8 Key Points

- 9 • Recent satellite geodetic data shed new light on the origin of the active deformations
10 affecting Southeastern Sicily.
- 11 • Several deformation processes, including crustal flexure and faulting, are investi-
12 gated to determine the most reliable mechanical explanation.
- 13 • Seismic cycle, surface, and crustal deformations of Southeastern Sicily are mainly
14 driven by the southward migration of the Ionian slab roll-back.

15 Abstract:

16 New satellite geodetic data challenge our knowledge of the deformation mech-
17 anisms driving the active deformations affecting Southeastern Sicily. The PS-InSAR
18 measurements evidence a generalized subsidence and an eastward tilting of the Hyblean
19 Plateau combined with a local relative uplift along its eastern coast. To find a me-
20 chanical explanation for the present-day strain field, we investigate short and large-scale
21 surface-to-crustal deformation processes. Geological and geophysical data suggest that

22 the southward migration of the Calabrian subduction could be the causative geodynamic
23 process. We evaluate this hypothesis using flexural modeling and show that the com-
24 bined downward pull force, induced by the Ionian slab roll-back, and the overloading of
25 the Calabrian accretionary prism, is strong enough to flex the adjacent Hyblean continen-
26 tal domain, explaining the measured large-scale subsidence and eastward bending of the
27 Hyblean Plateau. To explain the short-scale relative uplift evidenced along the eastern
28 coast, we perform elastic modeling on identified or inferred onshore and offshore normal
29 faults. We also investigate the potential effects of other deformation processes including
30 upwelling mantle flow, volcanic deflation, and hydrologic loading. Our results enable us
31 to propose an original seismic cycle model for Southeastern Sicily, linking the current
32 interseismic strain field with available long-term deformation data. This model is mainly
33 driven by the southward migration of the Ionian slab roll-back which induces a downward
34 force capable of flexuring the Hyblean crust.

38

39 1 Introduction

40 Geodetic measurements, instrumental seismicity, onshore/offshore geology, and
41 geophysics, all indicate that Southeastern Sicily is actively deforming (e.g., Azzaro and
42 Barbano, 2000; Mastrolembo et al., 2014; Meschis et al., 2020; Anzidei et al., 2021). This
43 region also suffered the most powerful and devastating earthquake, the 1693 Mw \sim 7.4
44 Val-di-Noto earthquake, reported in the Italian seismicity catalog (Rovida et al., 2022).
45 This earthquake is thought to have occurred offshore the eastern margin of the Hyblean
46 Plateau, triggering a widespread tsunami (e.g., Azzaro and Barbano, 2000; Gutscher et al.,
47 2006; Scicchitano et al., 2022). The current geologic and tectonic framework is in line with
48 the Cenozoic geodynamic evolution of the Central Mediterranean (Figure 1) but also ap-
49 pears to be influenced by the Mesozoic pre-structuration of this region (e.g., Carminati
50 and Doglioni, 2005; Frizon De Lamotte et al., 2011; Henriquet et al., 2020; Van Hinsbergen
51 et al., 2020). In the Late Cretaceous, the Africa/Eurasia plates convergence initiated the

