11
12 **Abstract:**

13 Coastal environments provide an ideal setting for investigating the intermixing
14 processes between terrestrial and marine aerosols. In this study, fine particulate matter
15 (PM_{2.5}) samples were collected from a coastal location in Northern China and
16 categorized into terrestrial, marine and mixed air masses. The chemical and
17 biological constituents, including water-soluble ions (WSIIs), metallic elements, and
18 bacterial and fungal aerosols, were investigated from January to March 2018.
19 Terrestrial air masses constituted 59.94% of the total air masses at the sampling
20 site throughout the period, with a significant increase during periods of severe haze
21 pollution (up to 90%). These air masses exhibited higher concentrations of PM_{2.5} (240
22 µg/m³) and carried more water-soluble ions and metal elements. The terrestrial air
23 mass also contained a greater number of animal parasites or symbionts, as well
24 as human pathogens from anthropogenic emissions, such as *Staphylococcus*,
25 *Deinococcus*, *Sphingomonas*, *Lactobacillus*, *Cladosporium* and *Malassezia*.

26 In contrast, saprophytic bacteria and fungi, including hydrocarbon-degrading
27 bacteria and gut bacteria from *Comamonas*, *Streptococcus*, *Novosphingobium*, and
28 *Aerococcus*, and *Aspergillus*, were the most prevalent species in the marine air mass.

29 The mixed air mass revealed the intermixing processes of terrestrial and marine sources,
30 resulting from microorganisms from anthropogenic and terrestrial emission, which
31 including pathogenic microorganisms from hospitals and sewage treatment plants, and
32 numerous soil bacteria. Correlation analysis indicated a stronger correlation between
33 microorganisms and continental elements in terrestrial and mixed air mass samples,
34 such as K^+ , Mg^{2+} , and Ca^{2+} from soil dust. Marine air masses contain a significant
35 quantity of saprophytic and intestinal microorganisms and exhibited a significant
36 correlation with sea salt ions, specifically Na^+ . In the mixed air mass sample, a fusion
37 of marine and terrestrial microorganisms is characterized by alterations in the ratio of
38 pathogenic to saprophytic microorganisms when compared to samples derived from
39 either terrestrial or marine sources. This study on the constituents and amalgamation of
40 bioaerosols over the coastal atmosphere encompassing distinct air masses is crucial for
41 understanding the transport, intermixing processes, and health implications of terrestrial
42 and marine air masses.

43 **Keywords:** PM_{2.5}, water-soluble ions, terrestrial air mass, marine air mass, bioaerosols

44 1. Introduction

45 Bioaerosols, encompassing bacteria, fungi, viruses, pollen, and cellular debris, etc.,
46 are vital aerosol particles in the atmosphere. Notably, bacterial aerosols which can be
47 either free-floating or attached to airborne particles, typically measure between 0.3 and
48 10 μm (Shen and Yao, 2023; Zhao et al., 2022). Such characteristics allow for extended
49 residence times and a heightened likelihood of long-distance transport from local to
50 distant regions within the atmospheric circulation (Galbán et al., 2021; Smets et al.,
51 2016). Fungal aerosols are prevalent in Earth's near-surface atmosphere, with their
52 origins being diversely found in water, soil, and plants (Janine et al., 2009).
53 Furthermore, the presence of pathogenic bacteria and fungi in the atmosphere may lead
54 to significant penetration efficiency within the human respiratory system (Fakunle et
55 al., 2021; Jiang et al., 2022).

56 Relevant studies have demonstrated that the bacterial and fungal concentration and
57 community structure are significantly influenced by emission sources, atmospheric
58 circulation, meteorological conditions, geographical and topographical factors (Liu et
59 al., 2021; Núñez et al., 2021; Li et al., 2019). The geographical and topographical
60 factors, such as terrestrial and marine environments exhibit significant
61 differences in bioaerosol sources and pollution characteristics. Studies focusing on
62 continental environments, particularly in large inland cities like Beijing (Zhang et al.,
63 2019; Zhang et al., 2022), Xi'an (Wang et al., 2020; Yao et al., 2019), Jinan (Wei et al.,
64 2020) , and Nanjing (Hu et al., 2020) during severe air pollution, have revealed that
65 continental pollutant emissions significantly contribute to air pollution. Furthermore,
66 transboundary transportation of terrestrial air masses on hazy days plays a crucial role
67 in the progression of regional heavy pollution (Xie et al., 2020). The ocean serves as
68 both a potential source and sink for airborne microorganisms (Archer et al., 2020;

69 Mayol et al., 2017), exhibiting the intricate interplay between continental communities
70 and their transmission across oceanic regions (Cho and Hwang, 2011; Deleon-
71 Rodriguez et al., 2013). Bioaerosols from the oceans maybe influenced by long-
72 distance transport from continental sources, such as plants and human pathogens
73 (Elbert et al., 2007; Sharoni et al., 2015). Studies have shown that the concentration and
74 diversity of bacterial and fungal aerosols from marine are typically lower than those
75 derived from continental sources (Cao et al., 2024; Xue et al., 2022; Shi et al., 2022).
76 Xu et al. (2019) undertook a thorough investigation of bacterial abundance in Mt. Tai,
77 China. Their findings indicate that variations in air mass from diverse sources could
78 potentially influence the chemical composition of PM_{2.5}. This in turn prompts shifts in
79 bacterial groups. Limited studies have examined the impacts of terrestrial and marine
80 air masses on chemical constituents and microbial aerosols (Shi et al., 2022; Aswini
81 and Hegde, 2021; Lang-Yona et al., 2022). Generally, the chemical aerosols can be
82 affected by various sources of air masses, which may include local aerosols or remotely
83 transported aerosols. However, it remains unclear whether different air trajectories
84 contribute to the formation of bacterial communities within these particles. There is a
85 dearth of research focused on determining the chemical and biological composition of
86 coastal cities affected by these air masses.

87 Marine microbial aerosols can be released from ocean micro-surface or transported
88 from land (Prospero et al., 2005) and settle thousands of kilometers away from their
89 source of release (Mayol et al., 2014), exerting significant impacts on ecological and
90 climate systems. Gong et al (2020a) conducted an examination of the microbial
91 composition along Qingdao's coastlines, revealing a higher proportion of bacteria to
92 total microorganisms in samples from continental sources compared to marine
93 sources. Some marine bacteria persist in aerosols after land transportation, Xu et al

94 (2020b) studied the diversity of bacterial populations in PM_{2.5} across urban and rural
95 areas of Shanghai, finding that airborne microbial communities over coastal cities
96 are more influenced by long-distance transport than those inland. Air samples taken at
97 high altitude zones in coastal Europe and Japan demonstrated the continental
98 transportation of marine microorganisms (Maki et al., 2014). The introduction of
99 marine bacteria into tropospheric free space may modify the airborne microbial
100 composition in continental regions (Cho and Hwang, 2011; Amato et al., 2007; Maki et
101 al., 2014; Polymenakou et al., 2008; Cáliz et al., 2018). **Consequently, it is imperative
102 to ascertain the impact of terrestrial and marine air masses on the composition of
103 atmospheric microorganisms, with a particular focus on the influence of the mixing
104 process between terrestrial and marine air masses on bioaerosols. The coastal aerosols
105 provide the ideal conditions for understanding the mixing processes taking place
106 between natural and anthropogenic air masses from terrestrial and marine.**

107 Weihai, a coastal city situated at the confluence of eastern Asia continent and the
108 Northwest Pacific Ocean, is prone to the impact of marine and terrestrial air masses.
109 Typically, Weihai maintains low pollutant emissions with an annual average PM_{2.5}
110 concentration below 35 µg /m³. However, in winter and spring, regional air pollution
111 intensifies, leading to severe air quality issues. This is due to increased inter-regional
112 transportation, resulting in daily average PM_{2.5} concentration greater than 150 µg/m³
113 (Wei et al., 2020). In this study, we conducted an integrated atmospheric observation
114 experiment to examine the potential impact of terrestrial and marine air-mass on the
115 constituents and amalgamation of bioaerosols over the coastal atmosphere. This
116 approach allows for a comprehensive exploration of the effects of sea-land air mass
117 exchange on the spatial and temporal distribution of aerosols, as well as potential
118 intermixing processes in coastal regions.

