to test the null hypothesis: there is no difference between the total mass concentration profile in low (L), medium (M) and high (H) AOD events. Bold values are significant to a 95 % confidence interval. This is tested for the Fennec (Sahara and Canaries) and the AER-D (Cape Verde) campaign data. Each set of aircraft profiles from each location was split into thirds based on AOD at 550 nm measurements from the aircraft. The thresholds separating the low, medium and high AOD categories at the Sahara, Canaries and Cape Verde are: 0.75 and 1.5, 0.5 and 0.75, and 0.4 and 0.6, respectively.

Total concentration $\mu\text{g m}^{-3}$		
Sahara	M	H
L	0.014	$4.473e^{-18}$
M	-	$1.100e^{-8}$
Canaries	M	H
L	$2.460e^{-7}$	$6.837e^{-10}$
M	-	0.463
Cape Verde	M	H
L	$3.167e^{-8}$	$1.028e^{-14}$
M	-	$1.110e^{-4}$

Next, we look at the relationship between the AOD and the relative mass contribution of coarser particles to the total mass concentration at each location. Conducting a Student’s t-test, where our null hypothesis states that there is no difference in the relative contribution of mass from particular size ranges between differing magnitude AOD events. We apply this test for dust size measurements firstly up to $6.32 \mu\text{m}$ and secondly up to $63.2 \mu\text{m}$ (i.e. testing the variability in the positioning of the bold blue and green lines in Figure 3 and whether this is dependent on AOD). Table 7 shows the resulting p-values and whether they are significant to a 95 % confidence interval (shown by bold font). Due to the amount of non-significant values, we cannot reject the null hypothesis for either size range tested. Hence, the percentage mass contribution by coarser particles did not vary significantly between magnitudes of AOD. These results indicate that high, medium and low magnitude dust events have the same proportion of coarser particles, despite having a significantly different total mass concentration (Table 6). This is consistent with little case-to-case variability in the size distribution found in the Fennec and AER-D data (Ryder et al., 2013b, 2018). Hence, despite differing conditions altering the total mass of particles lofted, the coarser size contribution remains approximately steady at each individual location within the uncertainties of the data.

Table 7. P-values resulting from a Student’s t-test to test the null hypothesis: there is no difference between the percentage mass contribution of particles $< 6.32 \mu\text{m}$ (left) or $< 20 \mu\text{m}$ (right) to the total mass profile in low (L), medium (M) and high (H) AOD events. Bold values are significant to a 95 % confidence interval. This is tested for the Fennec (Sahara and Canaries) and the AER-D (Cape Verde) campaign data. Each set of aircraft profiles from each location was split into thirds based on AOD at 550 nm measurements from the aircraft. The thresholds separating the low, medium and high AOD categories at the Sahara, Canaries and Cape Verde are: 0.75 and 1.5, 0.5 and 0.75, and 0.4 and 0.6, respectively.

$< 6.32 \mu\text{m}$			$< 20 \mu\text{m}$		
Sahara	M	H	Sahara	M	H
L	0.821	$6.304e^{-5}$	L	0.569	0.019
M	-	0.392	M	-	0.299
Canaries	M	H	Canaries	M	H
L	0.651	0.359	L	0.817	0.355
M	-	0.120	M	-	0.471
Cape Verde	M	H	Cape Verde	M	H
L	0.002	0.059	L	0.498	0.162
M	-	0.202	M	-	0.500

Therefore, we find that in low or high AOD events, the coarser dust size distribution remains consistent enough that any variation in AOD magnitude, due to varying meteorology between campaign years or bias in data collection will be minimal in terms of impact on the coarser size distribution.

4 Results

In this section, the observations at the four observed locations (Sahara, Canaries, Cape Verde and Caribbean) will be compared to the model simulation. Initially, this comparison will investigate the specifics of the vertical structure of the dust layer before focusing on the evolution of the observed and modelled size distributions over long range transport.

4.1 Vertical structure

In terms of the absolute values (black lines in Figure 3), we have analysed the mean total mass concentration profile from each location between $0.063\text{-}63.2 \mu\text{m}$ diameter to match the modelled size range and between 1-6 km altitude to avoid contamination from the MBL or above the SAL. The mean mass concentration from observations between 1-6 km from each set of profiles has been calculated: $347 \mu\text{g m}^{-3}$ at Sahara, $133 \mu\text{g m}^{-3}$ at Canaries, $149 \mu\text{g m}^{-3}$ and $1789 \mu\text{g m}^{-3}$ at Cape Verde (AER-D and SALTRACE-E, respectively) and $308 \mu\text{g m}^{-3}$ at Caribbean. Despite expectation that the highest mean concentration would be measured at the Sahara, the SALTRACE-E mean is almost 3 times larger, while the SALTRACE-W mean is nearly as large as that measured at the Sahara. This suggests that the events measured during the SALTRACE campaign were

significantly larger than those measured during Fennec and AER-D. Despite these campaigns covering a range of magnitudes,
330 the model tends to underestimate the mean total dust mass by a factor of between 4 and 44, with the largest underestimations
occurring with the comparison to the SALTRACE-E data. It is likely that this underestimation is partly due to a bias in the
model size distribution towards smaller particles which constitute less mass. This underestimation is also likely a consequence
of the tuning which has been applied to the model emissions as well as the different temporal scales which we are comparing.
Due to the large magnitude of difference between the model and campaigns, the vertical mass profiles have been normalised.
335 In order to compare the vertical distribution of dust, the profiles have been normalised by the mean dust mass between 1-6 km
altitude.