52 subduction of the Alpine Tethys under the Apulia-Adria and Iberia plates, giving rise to
53 the Alpine orogeny (e.g., Handy et al., 2010, 2015; Van Hinsbergen et al., 2020; Jolivet,
54 2023). During the early Cenozoic, the subduction experienced polarity reversal (e.g.,
55 Handy et al., 2010; Almeida et al., 2022) followed by, since at least the Oligocene, long-
56 lasting slab roll-back, causing the drifting of continental micro-blocks, detached from the
57 Iberian margin and the opening of back-arc basins throughout the Mediterranean realm
58 (e.g., Gueguen et al., 1998; Faccenna et al., 2001; Rosenbaum et al., 2002; Carminati et al.,
59 2012; Van Hinsbergen et al., 2020). During the Mio-Pliocene (10-5 Myr), the collision
60 between the southeastward migrating Calabrian-Peloritan Arc and associated Calabrian
61 Accretionary Prism (CAP) with the Northern African passive margin led to the forma-
62 tion of the Sicilian fold-and-thrust belt (e.g., Gueguen et al., 1998; Henriquet et al., 2020).
63 During the Plio-Pleistocene (5-2 Myr), the Calabrian Arc and the retreating Ionian slab
64 continued strongly interacting with the crustal structure of the African margin, partic-
65 ularly with the thick Pelagian continental Platform and the Malta Escarpment (Wortel
66 and Spakman, 2000) (Figure 1). These major tectonic domains, which originated during
67 the Triassic period, were shaped by the fragmentation of the Pangea in the early Jurassic,
68 leading to the opening of the Neo-Tethys Ocean (e.g., Stampfli et al., 2002). Nowadays,
69 the Calabrian subduction zone keeps moving south but at a much slower rate, suggesting
70 that the system **as a whole is undergoing** opposing forces and/or that its driving mecha-
71 nism, slab roll-back, is losing **its effectiveness**.