119 2. Materials and methods

120 2.1 Sample collection

121 The sampling site was situated at the national air sampling station (37.53°N,
122 122.06°E), 41 m above sea level, and approximately 1-2 km from the coast, (Fig. S1).
123 The sampling platform was about 15 m above ground level, and devoid of any
124 significant obstructions. PM_{2.5} samples were gathered between January to March, 2018,
125 during the winter heating and spring dust seasons in northern China. Two parallel PM_{2.5}
126 samplers (TH-150C-III, Wuhan Tianhong Instrument Co., Ltd., China) with a particle
127 size of 2.5 ± 0.2 μm were utilized equipped with Quartz membrane for the collection
128 of PM_{2.5}, inorganic ion, metal elements, and microorganisms at a flow rate of 100 L
129 min⁻¹. The Quartz membranes were cauterized in a muffle furnace at 450°C for 6 hours
130 to remove carbonaceous and contaminant materials. Intermittent sampling was used
131 and samples were collected twice a day (7:00~18:30 and 19:00~06:30 the following
132 day). During the sampling process, the pre-weighed filter membrane was carefully
133 positioned onto the filter mesh within a clean sampling folder using tweezers. The
134 membrane's rough side should be oriented towards the direction of air intake, and it
135 should be firmly pressed until there is no detectable air leakage. Prior to membrane
136 replacement, the membrane tray should be wiped with alcohol cotton and dried. After
137 sampling, it should be removed using tweezers. Blank samples were procured by
138 putting the membrane into the sampler head without initiating the sampler. After
139 sampling, the blank samples were extracted simultaneously with the collected sample
140 membrane. All samples were then placed in a sterile filter cassette, encased in clean
141 aluminum foil, and stored at -80°C until further analysis. During the whole sampling
142 period from January 1 to March 31, a total of 102 PM_{2.5} samples over 51 days were

143 obtained, out of which 24 samples were chosen for subsequent analysis based on
144 air mass categories. Meteorological parameters, such as air temperature, relative
145 humidity, wind direction, and wind speed, were monitored in situ utilizing a PC-4
146 automatic weather station (PC-4, JZYG, China). The hourly concentrations of PM_{2.5},
147 PM₁₀, CO, SO₂, NO₂, and O₃ were systematically retrieved from the National Ambient
148 Air Quality Monitoring System (<http://www.cnemc.cn/>).

149 The mass concentration of PM_{2.5}, water-soluble ions, and metal elements were
150 quantified after sampling. The membranes were meticulously weighed utilizing a
151 Mettler XP-6 balance with an accuracy of 10⁻⁶ g. Prior to the weighing, the membranes
152 were maintained in a controlled environment with consistent temperature and humidity
153 for a duration of 24 hours. Ion chromatography (ICS-2100, Chameleon 6. 8, AS-DV
154 autosampler Thermo Fisher) was employed to determine the concentration of water-
155 soluble ions such as Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻, NO₃⁻, SO₄²⁻, and NH₄⁺. These ions were
156 extracted by sonication with ionized water for 45 min and then separated by anion
157 (IonPacAS23) or cation column exchange (IonPacCS12A). Then, these ions were
158 detected using a conductivity detector with an anion separation column of IonPacAS23,
159 flow rate: 1.0 mL/min, an anion suppressor of AERS500, and conductivity detector. The
160 injection volume was 25 μL, and the cation separation column was IonPacCS12A, flow
161 rate:1.0 mL/min, cation suppressor was CERS500 (Zhang et al., 2022). Metallic
162 elementals including Al, Fe, Ti, Mn, Co, Ni, Cu, Zn, Ga, Sr, Cd, Sn, Sb, Pb, V, Cr, and
163 As, were extracted using microwave digestion extraction (ETHOS ONE, Milestone),
164 with the concentrations determined by ICP-MS or ICP-OES (Thermo Fisher).

165 2.2 Air mass clustering and classification

166 The potential sources and transportation of air mass were examined using the

167 Meteoinfo backward trajectory model ([MeteoInfo 3.7.4 – Java,](#)
168 <http://www.meteothink.org/downloads/index.html>) developed by the Chinese Academy
169 of Meteorological Sciences. Backward trajectories were simulated one-hour intervals
170 and estimated over a 24-hour period. The meteorological data were sourced from
171 GDAS1 (<ftp://arlftp.arlhq.noaa.gov/pub/archives/gdas1/>). Backward trajectories of air
172 masses at an altitude of 500 meters were categorized and clustered, with daily plots
173 illustrating these trajectories. **In this study, air mass categories were defined that if more**
174 **than 90% of the masses originated from the ocean it was a typical sample affected by**
175 **marine air-mass; a typical terrestrial air-mass sample if more than 90% originated from**
176 **the continent; and mixed air-mass sample if the proportions of terrestrial and marine air**
177 **masses were similar or accounted for more than 40% of the total air masses in one day.**

178 **2.3 DNA extraction and qPCR amplification**

179 Microbial genomic DNA were procured from filters utilizing the Fast-DNA™ SPIN
180 kit for soil (MoBio Laboratories, Carlsbad, CA, USA). The concentration and quality
181 of the extracted DNA was measured via a Nanodrop spectrometer (Nanodrop 2000,
182 Thermo Scientific USA). **The DNA concentration in the collected samples ranged from**
183 **10 to 20 ng/μL, satisfying the prerequisites for subsequent PCR amplification.** The
184 quantitative polymerase chain reaction (qPCR) was employed to identify bacterial 16S
185 rRNA and fungal ITS gene copy numbers, as well as to estimate the count of bacteria
186 and fungi per cubic meter of air. The bacterial 16S V3-V4 variable region was selected
187 for PCR amplification using primer 338F (5'-ATCTACGGGGGGCAGCAG-3') and
188 806R (5'GGACTACHVGGGTWTCTAAT-3') (Masoud et al., 2011). The fungal ITS
189 region were amplified using the primers ITS1 (5'-CTTGGTCATTTAGAGGAAGTAA-
190 3') and ITS2 (5'-GCTGCGTTCTTCATCGATGC-3') (Liu et al., 2021).

191 The PCR amplification conditions comprised an initial denaturation at 95°C
192 for 5 minutes, succeeded by 30 seconds at 95°C, 30 seconds at 50°C, and then 35 cycles
193 at 72°C for 40 seconds, followed by a final extension at 72°C for seven minutes to
194 ensure comprehensive amplification. Fluorescent signals were gathered during this
195 extension phase. For each sample, qPCR was conducted in triplicate, with ultrapure
196 water serving as a negative control to identify potential PCR contamination. Standard
197 curves were constructed using *E. coli* harboring the 16S rRNA gene and *Streptomyces*
198 plasmids containing the ITS gene. Additionally, gradient dilutions of these plasmids
199 were performed, ranging from 10²-10⁷ copies/μL. The FTC-3000 real-time quantitative
200 PCR system was employed for standard curve construction and data processing.

201 **2.4 16S rRNA and ITS gene sequencing and data processing**

202 The V3-V4 region of the bacterial 16S rRNA and the fungal ITS1 gene were targeted
203 for PCR amplification utilizing barcode-specific primers 338F-806R and ITS1F-ITS2,
204 respectively. To ensure optimal amplification efficiency and precision, a high-fidelity
205 enzyme (Phusion® High Fidelity PCR Master Mix from NewEngland Biolabs) in
206 conjunction with GC buffer was employed during PCR amplification.
207 This procedure entailed a pre-denaturation step at 98°C for one minute, followed by 30
208 cycles of 98°C for ten seconds; 58°C for bacteria (56°C for fungi) for 30
209 seconds; and 72°C for an additional 30 seconds, with a final extension at 72°C for five
210 minutes. Following amplification, samples were purified using the Agencourt Ampure
211 XP kit (from Beckman Coulter, Brea, CA, USA). Subsequently, the purified samples
212 were combined to achieve equimolar concentrations and analyzed on the Illumina
213 MiSeq PE300 platform (Illumina, Inc. in San Diego, CA).

214 Following sequencing, the barcode sequences were extracted and subsequently

215 stored in fastq format utilizing the QIIME toolkit (Caporaso et al., 2010). Sequences
216 shorter than 200 base pairs, with mass of less than 25, and containing ambiguous bases
217 underwent quality control screening using Trimmomatic (Bolger et al., 2014) and
218 Mothur (Schloss et al., 2009). The assembled sequences were then de-duplicated and
219 trimmed to equal length. De-chimerized sequences were eliminated (Edgar, 2013), and
220 sequences were clustered into operational taxonomic units (OTUs) using UPARSE at a
221 97% identity threshold. Subsequently, individual OTUs were removed. Taxonomic
222 assignments were determined using a Basic Local Comparison Search Tool (BLAST)
223 search against the bacterial SILVA taxonomy release 138.2 dataset and fungal UNITE
224 ITS reference v8.0 dataset. The original raw sequences were deposited in the Sequence
225 Read Archive under the accession number PRJNA1096829.