Figure 2 shows the normalised observed and modelled vertical profiles of total dust mass concentration at each location
from each campaign. Firstly, in terms of the observations, at the Sahara (Figure 2a), dust mass is highest near to the surface,
340 likely due to the high quantity of coarse and super-coarse particles which are lofted and settle relatively close to the source.
The mass concentration gradually decreases to near zero at 5.5 km, marking the top of the Saharan atmospheric boundary layer
(SABL). At the Canaries (Figure 2b), the observations start to show the formation of the SAL, with higher concentrations of
dust between 2.5-3.5 km altitude, though the profile has relatively high concentrations up to 5.5 km where it is capped at the top
of the SAL. With more time and distance from the Sahara, profiles at Cape Verde (Figure 2c) represent a more mature version
345 of the SAL; the AER-D profile has a more well-defined base and cap to the SAL with a more concentrated centre between
2-4 km. Though not as dramatic as the AER-D profile, the SALTRACE-E profile still peaks between 2-4.5 km and tails off at
both the top and bottom ends of the profile. Finally, at the Caribbean (Figure 2d), the dust plume has lowered, bringing the dust
mass closer to the surface and lowering the SAL cap to below 5 km.

350 Generally, the shape of the modelled vertical profile resembles the observed profile. However, the model has struggled
to represent the rate of change of concentration with height, failing to capture the relative magnitude of the maximum and
minimum values measured during Fennec and AER-D (Figure 2 a, b, and c). At the Sahara, the model represents a more well-
mixed profile whereby the concentration decreases more gradually with altitude than in the observations. The model does not
have the same sharp cap at the top of the SABL that we see in the observations. Although the model does not represent the
355 greater mid-SAL concentrations measured in AER-D well at Cape Verde, its vertical distribution lies fairly close to that from
SALTRACE-E (Figure 2c).

The model appears to represent the top of the SAL most effectively at the Caribbean as the only location where the modelled
concentration drops close to 0 at the SAL top. The model failing to capture this sharp decrease could be in part due to our
360 temporal averaging of the model data, suggesting that the top of the modelled SAL could vary significantly and can occur
above 6 km altitude, except for at the Caribbean. The smooth profiles could also be a consequence of limited spatial resolution
and numerical diffusion in the model.