72

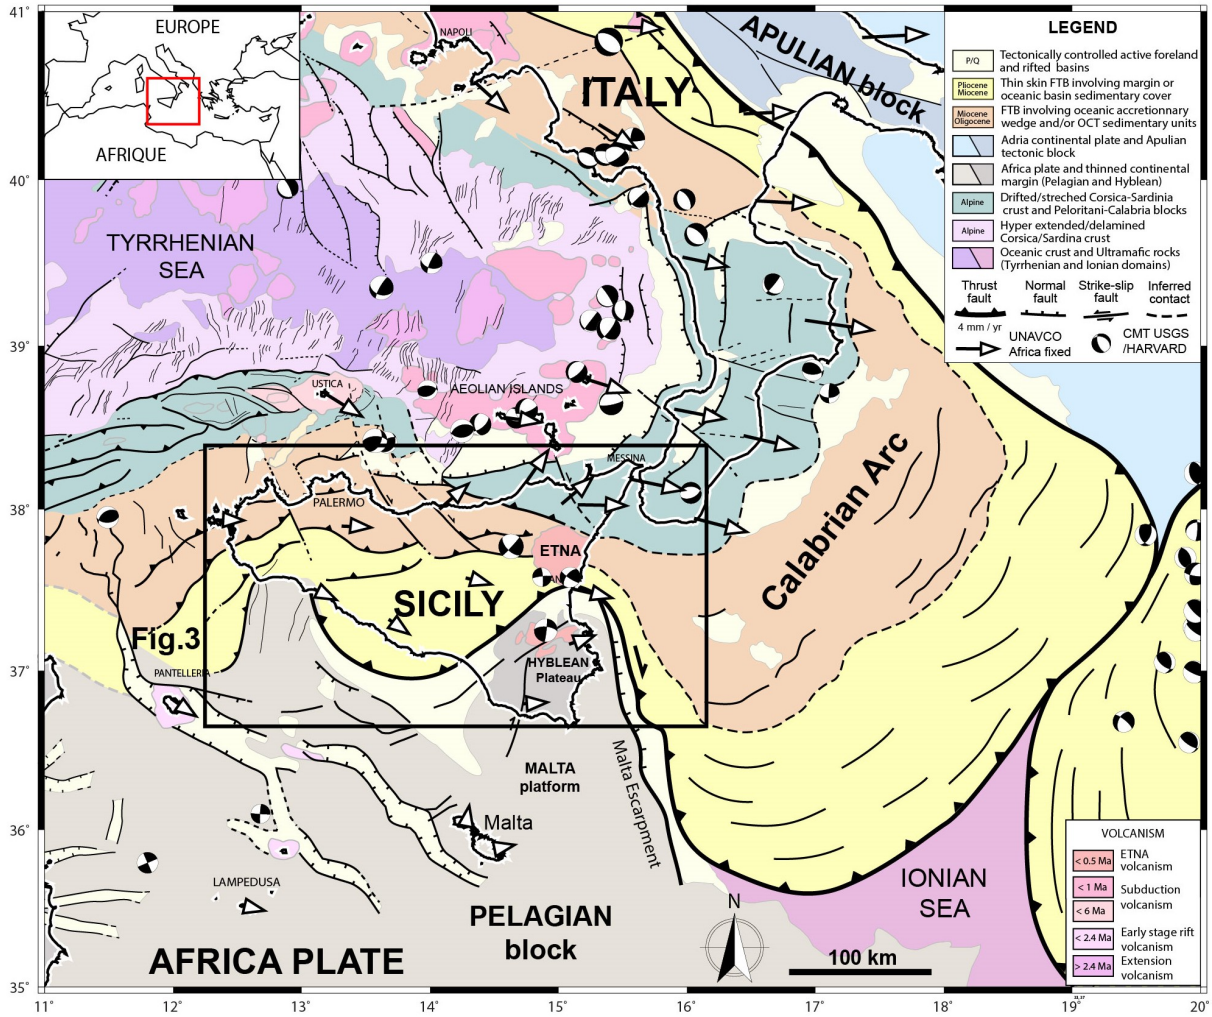

Figure 1 : Geodynamic and tectonic map of Central Mediterranean (modified from Henriquet et al., 2020). Geological and structural data were synthesized from previous publications (e.g., Funicello et al., 1981; Bigi et al., 1991; APAT, 2005; Finetti et al., 2005; Lentini and Carbone, 2014; Prada et al., 2014). Present-day Centroid Moment Tensors ($M_w > 4.5$) and GNSS data were retrieved from <https://www.globalcmt.org/CMTsearch.html> and <https://www.unavco.org/data/gps-gnss/gps-gnss.html> websites, respectively.

73 Recent PS-InSAR satellite measurements (radar interferometry) published by Hen-
74 riquet et al. (2022) have revealed an unexpected pattern of surface deformation across
75 Southeastern Sicily, particularly, an eastward increasing subsidence of the whole Hyblean
76 Plateau (Figure 2). This region has been partially investigated in previous studies using
77 similar techniques but only captured local surface deformation features (Canova et al.,
78 2012; Vollrath et al., 2017). Up to now, the origin of such a pattern of deformation re-
79 mains, then, unexplained. Since satellite measurements were acquired over a very short
80 period compared to typical seismic cycle durations (five versus several hundreds of years),
81 and considering the discrepancy between satellite measurements and inferred long-term
82 coastal uplift estimations (e.g., Bianca et al., 1999; Ferranti et al., 2006, 2010; Scicch-
83 tano et al., 2008; Meschis et al., 2020) (Figure 2a), we hypothesize that the satellite data

84 are representative of the interseismic period. We further infer that the PS-InSAR data
85 mainly document elastic loading mechanisms and reversible deformations. To explain
86 the geodetic observations, we investigate the surface deformation signature of crustal and
87 lithospheric deformation processes, including the impact of the southward migration of
88 the Calabrian subduction system on the structural evolution of the eastern Hyblean mar-
89 gin as well as elastic loading and aseismic creep on coastal and offshore normal faults. We
90 also test the potential surface expression of other processes, such as volcanic deflation,
91 hydrologic loading, and upwelling mantle flow.

92 **2 Present-day deformation of SE Sicily**

93 The kinematics and active tectonics in SE Sicily are still a matter of debate,
94 with [marked developments](#) in the last decade (e.g., Bianca et al., 1999; Argnani et al.,
95 2012), in particular with the acquisition of high-resolution bathymetry and seismic re-
96 flection/refraction profiles in the adjacent Ionian domain (Argnani and Bonazzi, 2005;
97 Gutscher et al., 2016; Dellong et al., 2020), and seismotectonic analysis (e.g., Gambino
98 et al., 2021, 2022b). The main reasons include the complex polyphased geological history
99 of this region and the relatively low present-day horizontal strain rate (< 5 mm/yr), re-
100 sulting from the culmination of the Calabrian Arc and African Margin collision and the
101 subsequent slowdown of the Calabrian subduction (roll-back and back-arc extension) in
102 the last million years (Goes et al., 2004; D’Agostino et al., 2011; Zitellini et al., 2020).