226 **2.5 Statistical analysis**

227 Bacterial community functional was conducted using FAPROTAX, a manually
228 constructed database that maps prokaryotic taxa to metabolic or other ecologically
229 functions, such as sulfur, nitrogen, hydrogen, and carbon cycling (Chen et al., 2022).
230 FUNGuild (Fungi Functional Guild) was used to predict the fungal ecological function.
231 This tool could classify and analyze fungal communities by the microecological guild
232 based on current published literature or data from authoritative websites to classify
233 fungi functionally (Nguyen et al., 2016). Three primary groups are obtained based on
234 the nutritional mode: Pathotroph, Symbiotroph, and Saprotroph. Samples affected by
235 different airmasses were examined for intergroup species variability, based on
236 community abundance data. This was achieved using rigorous statistical methods to
237 identify species demonstrating differences in abundance within the microbial
238 communities of different groups, and hypothesis testing to evaluate the significance of

239 these observed differences. Statistical analysis, including Analysis of variance
240 (ANOVA) and Kruskal Wallis tests, were employed to discern bacteria and fungi with
241 varying abundances between samples and groups. A p value less than 0.05 or 0.01 was
242 considered significant. ANOVA was used to analyze variation in a response variable
243 measured under conditions defined by discrete factors (Martin G. Larson, 2008). The
244 Kruskal-Wallis test determines whether there is a statistically significant difference
245 between the medians of three or more independent groups (Kassambara, 2019). **The**
246 **Mantel analysis was utilized to reveal the correlation between microbial community**
247 **and various environmental factors. The Pearson's r coefficient at $p < 0.05$ and $p < 0.01$**
248 **indicates the significant correlation.**

249 **3. Results**

250 **3.1 Air masses categorization and typical pollution processes**

251 The Meteolnfo backward trajectory model was employed to simulate the trajectories
252 of air masses at an altitude of 500 m in Weihai over 24-hour period,
253 identifying and classifying potential sources of air mass transport (Fig. S1). **The**
254 **terrestrial air mass accounted for 59.94% of the total air masses at the sampling**
255 **site throughout the period, exhibiting an average $PM_{2.5}$ concentration of 36.15 ± 26.52**
256 **$\mu g/m^3$.** Severe air pollution episodes occurred on January 20, with $PM_{2.5}$ was the
257 primary pollutant and the concentration reaching $240 \mu g/m^3$. During regional haze
258 pollution, the terrestrial air masses primarily influenced Weihai were typically
259 originating from the Beijing-Tianjin-Hebei region and the surrounding areas. The
260 primary contributors to emissions in the terrestrial air mass of this region are the dense
261 population, industrial and agricultural activities. The impact of the spring dust is mainly
262 reflected in the primary pollutant PM_{10} on March 30. **A significant increase in PM_{10}**

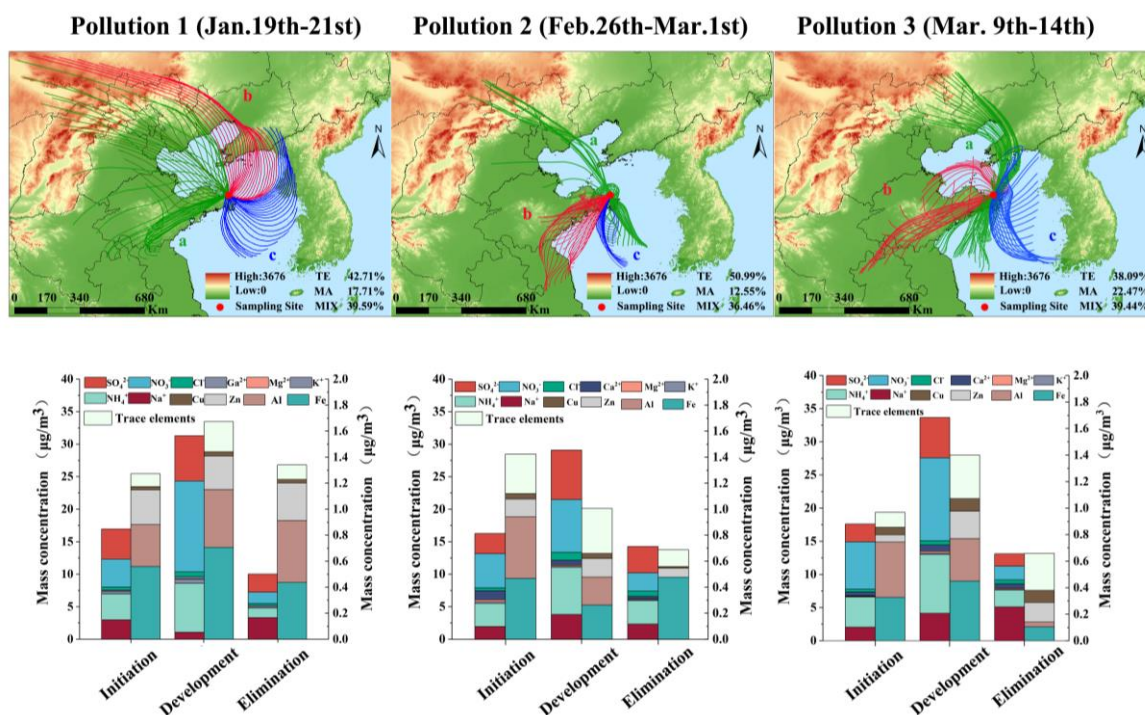

263 concentration was observed on March 30, with an hourly maximum value of $197 \mu\text{g}/\text{m}^3$.

264 A relatively low $\text{PM}_{2.5}/\text{PM}_{10}$ ratio of 0.28 indicated pronounced dust pollution.

265 The typical marine air masses mainly from the eastern and southern areas from the
266 Yellow Sea and the western Pacific edge. Marine air masses from northern areas partly
267 come from the Bohai Sea, crossing inland areas and possibly making contact with the
268 land prior to reaching the study area (Fig. S1). A total of 14% of the sampling days were
269 influenced by marine air masses, resulting in an average $\text{PM}_{2.5}$ concentration of
270 $23.99 \pm 11.00 \mu\text{g}/\text{m}^3$. Mixed air masses, characterized by simultaneous influence from
271 the northwestern winds of Inner Mongolia and the offshore air masses of the Bohai Sea
272 or Yellow Sea, accounted for 27% of all affected sampling days. These mixed air masses
273 yielded an average $\text{PM}_{2.5}$ concentration of $45.11 \pm 12.69 \mu\text{g}/\text{m}^3$. In comparison, under
274 the influence of mixed air masses, pollutant concentrations were notably high. During
275 the spring dust season, there is a notable increase in the proportion of mixed air mass.
276 This elevated concentration of particulate matter correlates with the transmission of
277 sand dust (Xie et al., 2020).

278 Three heavy pollution episodes were examined to investigate air mass shifts during
279 pollution (Fig. 1, Fig. S2). Generally, the initiation and development stages of pollution
280 events were predominantly characterized by terrestrial and mixed air masses. Cold
281 northwestern airmass form the continent, and marine air masses were the primary
282 contributors during pollution mitigation. For pollution episode I occurred from January
283 19 to January 22, the western terrestrial air mass was predominantly responsible for
284 initiating the pollution, evidenced by a $\text{PM}_{2.5}$ concentration of $51.35 \mu\text{g}/\text{m}^3$. As the
285 pollution progressed, it transitioned into a mixed air mass with a $\text{PM}_{2.5}$ concentration
286 peaking at $240 \mu\text{g}/\text{m}^3$. This change was accompanied by significant increases in WSIs
287 and elemental concentrations. Pollution elimination was initiated with high winds,

288 snowfall influenced by the cold northwestern airmass from the continent and marine air
 289 masses from the northeast sea. An average PM_{2.5} concentration reduction to 7.92 μg/m³,
 290 with lower WSIs and elemental concentrations.