Normalised total mass profile from observations and model

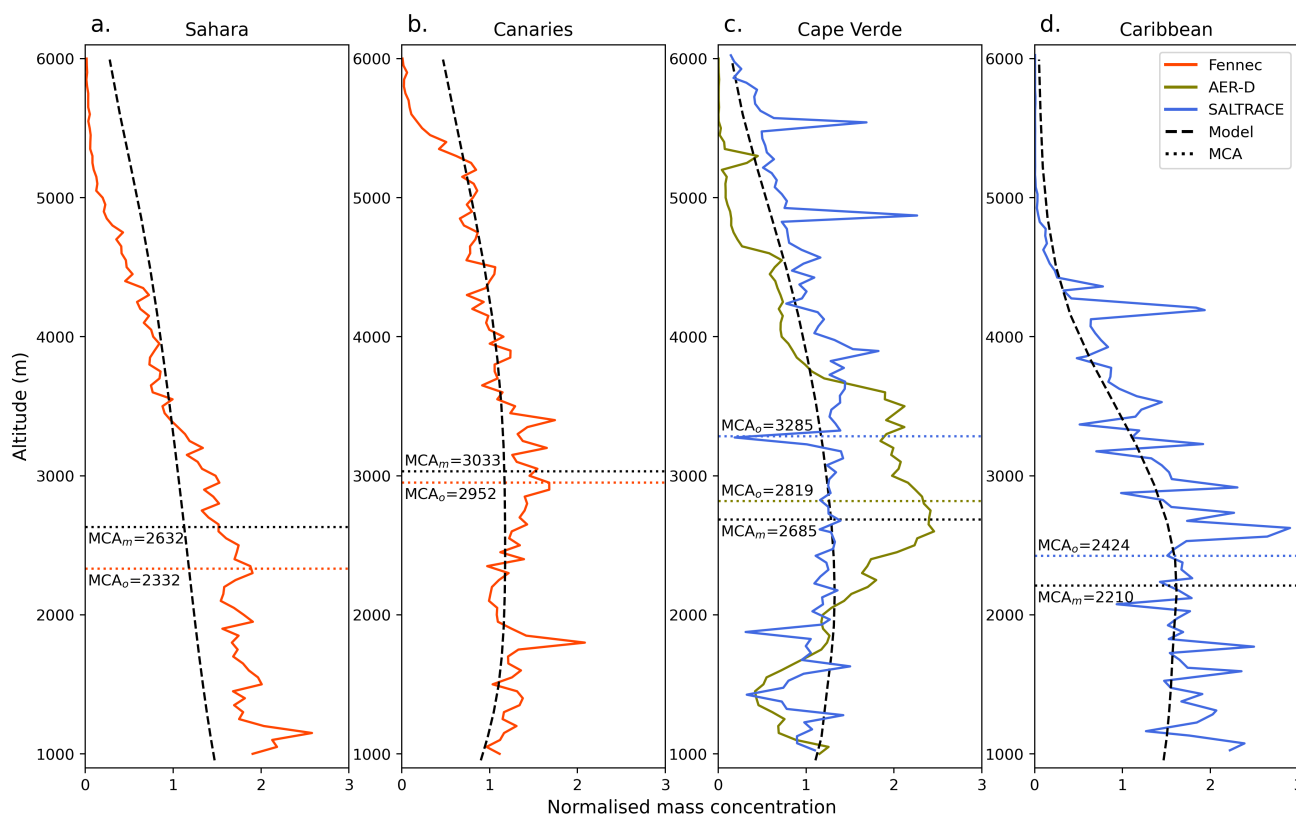

Figure 2. Normalised observed (coloured solid line) and modelled (black dashed line) total dust mass concentration profile and dust mass centroid altitude (MCA; dotted horizontal lines in metres) between 1-6 km. MCA_o and MCA_m respectively represent the observed and modelled MCA values. Plots show all four observed locations: Sahara (a), Canaries (b), Cape Verde (c; AER-D and SALTRACE-E) and Caribbean (d; SALTRACE-W) from the Fenec (orange), AER-D (green) and SALTRACE (blue) campaigns. Data has been normalised by the mean profile concentration between 1-6 km altitude.

The model represents the shape of the observed profiles very well despite the campaigns measuring fairly different total mass concentrations. However, although the AER-D campaign measured similar mean mass concentrations at Cape Verde to the Canaries during Fenec, the AER-D profile is the least well-fitted to the model profiles, as well as appearing fairly different in structure to the SALTRACE-E profile. This difference could be caused by variation in the location of dust emission, which may alter the dust size distribution and distance transported before measurement. The difference could also be a consequence of the different time of year in which the AER-D campaign took place in; Fenec and SALTRACE both occurred in June, whereas AER-D happened during August. The time of year impacts the location of the inter-tropical convergence zone (ITCZ) and the strength of the Saharan Heat Low (SHL), which work together as the main cause of intense dust uplift in the early

summer (Marsham et al., 2008). The difference in meteorology could be why we see a different profile structure measured during the AER-D campaign.

375 The dust mass centroid altitude (MCA) between 1-6 km – the altitude at which 50 % of the mass is below and 50 % is above (Lu et al., 2023) – is shown in Figure 2. We have not included particles in the lowest 1 km of the atmosphere in our calculations of the MCA due to potential interference from non-dust particles measured in the observations which may lower the MCA. Hence, this value is not a total column mass, but is representative of the dust mass between 1-6 km at each location. At every location, the modelled MCA is in a similar altitude to the observed MCA, suggesting that the model distributes the total dust
380 mass well in the SAL when compared to observations, in terms of the vertical distribution.

Moving away from the Sahara where the observed MCA is 2332 m, the MCA rises as the dust mass travels to the Canaries and Cape Verde in the observations. The formation of the MBL aids in the removal of dust mass from the base of the SAL, causing the MCA to rise; 2952 m at the Canaries and 2819 m and 3252 m at Cape Verde. Though as the plume sinks over
385 the West Atlantic, the MCA reduces to 2490 m at the Caribbean. This raising and lowering of the MCA across the Atlantic is exactly what we would expect to see in our observations (e.g. Carlson (2016)). The model succeeds in representing vertical change in the MCA across the Atlantic. We have shown that the model represents the total dust mass vertical distribution fairly well. O’Sullivan et al. (2020) previously found that an NWP GA6.1 configuration of the MetUM placed dust too low in the atmosphere. Our analysis of these profiles suggests that this MetUM climate configuration may transport the dust at similar
390 altitudes and distributions to the observations, at least in terms of the total mass across the whole size distribution.

In order to analyse the size distribution that makes up the vertical structure at these locations, we have broken the profiles (shown in their normalised form in Figure 2) down into the six size bins used by the CLASSIC scheme in HadGEM3A-GA7.1. We analyse the percentage contribution of mass to the total mass as a function of size. Figure 3 shows the contribution by size
395 bin and the mean total mass concentration from each campaign for both model and observations. Table 8 contains the mean percentage mass contribution to total mass between 2-3.7 km altitude from the three coarsest size bins at each location from the observations and model.