103 **2.1 Geodesy**

104 Geodetic surface measurements in SE Sicily include GNSS (e.g., Palano et al.,
105 2012), PS-InSAR/DInSAR (e.g., Vollrath et al., 2017), and leveling datasets (e.g.,
106 Spampinato et al., 2013).

107

108 **PS-InSAR**

109 In the present study, we use the first geodetic velocity field covering the whole
110 Island of Sicily published by Henriquet et al. (2022) and derived from Sentinel-1 radar
111 satellite (InSAR data) acquired during the 2015-2020 period. The PS-InSAR pseudo-3D
112 velocity field (Up and E-W component) was obtained by merging ascending and

113 descending acquisitions, combined with a reanalysis of the GNSS time series. Due to the
 114 acquisition geometry, the Sentinel-1 radar satellite is not sensitive to the N-S component
 115 of horizontal surface deformation, which is, fortunately, very low in the studied region
 116 (Henriquet et al., 2022). We therefore consider that, even if affected by minor distortions,
 117 the Up and E-W components of the pseudo-3D velocity data can be used with confidence
 118 (Supplementary Figures S2 to S5). The vertical (Up) component of this dataset reveals
 119 that the central and eastern parts of the Hyblean Plateau experience subsiding rates
 120 increasing eastward from 1 to nearly 3 mm/yr relative to the western coast (Figure 2 and
 121 Supplementary Figure S1). It should be noted that PS-InSAR data also show a slowly
 122 decreasing E-W component to the east of the Hyblean Plateau, with velocities evolving
 123 from 3 to 2 mm/yr (fig.10, Henriquet et al., 2022).