291
 292 **Fig. 1** Transformation of terrestrial and marine air masses, and chemical composition in
 293 PM_{2.5} of three severe air pollution episodes. a, pollution initiation; b, pollution development;
 294 c, pollution elimination. TE, terrestrial air mass; MA, marine air mass; MIX, mix air mass.
 295

296 3.2 Water-soluble ions and metal elements over coastal atmosphere

297 During the sampling period, the daily concentration of water-soluble ions in PM_{2.5}
 298 was 22.92±12.19 μg/m³, ranging from 4.58 to 78.14 μg/m³. In marine air-mass samples,
 299 a lower concentration of water-soluble ions was observed, with the concentration of
 300 13.01±7.43 μg/m³, 27.94±13.61 μg/m³ and 30.38±11.38 μg/m³ in marine, terrestrial and
 301 mixed air masses, respectively. Notably, NO₃⁻ had the highest concentration (26.94%,
 302 6.4%~52.6%), succeeded by SO₄²⁻ (21.94%, 9.4%~33.4%) and NH₄⁺ (20.26%,
 303 5.8%~35.6%). The concentration of SO₄²⁻, NO₃⁻ and NH₄⁺, constituted the majority of

304 total ion in other studies conducted in Beijing, Shanghai, and Guangzhou (Pathak et al.,
305 2008; Hu et al., 2014; Zhou et al., 2012). These inorganic secondary ions were
306 significantly influenced by both terrestrial and mixed air masses, with the latter
307 exhibiting a more pronounced effect (NO_3^- , $10.65 \pm 3.26 \mu\text{g}/\text{m}^3$; NH_4^+ , $7.39 \pm 3.30 \mu\text{g}/\text{m}^3$;
308 SO_4^{2-} $6.76 \pm 1.77 \mu\text{g}/\text{m}^3$) (Fig. S3).

309 A high concentration of Na^+ was observed, with a range that from $3.15 \pm 1.69 \mu\text{g}/\text{m}^3$,
310 which accounted for 14.47% of the total water-soluble ion. The concentration of Na^+
311 and Mg^{2+} exhibited analogous trends across terrestrial, marine, and mixed air mass
312 samples. The ratio of $\text{Mg}^{2+}/\text{Na}^+$, typical components of sea salt, was determined to be
313 0.11. This value closely corresponded to the 0.12 found in seawater, indicating a
314 potential origin from marine environments (Sun et al., 2022). The concentration of K^+
315 $0.24 \pm 0.20 \mu\text{g}/\text{m}^3$ and $0.26 \pm 0.10 \mu\text{g}/\text{m}^3$ in the terrestrial and mixed air-mass samples,
316 and was twice as high as those in the marine air-mass samples ($0.11 \pm 0.05 \mu\text{g}/\text{m}^3$), which
317 suggested an important contribution from anthropogenic emissions. The concentration
318 of Cl^- , and Ca^{2+} was high in terrestrial and mixed air mass samples. Generally, these
319 two ions mostly come from anthropogenic or terrestrial environments, such as Cl^-
320 mainly comes from sea salt, coal and biomass combustion, and Ca^{2+} is a crustal element
321 associated with soil dust and sandstorms (Liang et al., 2021). Overall, from the
322 composition and concentration of water-soluble ions in $\text{PM}_{2.5}$, the coastal city was more
323 affected by sea salt, coal combination in winter heating season and dust events in early
324 spring.

325 The elements concentration in different air-mass samples are depicted in Fig. S3. The
326 top ten elements were found to be Fe, Al, Zn, Cu, Sn, Pb, Mn, Ti, Ni, and V. These metal
327 elements were categorized into macro and trace elements. The macro metals,
328 specifically Iron (Fe), Aluminum (Al), and Zinc (Zn), constituted a significant

329 proportion of the total heavy metal elements, accounting for 34%, 25%, and 23%
330 respectively. In general, the concentration of both macro and trace metal elements in
331 marine air masses was found to be lower than that in terrestrial and mixed air masses.
332 The V/Ni ratio in marine air-mass samples was found to be 0.78, a value significantly
333 higher than that of both terrestrial and mixed air masses. The V/Ni ratio is employed as
334 a measure of the influence of ship emissions. A ratio exceeding 0.7 typically indicates
335 a significant impact from these emission sources, and is commonly used as an indicator
336 in coastal cities (Zhang et al., 2014).

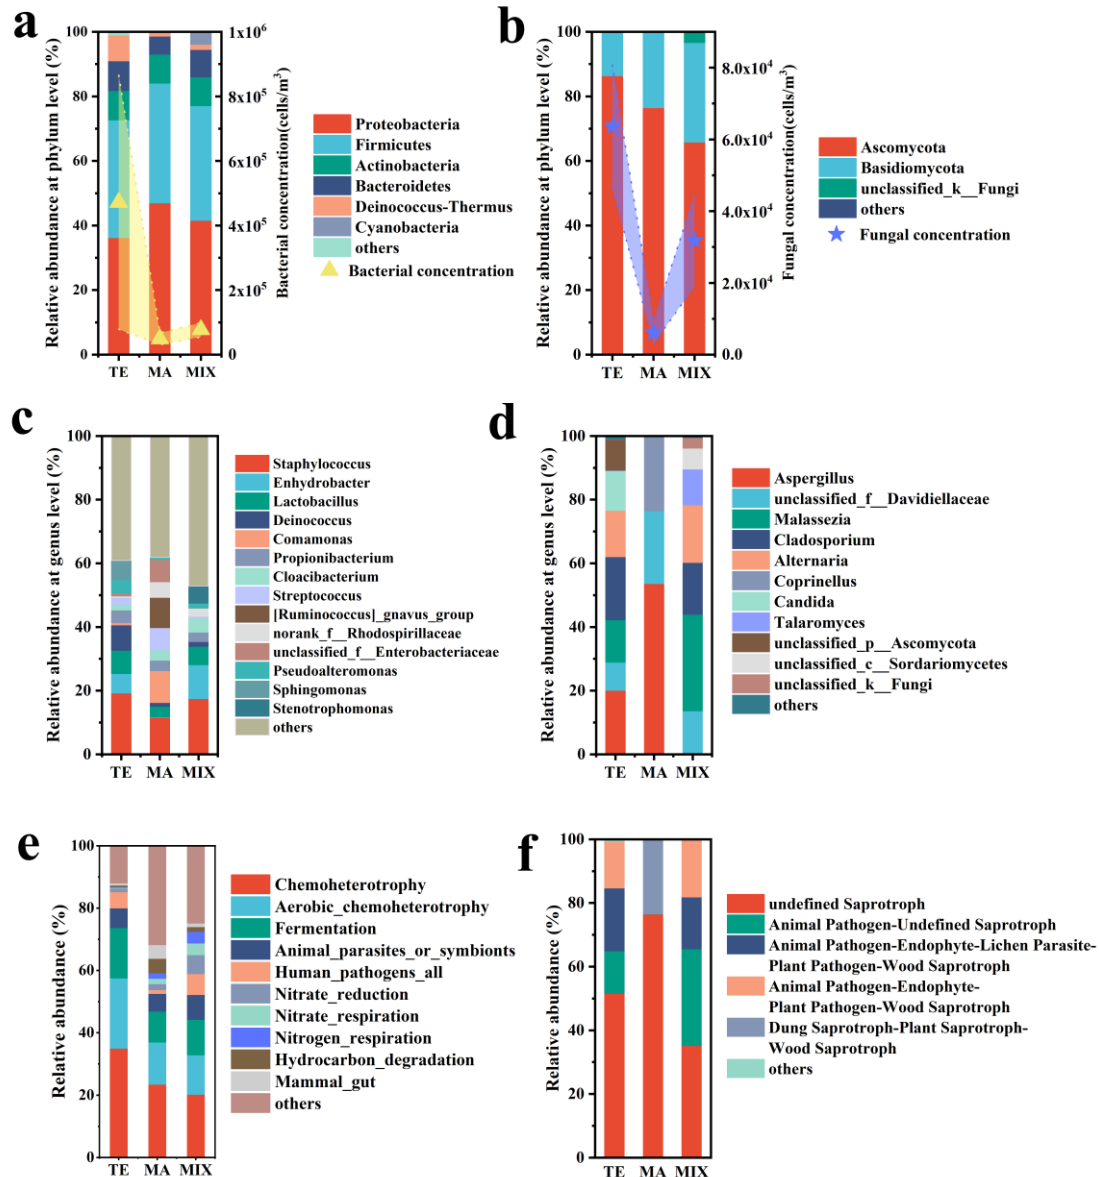

337 3.3 Microbial community over coastal atmosphere

338 Airborne bacterial and fungal concentration in PM_{2.5} were $1.99 \pm 1.46 \times 10^5$ cells/m³
339 ($P=0.06$) and $3.39 \pm 1.10 \times 10^4$ cells/m³ ($P=0.04$), respectively. This value was
340 comparable to the mean abundance of bacterial and fungal spores in the atmospheric
341 boundary layer over land, which is approximately 1.9×10^4 cells/m³ and 2.4×10^4
342 cells/m³, respectively (Spracklen and Heald, 2014; Mayol et al., 2014). A high
343 concentration was observed in terrestrial air-mass samples, with the average value of
344 $4.72 \pm 3.93 \times 10^5$ cells/m³ ($P=0.12$) and $6.37 \pm 1.70 \times 10^4$ cells/m³ ($P=0.007$) for bacteria
345 and fungi, respectively. Microbial concentration in marine air-mass samples was
346 significantly lower, with the average concentrations of bacteria and fungi being
347 $4.91 \pm 1.82 \times 10^4$ cells/m³ ($P=0.04$) and $6.15 \pm 3.09 \times 10^3$ cells/m³ ($P=0.07$).