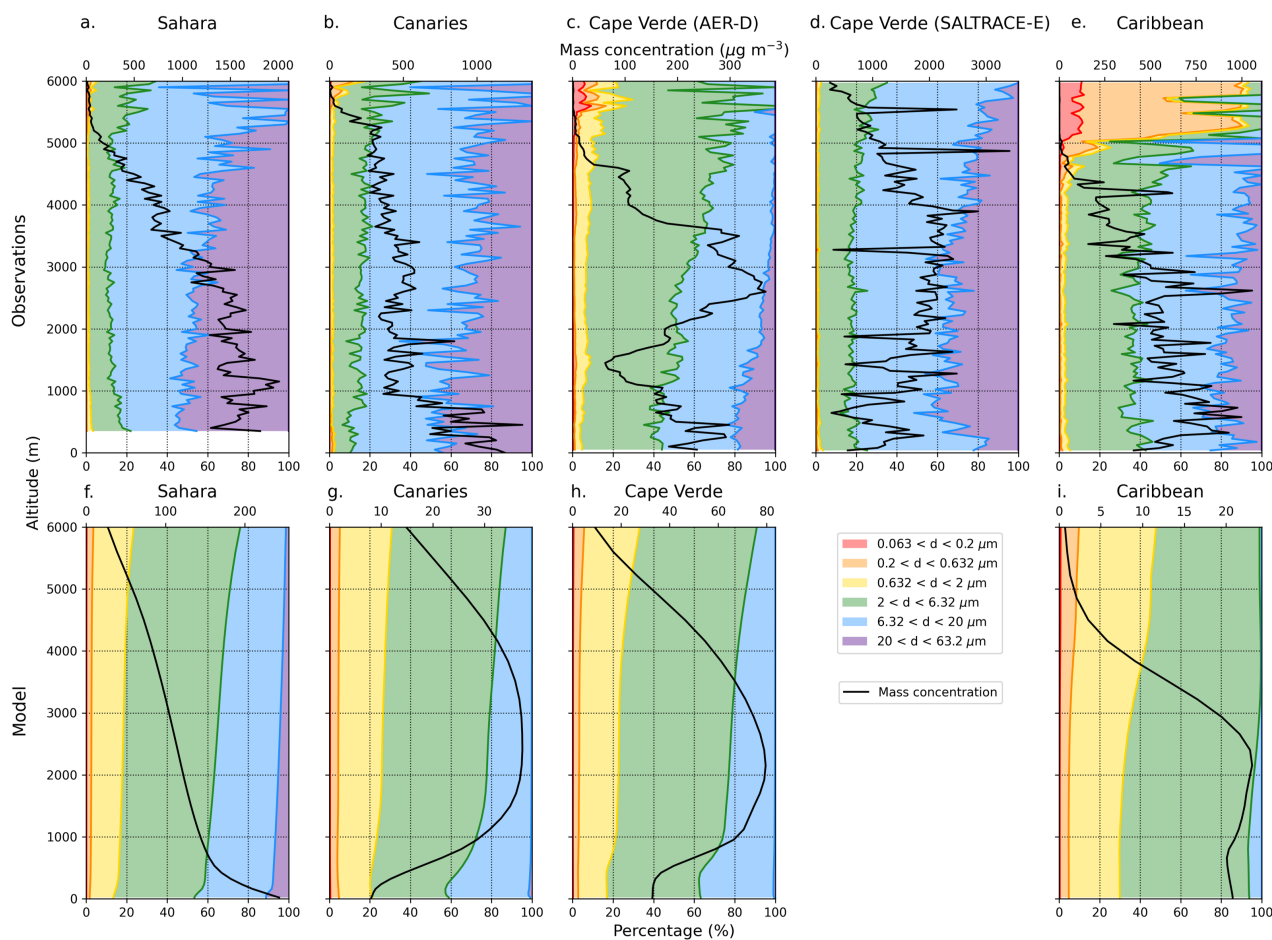

Figure 3. Dust mass concentration profiles, showing the total dust mass concentration in $\mu\text{g m}^{-3}$ (black line) and the percentage contribution of dust mass in the six model size bins (coloured areas). Plots include the mean profiles from the observations (top) and from the model (bottom) at the Sahara (Fennec; a and f), Canaries (Fennec; b and g), Cape Verde (AER-D and SALTRACE-E; c, d and h) and Caribbean (SALTRACE-W; e and i).

Table 8. Mean percentage mass contribution to total mass between 2-3.7 km altitude from the three coarsest model size bins at the Sahara, Canaries, Cape Verde (AER-D (A) and SALTRACE-E (S)) and Caribbean in the observations (Obs) and model. Data relates to Figure 3.

	Sahara		Canaries		Cape Verde			Caribbean	
	Obs	Model	Obs	Model	Obs (A)	Obs (S)	Model	Obs	Model
2-6.32 μm	10	46	14	52	49	17	55	34	64
6.32-20 μm	43	31	54	21	40	49	22	48	2
20-63.2 μm	46	4	30	0.2	4	34	0.1	15	9e-6

At the Sahara, up to 90 % of the observed dust mass up to 5 km comes from particles 6.32-63.2 μm in diameter (blue and purple; Figure 3a). As the dust moves westwards over the Atlantic, the contribution of these coarsest particles decreases as they are deposited from the dust plume. Between 2-3.7 km, the 6.32-63.2 μm contribution decreases from ~90 % at the Sahara to ~85 % at the Canaries, ~45 %-85 % at Cape Verde and ~63 % at the Caribbean (Table 8). As the coarser contribution decreases, the contribution of 2-6.32 μm particles (green) increases, while the contribution of the finest particles (0.063-2 μm ; red, orange and yellow) remains low up to the top of the SAL; less than 5 % at all locations except for Cape Verde during AER-D (Figure 3c). The coarse and super-coarse particles (blue and purple) show a higher dependence on altitude in the AER-D data, whereby their mass contribution is highest in the lowest 1 km at up to 60 % and decreases with altitude to half this contribution at 5 km. Fewer coarser particles were measured during the AER-D campaign, resulting in a higher contribution of 2-6.32 μm particles (green) compared to the other campaigns. The SALTRACE-E profile (Figure 3d) shows a similar structure to the Fennec observations, suggesting that the AER-D campaign is the more anomalous of the two datasets.