124

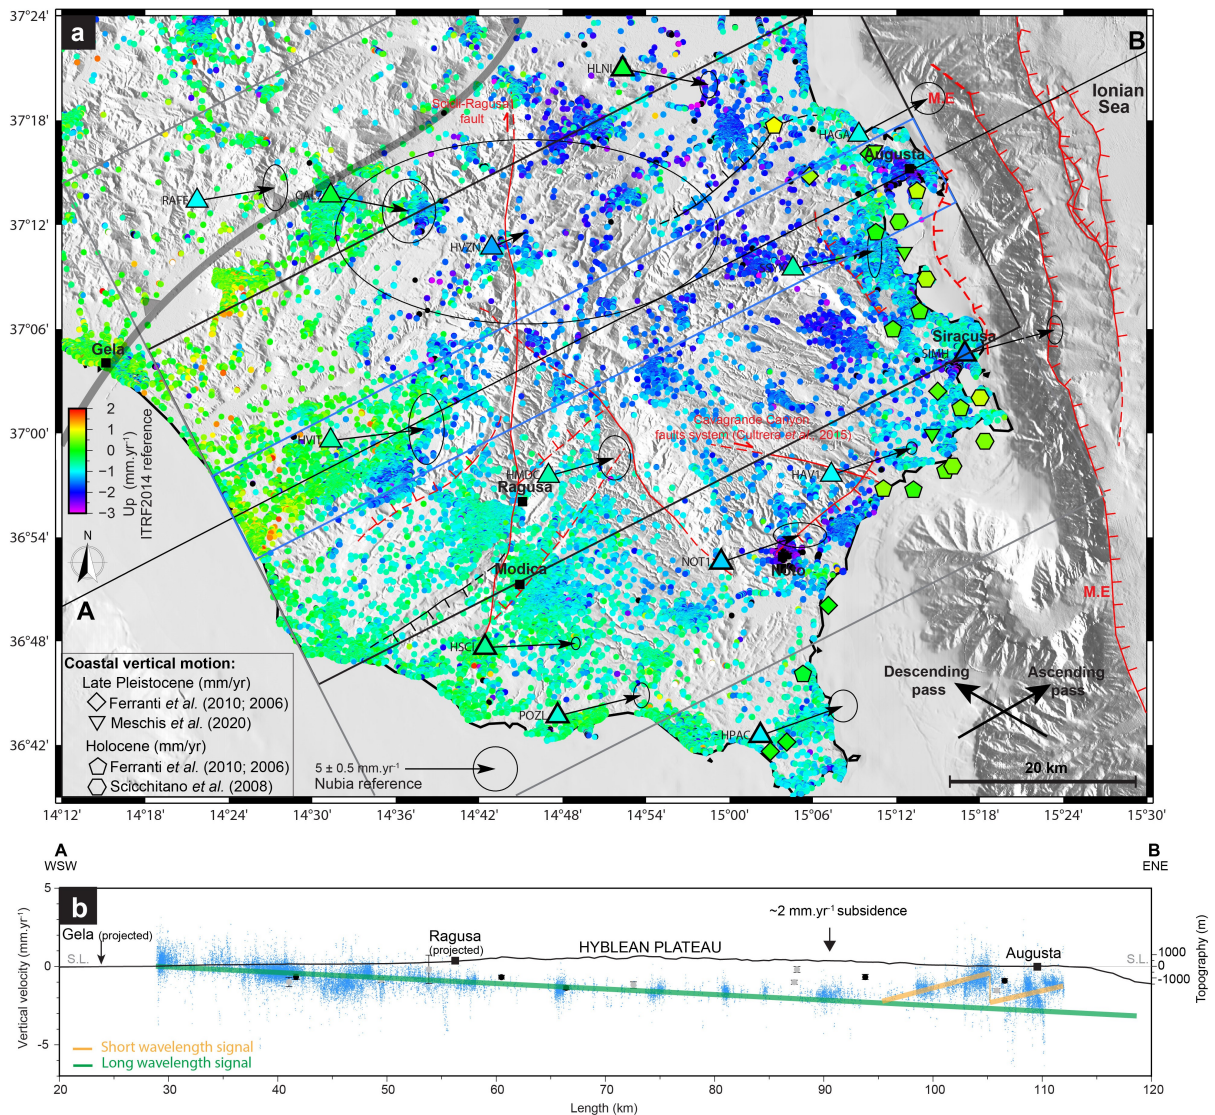

Figure 2 : Geodetic data across the Hyblean Plateau region (see location in Figure 3). a) Permanent-Scatterer (PS-InSAR 2015-2020) pseudo-3D Up velocities in map view from Henriquet et al. (2022). GNSS 3D surface velocities are derived from a reanalysis of the Nevada Geodetic Laboratory (NGL) data (Horizontal components reference: fixed Nubia; Up components reference: ITRF2014). Major faults of the Hyblean Plateau (H.P) and Malta Escarpment (M.E) including the offshore normal faults identified by Bianca et al. (1999); Argnani and Bonazzi (2005) and recently analyzed by Gambino et al. (2021) (red: active fault; red dashed: inferred active fault; black: inferred aseismic slip from Spampinato et al. (2013)). b) SW-NE trending velocity profile showing surface velocity (Up) derived from PS-InSAR and GNSS stations vertical velocities. We observed a long wavelength signal (in green) and a short wavelength signal at the eastern part of the H.P (in orange) along the AB profile, and a similar surface deformation is observed to the South of the AB profile (Supplementary Figure S1). PS-InSAR data are stacked across a 5 km width on both sides of the AB profile (in blue). GNSS data are stacked using 20 km (in black) and 40 km (in gray) widths on both sides of the AB profile. Topographic and bathymetric profiles are presented without vertical exaggeration (V.E.x1).