348 Airborne microbial community structure exhibited significant variation influenced
349 by marine and terrestrial air masses (Fig. 2). Predominantly, *Proteobacteria* (40.06%),
350 *Firmicutes* (36.30%), *Actinobacteria* (8.97%), *Bacteroidetes* (8.29%), and
351 *Deinococcus-Thermus* (4.59%) were identified as the most abundant bacteria. Notably,
352 *Actinobacteria* and *Deinococcus-Thermus* were found in high concentration in samples

353 from terrestrial air masses. In particular, *Deinococcus-Thermus* demonstrated a relative
354 abundance of 7.9% in terrestrial air mass samples, significantly surpassing that of
355 marine (1.2%) and mixed air mass samples (1.5%). *Cyanobacteria* exhibit a higher
356 concentration in both terrestrial and mixed air-mass samples. *Cyanobacteria* are
357 prevalent in freshwater, soil, surface crusts in deserts (Cordeiro et al., 2020; Temraleeva
358 et al., 2016; Curren and Leong, 2020). In comparison to terrestrial environments, the
359 prevalence of *Cyanobacteria* is notably diminished in colder marine environments
360 (Koh et al., 2012). Atmospheric *Cyanobacteria* in the coastal city may originate from
361 the terrestrial environment, subsequently transported via terrestrial and mixed air
362 masses. *Proteobacteria* was the most prevalent taxon in marine air-mass samples. The
363 predominant metabolic activity in deep-sea sediments is attributed to this group, with
364 major taxa being found in marine sediments (Huang et al., 2021). The predominant
365 bacterial genera included *Staphylococcus* (21.02%), *Enhydrobacter* (6.43%),
366 *Lactobacillus* (6.03%), and *Deinococcus* (4.56%). These bacteria including a series of
367 opportunistic pathogens and were found abundant in terrestrial and mixed air masses
368 samples. Relative abundance of bacteria such as *Comamonas*, *Streptococcus*,
369 *Ruminococcus*, and *Enterobacteriaceae* were higher in marine air-mass samples. These
370 predominantly consisted of saprophytic bacteria and intestinal microorganisms.

371 The dominant fungal phyla were *Ascomycota* (77.29%) and *Basidiomycota* (21.58%),
372 which were similar to the previously studies (Du et al., 2018; Liu et al., 2019; Zeng et
373 al., 2019). Fungal community influenced by terrestrial and mixed air masses were quite
374 similar, with relatively higher abundances of opportunistic pathogens such as
375 *Malassezia*, *Alternaria*, *Cladosporium*. In contrast the saprophytic *Aspergillus*,
376 *Davidiellaceae* and *Coprinellus* were abundant in marine air-mass samples.

377

378 **Fig. 2. Bacterial and fungal community composition and function influenced by different air**
 379 **masses. The community concentration, main phylum (a), (b), genus (c), (d), and community**
 380 **function (e), (f) are indicated.**

381

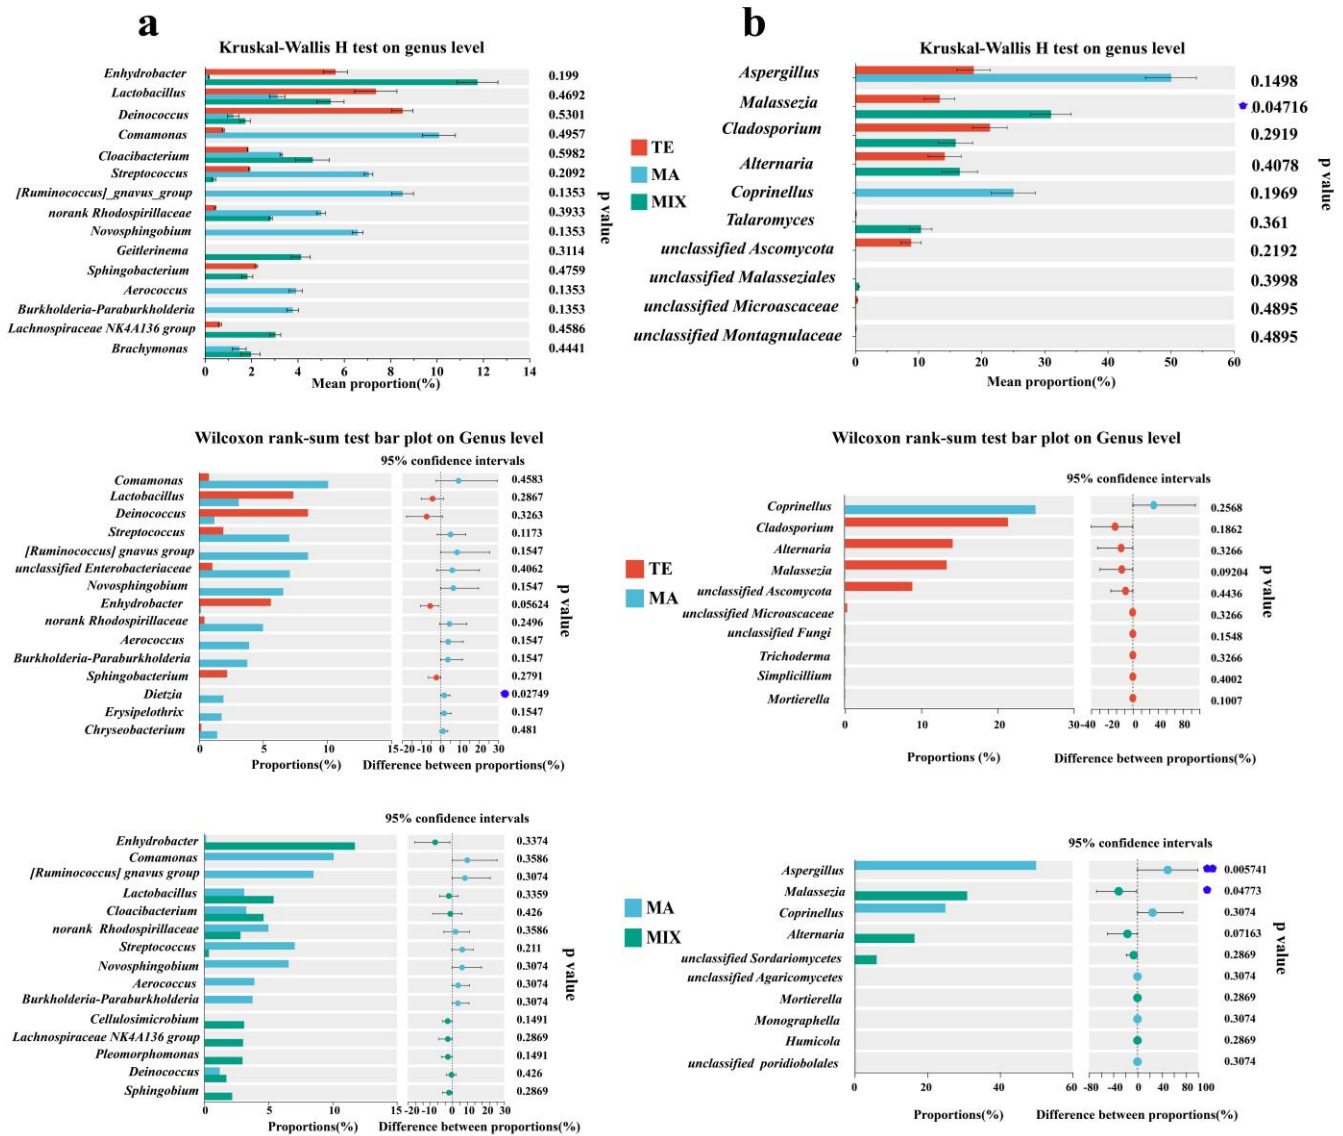

382 The FAPROTAX analysis revealed that the primary bacterial ecological functions
 383 were chemoheterotrophy, aerobic chemoheterotrophy, fermentation, and human
 384 pathogens. These accounted for 74%, 47%, and 44% respectively in terrestrial, marine,
 385 and mixed air-mass samples. Notably, human pathogens and animal parasites or
 386 symbionts were more prevalent in terrestrial and mixed air-mass samples than in marine
 387 air-mass samples. Marine air-mass samples were enriched with mammal gut bacteria,