410

In general, the model overestimates the mass contribution from 0.063-6.32 μm dust particles (red, orange, yellow and green) and underestimates the 6.32-63.2 μm particle (blue and purple) contribution at all locations. At the Sahara, the modelled dust mass between 6.32-63.2 μm between 2-3.7 km accounts for 35 % of total mass, less than half of the observed contribution of ~89 % (Figure 3a and f). In the model, less than 15% of the contribution at the surface is made up of the coarsest particles (20-63.2 μm ; purple), decreasing to ~4 % between 2-3.7 km altitude, which is 10 times less than the observed contribution. The mass contribution of 20-63.2 μm particles (purple) in the model decreases quickly beyond the Sahara to become negligible. At the Canaries and Cape Verde, the vast majority of 20-63.2 μm particles have been removed between 2-3.7 km, leaving a contribution of less than 0.1-0.2% from this size bin, which is two orders of magnitude less than the observed contribution measured during Fennec and SALTRACE (Figure 3b, c, d, g and h; Table 8). Upon reaching the Caribbean, only a very small fraction of the mass comes from the 20-63.2 μm particles (purple), and the 6.32-20 μm (blue) contribution below 1 km is less than 10 % and only 2 % between 2-3.7 km. The rate at which the model is losing coarse and super-coarse particles is resulting in an increasing bias of particles smaller than 6 μm and thus an underestimation of the total dust mass remaining after long range transport.

425 From the Sahara, the modelled contribution of particles smaller than 2 μm (red, orange and yellow) is overestimated by a factor of 10, and up to 13, 3-12 and 9 at the Canaries, Cape Verde and Caribbean, respectively. This overestimation of the fine particle mass confirms that the model shows a bias towards fine particles over coarser particles.

In the two largest size bins, the model shows a decreasing percentage mass contribution with altitude (Figure 3). At the Canaries for example, the model 6.32-20 μm mass contribution (blue) drops from ~30 % at 1 km to ~15 % at 5 km. Whereas in the observations, only the coarsest size bin shows this altitude dependence, whereby the 20-63.2 μm particle contribution (purple) decreases with altitude: from ~50 % at 1 km to ~30 % at 5 km at the Sahara and from ~25 % at 1 km to ~10 % at 4 km at the Caribbean. Alternatively, the 6.32-20 μm contribution (blue) remains more consistent with altitude in the observations,

or showing an increasing relative contribution due to the decreased contribution of the 20-63.2 μm contribution (purple). Thus, where the model shows an altitude dependence in the percentage mass contribution of the coarse and super-coarse dust, the observations only show this dependence only visibly affects the super-coarse mass contribution (i.e. 20-63.2 μm).

The model represents the relative mass contribution of coarse and super-coarse particles as relatively height dependent, decreasing with altitude. However, the observations show little variation of coarse dust with height and a decreasing super-coarse dust contribution with height. The model fails to retain the super-coarse dust during trans-Atlantic transport and incorrectly represents the vertical distribution of coarse dust, with a bias towards lower altitudes.

4.2 Size distribution evolution

The height resolved modelled and observed volume size distributions have been normalised by total volume (Figure 4). This highlights the peak of the size distribution, and the difference in shape between the model and observations when the total concentrations are different. There are two things which are clear amongst all campaigns. Firstly, the shape of the distributions from the smallest size bin to the peak in volume; the model displays a broader shape, while the observations show a more steeply curved, peaking shape. Secondly, the modelled underestimation of volume in the largest size bin at all locations. Beginning at the Sahara, the difference is around one order of magnitude. Moving downwind, the difference between the model and observations continues to grow by orders of magnitude, such that the model volume distribution drops much more sharply to around 5 orders of magnitude less than the observations in size bin 6 (20-63.2 μm) by the Caribbean. At all locations (except for Cape Verde during AER-D) the observed volume in the 2-6.32 μm range is very similar in magnitude to the volume in the 20-63.2 μm range (i.e. size bins 4 and 6), whereas in the model, there is a notable drop from the fourth to the sixth size bin. The increasing difference between the model and observations at the coarsest range is an indication of rapid deposition of the coarser particles in the model. Not only do we see a growing difference with distance from the Sahara, but the underestimation of coarser dust volume at the Sahara suggests there may be an issue with the model emissions and/or vertical transport whereby not enough coarse and super-coarse particles are emitted and transported through the SABL. This underestimation is exacerbated through long range transport by the overly swift deposition of the coarser particles.

The model tends to peak in volume in the 2-6.32 μm bin, whereas the observations measured during the Fennec and SALTRACE campaigns peak in the next size bin up (6.32-20 μm). Contrary to the other campaigns, the volume distribution from the AER-D campaign at Cape Verde peaks in the 2-6.32 μm bin. As mentioned previously when observing the different vertical structure, this difference could be a consequence of the different time of year in which this campaign occurred. Despite the differences between the data collected from the AER-D campaign and the Fennec and SALTRACE campaigns, the AER-D data remains consistent with the other campaigns in showing that the model underestimates coarser dust particle mass and transport.