125 One should note that the zero reference of the PS-InSAR vertical velocity field
 126 is not precisely known. The vertical component of the pseudo-3D PS-InSAR velocity
 127 field and GNSS data have a ± 0.5 mm/yr uncertainty in the ITRF2014 (Altamimi et al.,
 128 2016), which implies that the observed subsidence over the Hyblean Plateau could be
 129 a little bit higher or slower. In the last case, slow uplift rates could be present in the
 130 Gela region. The vertical velocity trend is obtained by projecting and stacking the PS-
 131 InSAR data across a 5 km wide band along an N30°E AB profile (Figure 2b). Along
 132 this profile, oriented perpendicular to the main regional faults, the subsidence velocity
 133 reaches, on average, ~ 1 mm/yr between Gela and Ragusa and increases progressively
 134 to ~ 2.5 mm/yr between Ragusa and Augusta. All along the eastern coast, **geodetic**
 135 **data evidence** a significantly slower subsidence (or a relative uplift). From Augusta to
 136 Siracusa, and in the southernmost part of the Hyblean Plateau (HP), the subsidence rate
 137 decreases to about 1 mm/yr compared to the maximum subsidence rate in the central
 138 Hyblean Plateau (Figure 2). In the Gela region, PS-InSAR vertical velocities indicate a
 139 possible slow uplift rate of ~ 0.5 mm/yr (Figure 2). To the South of the AB profile, a
 140 similar surface deformation pattern is observed; an eastward increase in subsidence rates
 141 evolving towards a similar relative uplift in the coastal (Siracusa) region (**Profile CC'**,
 142 Supplementary Figure S1).

143 Along the AB velocity profile, neither the Scicli-Ragusa inferred active fault (Voll-
 144 rath et al., 2017) nor the other major faults of the Hyblean Plateau can be evidenced in
 145 the E-W and vertical components of the PS-InSAR data (Henriquet et al., 2022) (Figure
 146 2a), indicating that these faults are locked or are creeping at a slip rate lower than the

147 PS-InSAR resolution (± 0.5 mm/yr). Locally, fast ($\gg 3$ mm/yr) subsiding zones, most
148 probably related to human activities such as water pumping (Canova et al., 2012), can
149 be identified near the main cities of Augusta, Siracusa, and Noto (Figure 2a).

150 Surface deformation signals extending over a hundred or more kilometers are
151 most probably related to crustal or lithospheric scale processes (e.g., Stephenson et al.,
152 2022), whereas those extending over tens of kilometers are likely associated with
153 much shallower and localized mechanical processes such as seismic cycle deformation,
154 volcanic bulging/collapse, hillslope instabilities (landslides), or human activities (water
155 pumping, mining) (e.g., Vilardo et al., 2009). We therefore hypothesize that the
156 PS-InSAR vertical velocity field consists of two superimposed signals: (1) a long
157 wavelength (> 100 km) subsidence, and gradual eastward tilt of the Hyblean Plateau
158 (green line in Figure 2b), compatible with the decreasing PS-InSAR E-W velocities,
159 and (2) a short wavelength signal, extending along the Eastern coast and characterized
160 by sharp variations of the vertical velocities at kilometeric scale (orange lines in Figure 2b).

161

162 GNSS

163 The Global Navigation Satellite System (GNSS) data used to calibrate the pseudo-
164 3D PS-InSAR velocity field (Henriquet et al., 2022) were based on the analysis of time
165 series, retrieved from the Nevada Geodetic Laboratory (Blewitt et al., 2018). We refine
166 this analysis by correcting for annual and semiannual seasonal signals, instantaneous
167 offsets, and gaps, using the time series inversion software developed by Masson et al.
168 (2019). Across the Hyblean Plateau, GNSS velocities show horizontal velocities of ~ 2
169 mm/yr oriented homogeneously toward the ENE, in the Nubia reference frame (Figure
170 2). The vertical component of most of the GNSS stations shows an overall subsidence
171 of the HP (-0.8 mm/yr on average) in the ITRF2014 reference frame (Altamimi et al.,
172 2016). This tendency is well illustrated by the high-quality NOT1 GNSS station located
173 near the city of Noto, which has recorded the longest time series (23 years, 2000-2023),
174 or by the SSYX and HMDC stations (Supplementary Figures S2 and S3). Overall, the
175 GNSS vertical velocities are consistent with the median of the PS-InSAR vertical velocities
176 calculated over a 3×3 km² region centered on each GNSS station (Supplementary Figures
177 S2 to S5).