388 as well as hydrocarbon and automatic compound degradation bacteria. The fungal
389 community function in terrestrial and mixed air-mass samples were similar, with
390 undefined Saprotroph, Animal Pathogen-Undefined Saprotroph, Animal Pathogen-
391 Endophyte-Lichen Parasite, Animal Pathogen-Endophyte-Plant Pathogen were the
392 main functions, which totaled 99.27%, 99.98%, 99.27% in the terrestrial, marine, and
393 mixed air-mass samples. In particular, the prevalence of Saprotroph fungi was observed
394 higher in samples from marine air masses, such as those containing *Aspergillus*. Notably,
395 the fungi associated with terrestrial air masses predominantly carried animal pathogens
396 and exhibited greater pathogenicity, including species such as *Malassezia* and
397 *Alternaria*.

398 **4. Discussion**

399 **4.1 Community disparities influenced by terrestrial and marine air masses**

400 Overall, bacterial and fungal community concentration influenced by terrestrial and
401 mixed air masses were higher than those in marine air mass samples. Bioaerosols
402 originating from anthropogenic environments, such as sewage treatment plants and
403 hospitals, may harbor more resistant bacteria. Microorganisms from arid areas like
404 deserts possess a higher number of species adapted to harsh conditions, including
405 resistance to temperature fluctuations, dryness, and UV radiation. These include
406 bacteria such as *Bacillus*, *Streptococcus*, and *Deinococcus* ((Maki et al., 2010; Park et
407 al., 2018; Qi et al., 2021). These microorganisms can adhere to particulate matter during
408 long-distance transport of airmasses after being released from their terrestrial habitats.

410 **Fig. 3 Bacterial (a) and fungal (b) community disparities influenced by terrestrial (n=10),**
 411 **marine (n=6), and mixed mass (n=8).**
 412

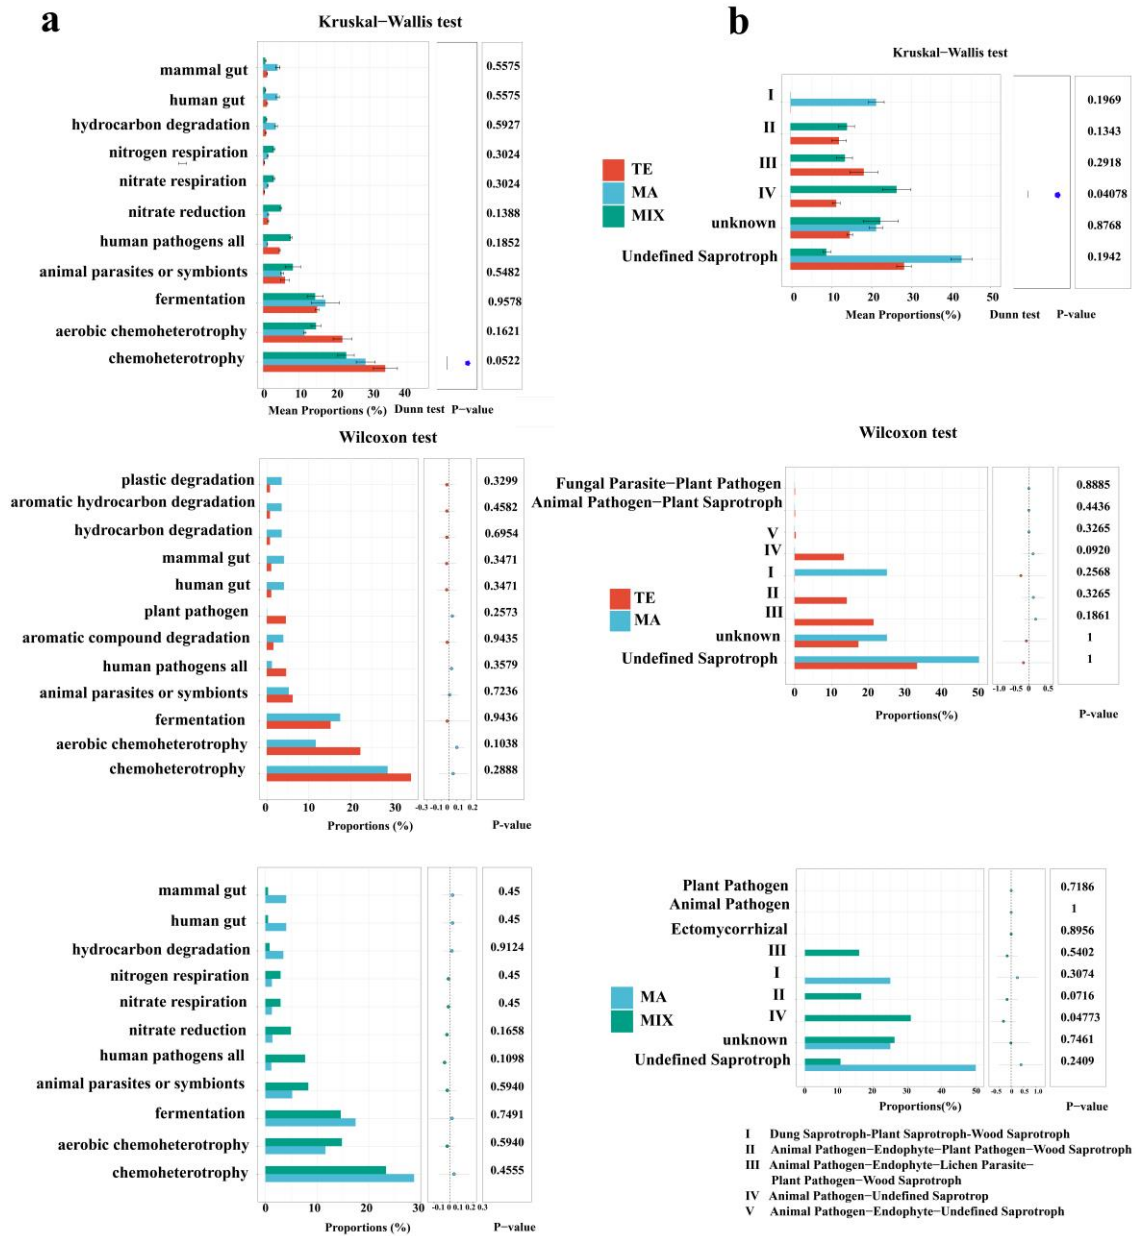

413 Community disparities influenced by terrestrial, marine, and mixed air masses was
 414 conducted in Table S2, S3, Fig. 3 and Fig. 4. **The Principal Coordinates Analysis (PCoA)**
 415 **revealed distinct clusters corresponding to terrestrial, marine, and mixed air mass (Fig.**
 416 **S4).** In terms of bacterial community variations, numerous dominant microorganisms
 417 exhibited obvious differences in abundance between marine and terrestrial air mass
 418 samples. However, these differences were not statistically significant ($p > 0.05$). For
 419 instance, the bacterial enrichments in terrestrial and mixed air-masses included
 420 *Staphylococcus*, *Deinococcus*, *Lactobacillus*, and *Sphingomonas*. *Staphylococcus* is a

421 pathogenic bacterium widely found in human skin and intestines that can cause various
422 infections (Cheung et al., 2021). As a radiation-resistant bacterium, *Deinococcus-*
423 *Thermus* is capable of withstanding harsh environmental conditions (Callegan et al.,
424 2008; Rainey et al., 2007). *Lactobacillus*, a genus of Gram-positive bacteria, has also
425 been identified as abundant in atmospheric dust (Federici et al., 2018; Xu et al., 2017).
426 *Sphingomonas*, typically found in water and soil, which is widely known as the
427 metabolic mechanism able to endure poor nutrients and degradation of refractory
428 compounds, such as polycyclic aromatic hydrocarbons (PAHs) (Hu et al., 2007; Sun et
429 al., 2018). The majority of these bacteria possess the ability to produce spores, which
430 are capable of withstanding harsh conditions such as low temperatures, aridity, and
431 radiation during long-distance transmission processes, thereby ensuring their survival
432 throughout this process (Griffin et al., 2003). *Comamonas* was identified as the
433 dominant bacterium in the coastal atmosphere of Weihai, particularly prevalent in
434 marine air-mass samples. This bacterium is commonly associated with environmental
435 bioremediation and is predominant in oligotrophic environments (Yan et al., 2012;
436 Zhang et al., 2024). *Streptococcus* are mostly found in the oral and gastrointestinal
437 tracts and also play an important role in human infections (Brouwer et al., 2023).
438 *Ruminococci*, and *Enterobacteriaceae* are typical gut microorganisms present in
439 humans and animals. In the coastal atmosphere, the identified sequences of these gut
440 bacteria might be associated with intestinal microorganisms in marine fish and mammal
441 animals.