Observed and modelled normalised volume distribution

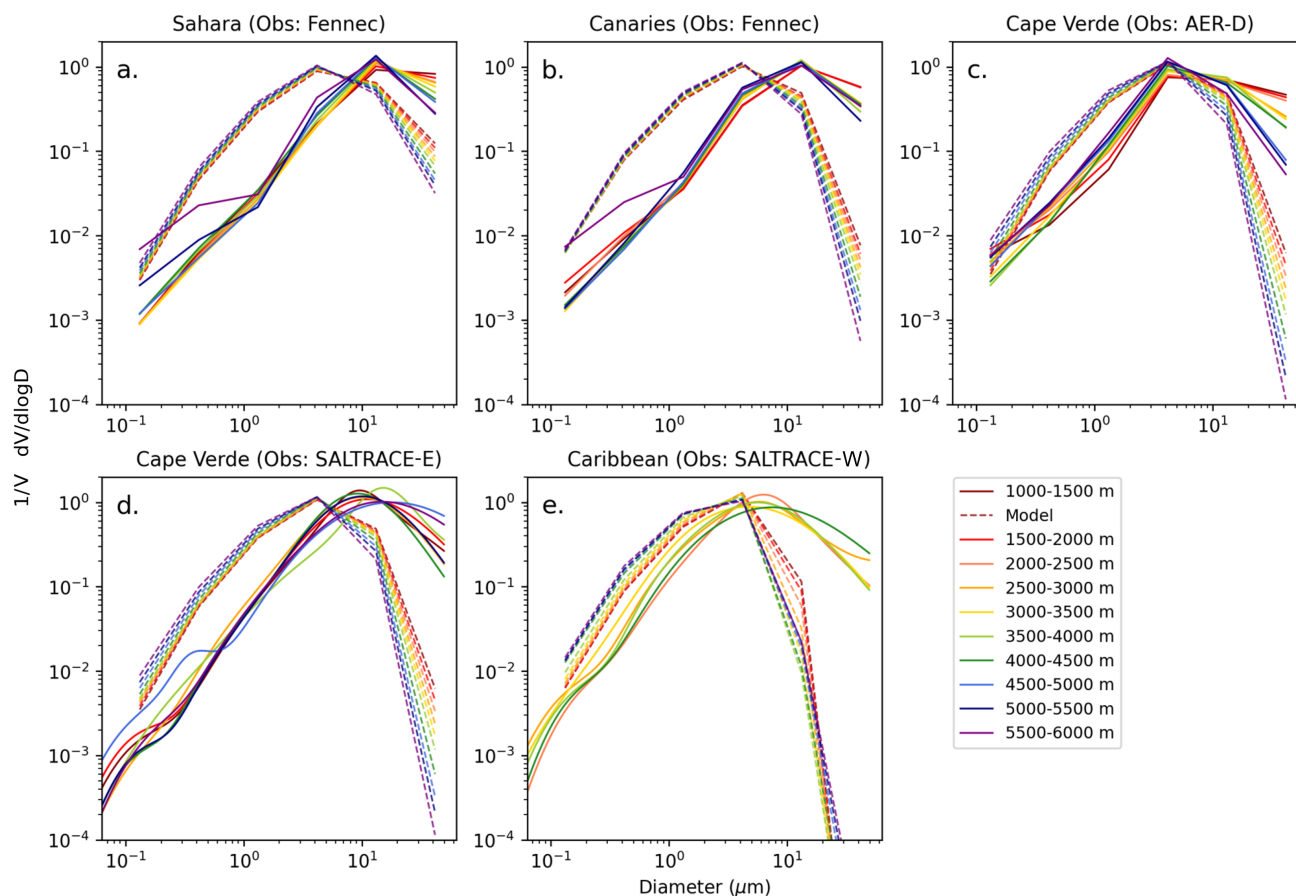

Figure 4. Vertically resolved modelled (dashed lines) and observed (solid lines) normalised volume distribution at the Sahara, Canary Islands (Fennec), Cape Verde (AER-D and SALTRACE-E) and Caribbean (SALTRACE-W) at different altitudes. The volume distributions have been normalised by the total particle volume.

When normalised, there is no particular pattern in relation to the altitude except for at coarsest size ranges, where dust volume tends to decrease with altitude in the model and observations. Otherwise, the shape of the distribution remains consistent with altitude. The only other exception being at high altitudes in the smallest size bin in the observations at the Sahara, Canary Islands and Cape Verde (Figure 4a, b and d). The volume distribution of fine 0.063-0.632 μm particles is greater above 5 km than at lower altitudes. This could be a signal of non-dust particles.

While no observations of vertically-resolved, size-resolved dust concentration over the mid-Atlantic exist, we are able to look at how the model simulates the concentration evolution across the Atlantic. Figure 5 shows the evolution of mass concen-

480 tration in each size bin from the Sahara to the Caribbean. Figure 5a shows the modelled mean June AOD as well as stippling which represents the 65th percentile of AOD between 1° S and 47° N at each longitude which has been used to identify the mean plume latitudinal extent. The 65th percentile of AOD was chosen so as to cover an area including all the observed locations. Figure 5b shows the modelled mass concentration in each of the six size bins in the defined dust plume location and between the 2-3.7 km altitude range. The 2-3.7 km altitude range has been selected to analyse the dust plume to minimise interference from the MBL and free troposphere above the SAL, across the entire Atlantic. Figure 5b shows that the 2-6.32 μm particles (green) are the dominant contributors to dust mass across the Atlantic in the model, as in Figure 3. Although the mass of 6.32-20 μm particles (blue) are double that of the 0.632-2 μm particles (red, orange and yellow) at the Sahara, these larger particles are removed more swiftly and have less mass than the finer particles west of Cape Verde (~25° W).