178 To estimate the regional horizontal strain rate tensor, we processed the GNSS

179 dataset using the inversion model of Mazzotti et al. (2005). The Hyblean Plateau is
180 characterized by an extension rate oriented $N55^{\circ}E \pm 1^{\circ}$ (close to the AB profile direction)
181 and a shortening rate oriented $N145^{\circ}E \pm 1^{\circ}$ (Supplementary Figure S6), consistent with
182 the focal mechanisms inversion (Figure 3).

183 2.2 Seismology

184 The instrumental seismicity map of SE Sicily, derived from INGV and Rovida et al.
185 (2022) datasets (Figure 3), shows minor to moderate events ($M < 5$) with deep crustal
186 hypocenters (15-30 km). Over the Hyblean Plateau, earthquake hypocenters tend to
187 roughly align along the inferred active, N-S trending, Scicli-Ragusa strike-slip fault (e.g.,
188 Vollrath et al., 2017) and near the Cavagrande Canyon faults system (Cultrera et al., 2015)
189 (Figure 3). Most of these faults are probably inherited from the Plio-Quaternary tectono-
190 magmatic phase of deformation (Henriquet et al., 2019) and were partly re-activated in
191 response to the ongoing Africa-Nubia/Eurasia plates convergence (e.g., Mattia et al., 2012;
192 Cultrera et al., 2015). In this framework, the identification of the seismogenic source that
193 triggered the 1693 event remains debated (e.g., Argnani and Bonazzi, 2005; Bianca et al.,
194 1999). The isoseists of the $M_w \sim 7.4$ Noto earthquake appear largely open toward the
195 Malta Escarpment and Ionian Sea domains, suggesting the seismogenic fault is located
196 offshore (Figure 3). East of the Hyblean Plateau, earthquakes essentially distribute along
197 the Malta Escarpment where a normal fault system, potentially responsible for the 1693
198 earthquake, has been identified (e.g., Bianca et al., 1999; Argnani and Bonazzi, 2005;
199 Gambino et al., 2021, 2022b), (Figure 3).

200 The focal mechanisms over the Hyblean Plateau have dominant strike-slip charac-
201 teristics, contrasting with the extensional deformation characterizing the NE corner of
202 Sicily (Figure 3).