442 For fungal community, *Aspergillus* demonstrated a significant differentiation
443 between marine and mixed airmasses ($P=0.005$). The highest proportion was noted in
444 samples from marine air masses, at 53.7%. In contrast, the values were 20.1% and 0.3%
445 in terrestrial and mixed air masses respectively. Previous studies have confirmed that

446 *Aspergillus* is widely distributed in nature and unpolluted environments (Kendrick,
447 1995). This fungus is predominantly found in offshore regions, such as Qingdao, China
448 (Li et al., 2011). Furthermore, the saprophytic *Aspergillus* was also prevalent in clean
449 samples during periods of haze pollution and was frequently detected on non-haze days
450 (Yan et al., 2016). *Malassezia* was higher in terrestrial and mixed air-mass samples
451 ($P=0.047$), which has been found to be widespread in a variety of animals. As a parasitic
452 fungus, *Malassezia* causes the majority of skin diseases, such as dandruff and
453 seborrheic dermatitis caused by *Malassezia sphericalis* (Deangelis et al., 2007).
454 Furthermore, *Cladosporium* exhibits higher abundance in terrestrial and mixed air-mass
455 samples compared to marine air masses, although this difference lacks statistical
456 significance ($P>0.05$). This species is ubiquitous worldwide, commonly found in a wide
457 variety of plants, known to be a common endophyte as well as a foliar fungus (El-Morsy,
458 2000; Islam and Hasin, 2000). It is frequently isolated from soils, foodstuffs and organic
459 matters (Bensch et al., 2012). Moreover, *Cladosporium* have been commonly observed
460 in terrestrial atmospheric environments, demonstrating the potential origins from
461 continental environments (Frączek et al., 2017; Han et al., 2019).

462 The significant variance in the ecological function of the microbial community
463 was predominantly evident in the IV group of fungi, which are classified as
464 Animal Pathogen-Undefined Saprotrophs ($P=0.04$). These pathogenic fungi were more
465 prevalent in terrestrial and mixed air-mass samples than in marine air-mass samples.
466 Marine air-mass samples were enriched with mammal gut bacteria, hydrocarbon and
467 automatic compound degradation bacteria, and undefined Saprotroph fungi.

468

469

470

Fig. 4. Bacterial (a) and fungal (b) community function disparities influenced by terrestrial (n=10), marine (n=6), and mixed mass (n=8).

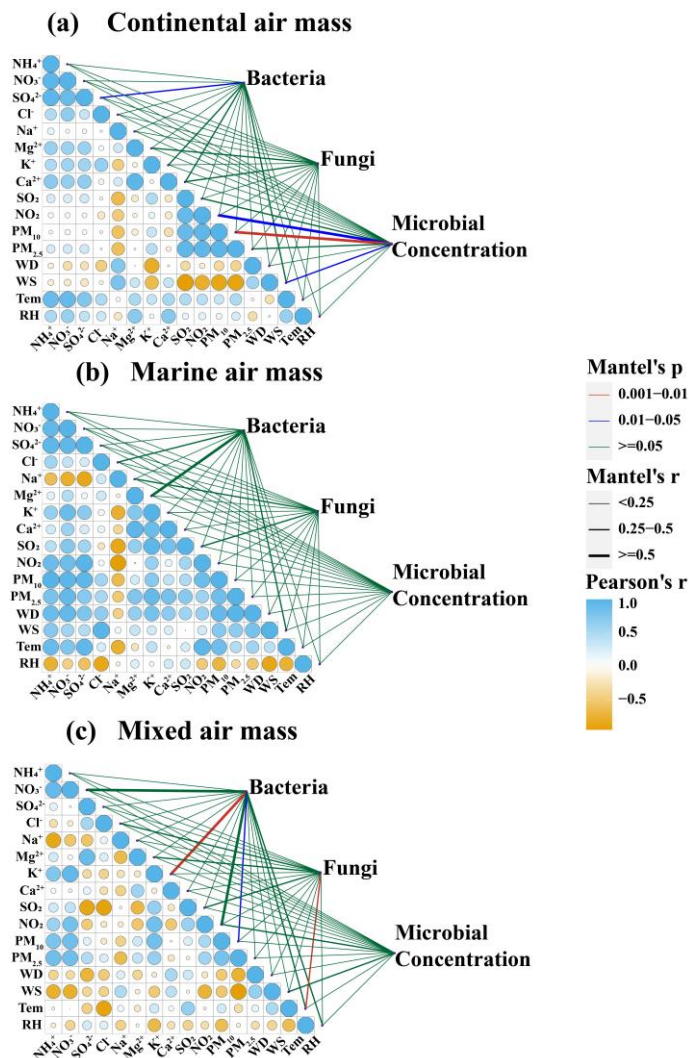

471 4.2 Implications of environmental factors on coastal airborne microbes

472 To elucidate the contributions of marine and terrestrial air masses to microbial
473 aerosols in the coastal city, a Mantel correlation analysis was conducted between
474 microbial aerosols and various environmental factors (Fig.5, Fig.S4). The bacterial
475 community exhibited a significant positive correlation with SO_4^{2-} due to the influence
476 of terrestrial and mixed air masses ($P < 0.05$). Both bacterial and fungal communities
477 demonstrated positive correlations with continental ions such as K^+ , Mg^{2+} , and Ca^{2+}
478 (Shi et al., 2022). Additionally, a positive correlation was observed between bacterial
479 and fungal concentrations and NO_2 ($P < 0.05$), as well as a significant positive
480 correlation with PM_{10} ($P < 0.01$).

481 Air masses transported over long distances from the continent appear to harbor
482 diverse and abundance microbial populations (Kakikawa et al., 2009; Deleon-
483 Rodriguez et al., 2013). For instance, the long-distance transportation of dust particles
484 from the northwestern winds in the Inner Mongolia region may have changed the
485 community structure and abundance (Squizzato and Masiol, 2015; Castañer et al.,
486 2017). Dust-borne bacteria (*Staphylococcus*, *Delftia*, *Pseudoalteromonas* and
487 *Deinococcus*) were injected into the atmosphere during dust events, and most of them
488 accompanied the dust transportation to the downwind of Asian Dust including the
489 coastal city of Weihai. Influenced by mixed air masses, bacterial community was
490 significantly positively correlated with K^+ ($P < 0.01$) and PM_{10} ($P < 0.05$).

491 Similarly, microbial communities showed high positively correlated with ions from
492 continental sources, such as K^+ , Mg^{2+} , and Ca^{2+} in terrestrial and mixed air mass
493 samples. K^+ is the signature ion of biomass combustion (Mason et al., 2016; Yu et al.,
494 2018). Mg^{2+} , and Ca^{2+} are mostly derived from crustal elements (Zhang et al., 2012).
495 The dominant bacteria within the microbial community exhibited a significant positive

496 correlation with these three ions simultaneously, suggesting a similar sources. They
 497 generally originate from terrestrial sources, including anthropogenic biomass
 498 combustion and soil dust.