485

Figure 5c shows the normalised mass concentration transect in the six size bins. These have been normalised by their value at the Sahara (~3° W) to allow a direct comparison of the rate of change of mass concentration between each size bin. All size bins experience change in their mass concentration in two distinct regions, one over the African continent (15-3° W) and over the Atlantic, where each size bin loses mass at a size-dependent rate. These two distinct areas hint at the different processes which alter dust transport over land and ocean. The rate of loss of the four finest size bins (0.632-6.32 μm ; red-green) appears fairly linear; each size bin loses 70-80 % of its mass between the west African coast and the Caribbean. The rate of loss of the coarsest size bins (6.32-63.2 μm ; blue and purple) is sharper. These much faster rates of loss result in a negligible mass of 20-63.2 μm particles remaining shortly west of Cape Verde and of 6.32-20 μm particles remaining near the Caribbean.

490

5 Conclusions

495 Vertically resolved, in-situ observations from three aircraft campaigns, Fennec, AER-D and SALTRACE, at the Sahara, Canary Islands, Cape Verde and Caribbean are analysed together to understand the evolution of dust particle size distribution over long range transport, with a particular focus on the coarser particles and their vertical distribution. The observations from these campaigns are used to evaluate the Met Office Unified Model (MetUM) HadGEM3A-GA7.1 climate model representation of the dust size distribution across the Atlantic. This work presents the first time that all three of these campaigns have been used together and analysed in such high vertical resolution in order to understand the size distribution evolution from the Sahara to the Caribbean, as well as being the most extensive evaluation of the MetUM HadGEM3A-GA7.1 model representation of long range dust size distribution evolution.

500

We have shown that the ratio of coarser particles to total mass in a dust event is not dependent on AOD in the Fennec and AER-D observations. By splitting our campaign data into low, medium and high AOD events, we were able to confirm that the percentage mass contribution of coarser particles did not vary significantly between these differing AOD events. Thus, low, medium and high AOD events have a similar relative contribution of coarser particles to total mass.

505

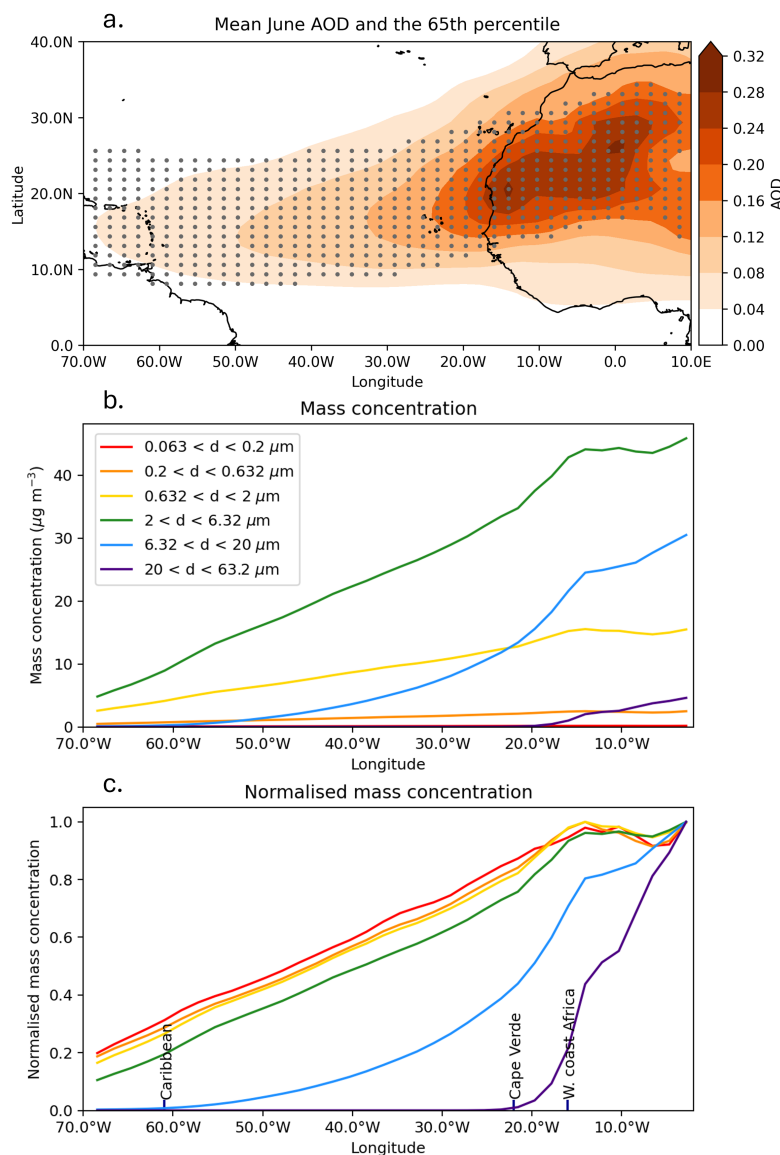

Figure 5. The 65th percentile (stippling) of mean June 2010-2014 AOD at 550 nm (orange shading) at each longitude has been used to locate the dust plume (a). The mean modelled dust mass concentration between 2.0-3.7 km altitude by longitude in the six CLASSIC size bins from the Sahara to the Caribbean (b). The binned concentrations have been normalised by the mass concentration in each bin at 3°W (c).

Aircraft observations from the Fennec, AER-D and SALTRACE campaigns show that coarser particles are being transported
 510 further than in the model, in which coarser dust particles (6.32-63.2 μm) are underestimated in both mass and volume size distribution at all stages of long range transport. At the Sahara, the model underestimates the normalized volume size distribution of the largest particles (20-63.2 μm) by more than one order of magnitude. The contribution of 20-63.2 μm particle mass to the

total mass is underestimated by a factor of 11 between 2-3.7 km altitude over the Sahara. These underestimations suggest either a challenge in representing the emitted size distribution, and/or a lack of immediate transport upwards through the atmosphere
515 after emission.