499
 500 **Fig.5 Mantel analysis reveal the correlation between microbial community and various**
 501 **environmental factors under different air masses, terrestrial air masses (a) marine air**
 502 **masses (b) and mixed air masses (c). The Pearson's r coefficient indicates the significant**
 503 **correlation at $p < 0.05$ and $p < 0.01$.**

504

505 The concentrations of particulate matter and water-soluble ions in samples
 506 influenced by the marine air mass are notably low, suggesting that most chemical
 507 elements did not significantly impact the composition and abundance of the microbial
 508 community. However, a significant positive correlation was observed between Na^+ and

509 certain dominant species such as *Talaromyces*, *Monographella*, and *Phoma* ($P < 0.05$).
510 Similarly, Mg^{2+} was found to be significantly positively correlated with *Malassezia* in
511 mixed air masses ($P < 0.01$) (Fig. S5). Except for anthropogenic sources, such as
512 industrial emissions, the origins of Mg^{2+} and Na^+ in coastal regions should also consider
513 the impact of sea salt (Sun et al., 2022). Samples collected under the influence of marine
514 air masses had a moderate correlation between Mg^{2+} and Na^+ ($r^2 = 0.67$), indicating that
515 they have a similar origin of sea salt. Moreover, the average Mg^{2+}/Na^+ ratio was 0.11,
516 close to the value of 0.12 in seawater (Seinfeld and Pandis, 1997).

517 Influenced by mixed air mass, temperature have a greater impact on fungal
518 community, which was positively correlated with *Malasseziales* and *Davidiellaceae*. In
519 marine airmass samples, a positive correlation between air temperature and certain
520 microorganisms (*Aerococcus*, *Cloacibacterium*, *Sphingobium*, *Enhydrobacterium*,
521 *Davidiellaceae*, *Malasseziales*) also indicated that the increase in air temperature in
522 spring favors the survival of airborne microbes (Jones and Harrison, 2004).

523 **4.3 Intermixing of bioaerosols from terrestrial and marine air-mass**

524 Coastal atmospheres exhibit a complex amalgamation of terrestrial and marine
525 aerosols, with the characteristics significantly influenced by the origins of the air
526 masses. Consequently, these coastal aerosols offer ideal conditions for examining the
527 mixing processes between natural and anthropogenic air masses from terrestrial and
528 marine sources, respectively. This work shows that enormous levels of haze aerosols
529 from the terrestrial and mixed air mass can be rapidly transported into the coastal city
530 during regional haze pollution. During the long-distance transportation of air masses, a
531 comprehensive mixture of soil-derived, biogenic, and anthropogenic microorganisms
532 from terrestrial air masses, and aquatic, saprophytic, gut microorganisms from marine

533 environments are fully mixed (Fig. 6). This mixing is particularly evident in the samples
534 of mixed air masses. Among that, not only large numbers of chemical components but
535 also bacteria and fungi, as well as opportunistic pathogens, were transported into the
536 coastal city. Microbial communities were strongly correlated with haze aerosols, e.g.,
537 WSIs in PM_{2.5} from terrestrial and mixed air mass. The primary influence on terrestrial
538 air mass was anthropogenic emissions, with coal combustion for winter heating and
539 biomass burning being the predominant pollution sources. Moreover, dust events in
540 spring carried higher concentrations of particulate matter. These air pollutants can act
541 as initial source of bioaerosols such as bacteria and fungi, thereby providing a site for
542 attachment reproduction (Jiang et al., 2022). Additionally, water-soluble ions in PM,
543 primarily secondary ions, sulfate, nitrate, and ammonium ions, can supply essential
544 nutrients for microbial growth (Fan et al., 2019). This explanation elucidates the
545 increased concentration of particulate matter and microorganisms in terrestrial air mass
546 during heavy pollution. Simultaneously, it is pertinent to highlight that during pollution
547 incidents, the terrestrial air mass intensifies the pollution process. This intensification
548 results in a significant increase in the proportion of pathogenic microorganisms.

549

550 **Fig. 6 Implications of intermixing of bioaerosols from terrestrial and marine air-mass on the**
 551 **composition of airborne microbial communities.**

552

553 In the coastal city, marine air masses predominantly originate from the expansive
 554 western Pacific Ocean, located to the eastern and southern areas. These air masses are
 555 typically characterized by their cleanliness and contain a significant quantity of
 556 saprophytic and intestinal microorganisms that infiltrate the atmosphere via ocean
 557 droplets (Mayol et al., 2014). The presence of microorganisms in marine air masses
 558 exhibited a significant correlation with sea salt ions, specifically Na^+ and Mg^{2+} . These
 559 ions, when introduced into the atmosphere, form aerosolized particulate matter. Marine
 560 bacteria can be introduced into tropospheric free space may modify the airborne
 561 microbial composition in continental regions (Cho and Hwang, 2011; Amato et al.,
 562 2007; Maki et al., 2014; Polymenakou et al., 2008; Cáliz et al., 2018), exerting
 563 significant impacts on bioaerosols over coastal atmosphere.

564 Notably, marine air masses from the northerly areas, traverse China's inland Bohai
 565 Sea and subsequently pass through urban and rural regions with high human activity
 566 levels. Consequently, these areas introduce anthropogenic emission source

567 microorganisms, including pathogenic microorganisms from hospitals and sewage
568 treatment plants. In the present study, samples within this category are identified as
569 those influenced by a mixed air mass. This also signifies the amalgamation of marine
570 and terrestrial microorganisms. Consequently, within the mixed air mass samples, the
571 prevalence of pathogenic and saprophytic microorganisms is comparable. This
572 similarity underscores the complex impact of both terrestrial and marine sources.
573 Populations in coastal cities may also be susceptible to exposure to these bioaerosols
574 and pathogens, which are transported over long distances during regional air pollution.

575 **5. Conclusion**

576 This study evaluated the potential influence and the mixing effects between natural
577 and anthropogenic aerosols respectively from terrestrial and marine air-mass on
578 biological constituents of PM_{2.5} over coastal atmosphere. The concentration of water-
579 soluble ions, metal elements and bioaerosols were higher in terrestrial and mixed air-
580 mass samples than marine air-mass samples. The V/Ni ration greater than 0.7 in marine
581 air-mass samples indicated significant influence from marine ship emissions. Bacterial
582 and fungal community influenced by terrestrial and mixed air masses were enriched in
583 animal pathogens, including the *Staphylococcus*, *Malassezia* and *Alternaria*. In contrast,
584 marine air mass carried more gut and saprophytic microbes, such as *Ruminococcus*,
585 *Enterobacteriaceae*, *Aspergillus*, and *Davidiellaceae*. Potential implications of
586 environmental factors on airborne microbes based on Mantel correlation analysis
587 suggested that the bacterial community was mainly significantly correlated with SO₄²⁻,
588 K⁺, Mg²⁺, and Ca²⁺ and PM₁₀ influenced by terrestrial and mixed air masses from
589 continental sources. In contrast, influenced by marine air masses, bacterial and fungal
590 community were strongly correlated with sea salt ions, such as Na⁺. The effects of

591 meteorological factors on bioaerosols vary significantly under different dominant air
592 masses. The predominant bacteria and fungi in marine and mixed air-mass samples
593 exhibited a positive correlation with air temperature, suggesting elevated temperature
594 in spring is conducive to the survival and reproduction of bioaerosols. **Our research**
595 **offers a novel perspective on the variability of airborne microbial communities and**
596 **provides evidence suggesting that the atmospheric microbiome in coastal cities is**
597 **influenced by terrestrial and marine air masses. This understanding will enhance our**
598 **comprehension of the environmental and climatic impacts on microbial aerosols within**
599 **the marine boundary layer. Future research endeavors will concentrate on the local**
600 **emission and long-distance transport, as well as the contributions of both terrestrial and**
601 **marine air masses on bioaerosol components in coastal cities.**

602 **CRedit authorship contribution statement**

603 All authors contributed to the manuscript and have given approval of the final version.
604 Min Wei designed the study. Qun He performed the data analysis and wrote the original
605 manuscript. Min Wei assisted with the sampling, Qun He, Zhaowen Wang and Rongbao
606 Duan conducted the experiments and performed the statistical analyses. Houfeng Liu,
607 Min Wei, and Pengju Xu contributed to the interpretation of results. Min Wei, Caihong
608 Xu and Jianmin Chen revised the manuscript.

609 **Data availability**

610 Hourly and daily average air quality and meteorological factor data were obtained
611 from Shandong Province Ecological Environment Big Data Platform
612 (<http://27.211.168.253:18102/portal/>); Meteoinfo backward trajectory model
613 (MeteoInfo 3.7.4 - Java, <http://www.meteothink.org/downloads/index.html>);

614 meteorological data were obtained from GDAS1
615 (<ftp://arlftp.arlhq.noaa.gov/pub/archives/gdas1/>), and meteorological data as well as
616 bacterial and fungal concentrations are available from the authors on request
617 (minwei@sdnu.edu.cn). The original 16S rRNA and ITS gene sequences are available
618 in the Sequence Read Archive (SRA) under accession number PRJNA1096829.

619 **Declaration of competing interest**

620 The authors declare that they have no conflict of interests.