We find that the model underestimates the coarser particle volume distribution by increasing orders of magnitude with distance from the Sahara. The normalised volume size distribution in the largest model size bin (20-63.2 μm) is underestimated by up to 3 orders of magnitude at the Canaries, 4 at Cape Verde and 5 at the Caribbean. This increasing disparity between
520 the model and observations is a consequence of overly swift removal of coarse and super-coarse particles from the modelled atmosphere which is marked over the Sahara, and is exacerbated during long-range transport. The majority of 20-63.2 μm particles have been removed from the Saharan Air Layer (SAL) shortly west of Cape Verde, where the observations show this size bin still contributing up to 35% of the total mass between 2-3.7 km. The model's fifth size bin (6.32-20 μm) shows a
525 slightly slower rate of removal from the model, however still leaving a negligible concentration at the Caribbean, where the mass contributed by this size bin to the total dust mass is underestimated by a factor of 24 between 2-3.7 km. We suggest that the model is simulating far too swift deposition of particles sized larger than 6.32 μm during the full course of long range transport, leading to an increasing underestimation of dust mass with distance from the Sahara.

We have shown that the model generally agrees with the vertical distribution of total dust mass in the observations. We
530 show that the mass centroid altitude (MCA) in the model is consistently within range of the observations. However, we find an underestimation in super-coarse volume size distribution which increases with altitude, showing that the model increasingly struggles with coarser particle representation over long range horizontal and vertical transport, and despite representing the MCA of total dust mass, transports coarser dust particles too low in the atmosphere.

535 Our results are subject to some limitations. Firstly, it is noted that the aircraft observations used in this study cannot be fully representative of climatic conditions due to limitations in the temporal and spatial coverage of the observations. This makes our comparisons to the model more complex as the model provides daily mean data, covering each full 24 hour period. Additionally, we find that the AER-D data has a slightly different vertical distribution of dust compared to SALTRACE-E at Cape Verde, as well as a finer size distribution in comparison to the Fennec and SALTRACE campaigns, despite having consistent
540 instrumentation with the Fennec campaign. It is not exactly clear what causes this disparity, but it could be a consequence of the measurements being taken in August compared to the other campaigns which were conducted in June. Additionally, we note that we excluded observations for which $d > 63.2 \mu\text{m}$ since this is the maximum size represented by the model, which were significant in the Sahara observations. Finally, we must consider that any biases in the model's representation of the dust vertical and horizontal distribution, as well as the size distribution, could be due to either the dust scheme or to biases in the
545 modelled climate.

We have shown that the model has difficulty with representing the coarse dust size distribution from the Sahara to the West Atlantic. This is consistent with other studies which have evaluated a range of models on more restricted spatial and vertical scales (Adebisi and Kok, 2020; Ansmann et al., 2017; O'Sullivan et al., 2020). Incorrect representation of dust size distributions in climate models will result in erroneous dust radiative effects, impacts on clouds, and deposition of nutrients within dust to the ocean and land surfaces (Adebisi et al., 2023; Kok et al., 2017; Dansie et al., 2022). It is therefore important to understand and improve modelled dust size distributions. The discrepancy in size distribution could be due to over-active processes affecting the dust deposition, such as sedimentation, wet deposition, convection or turbulent mixing. It could also be a consequence of the dust not absorbing enough shortwave radiation (Colarco et al., 2014; Balkanski et al., 2021) and potentially affecting heating and therefore dust plume height or being lofted high enough after emission. Alternatively, this long range transport could be due to processes not considered in the model and not yet fully understood in practice, such as electric charging (van der Does et al., 2018; Toth III et al., 2020), asphericity (Huang et al., 2020, 2021; Saxby et al., 2018), turbulence (Denjean et al., 2016; Cornwell et al., 2021) and vertical mixing (Gasteiger et al., 2017). Whilst model dust concentration and size distribution near sources could be improved by re-tuning the emissions scheme, this is unlikely to affect the evolution of size distribution with transport, where additional processes are necessary to retain coarser particles, and should be investigated in further research along with size-resolved dust emissions.

This study presents an in-depth analysis of the evolution of the vertically resolved dust size distribution from the Sahara to the Caribbean. We show that the model underestimates super-coarse particles over the Sahara compared to observations, a difference which is exacerbated by orders of magnitude during trans-Atlantic transport. The work presented here demonstrates the need for thorough analysis of model processes affecting dust transport and deposition across the Atlantic.

Data availability. Aircraft data for the Fennec and AER-D campaigns are available at the Center for Environmental Data Archive at <https://dx.doi.org/10.5285/1f4555d2589841a8a4bbbf1fe42f54c8> and <http://catalogue.ceda.ac.uk/uuid/d7e02c75191a4515a28a208c8a069e70>, respectively. Aircraft data for the SALTRACE campaigns are currently in the process having a doi created. Data from the model simulation are available at <https://doi.org/10.5281/zenodo.10722717>

Author contributions. NGR, CLR and NB designed the research. NGR carried out the analysis and wrote the paper. CLR, NB, SW, BJ and AJ discussed the methodology and results. BW, LMW and JG provided the SALTRACE size distributions and profiles. All authors read and commented on the paper.

Competing interests. The authors declare that they have no conflict of interest.