203

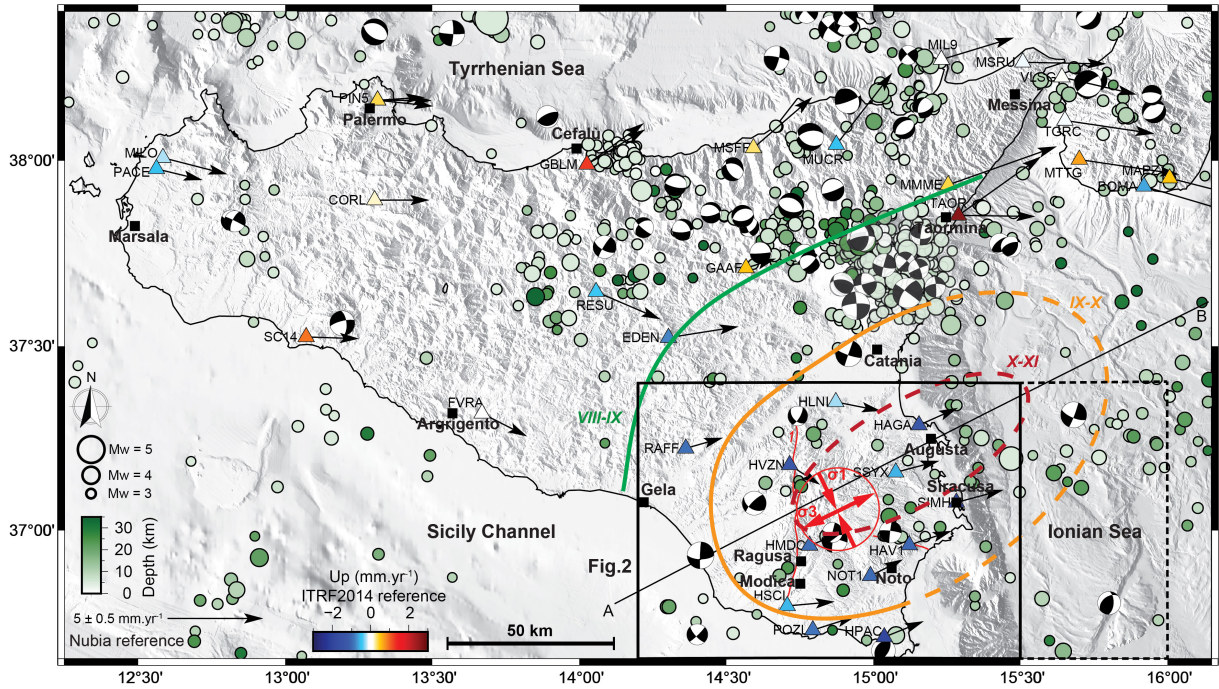

Figure 3 : Instrumental seismicity of Sicily at crustal scale (0-30 km depth) showing earthquake hypocentral locations and focal mechanism solutions of $M > 3$ events from 1985 to 2022 Istituto Nazionale di Geofisica e Vulcanologia (INGV) (2005); Scognamiglio et al. (2006). 3D surface velocity derived from GNSS time series published in Henriquet et al. (2022) (Horizontal components reference: fixed Nubia; Up components reference: ITRF2014). Macroseismic intensity data of the 1693 Val-di-Noto Earthquake ($M \sim 7.4$) from INGV CPTI15 database (Rovida et al., 2022): red dashed line = X-XI intensity, orange dashed line = IX-X intensity, green dashed line = VIII-IX intensity). Focal mechanisms stress inversion (red arrows) for the Hyblean Plateau region (black frame) and Ionian Sea (black dashed frame) using Michael's method (Vavryčuk, 2014; Levandowski et al., 2018). The AB profile shows the location of the PS-InSAR profile and synthetic structural cross-section presented in Figures 2 and 4.

204 To estimate the present-day regional stress field across SE Sicily, we analyzed
 205 the available focal mechanisms using Vavryčuk's numerical model (Vavryčuk, 2014;
 206 Levandowski et al., 2018) based on Michael's method (Michael, 1984). Results show that
 207 the regional stress across SE Sicily (Figure 3) is homogeneous (Supplementary Figures S7
 208 and S8). The maximum compressive stress (σ_1) is horizontal and oriented $N154^\circ E \pm 7^\circ$,
 209 compatible with the $N160^\circ E$ Africa-Eurasia plates convergence (e.g., Mattia et al., 2012;
 210 Kreemer et al., 2014). The minimum stress (σ_3) is oriented $N64^\circ E \pm 7^\circ$, compatible with
 211 the extension rate derived from GNSS data inversion (Figure 3).

212 If this regional stress field is compatible with the PS-InSAR surface deforma-
 213 tion data (E-W bending generating extensional stress), it does not explain the observed
 214 eastward-increasing subsidence rate across the HP.

215 **2.3 Synthetic structural profile**

216 To constrain the deep structure and rheology of the studied area, we synthesize
217 the available geological and geophysical data into a 200 km long simplified crustal-scale
218 structural cross-section following the N30°E AB profile. This section incorporates part
219 of the Hyblean Platform, the Malta Escarpment, the western Ionian domain, and cuts,
220 almost perpendicularly, the offshore normal faults along the Malta Escarpment and the
221 Alfeo and Ionian strike-slip fault systems, extending eastward (Figures 2, 3 and 4). The
222 eastern part of the synthetic structural profile is mainly based on seismic refraction profiles
223 from Dellong et al. (2018, 2020), particularly the DY-P3 profile running sub-parallel to
224 the AB profile and located 20 km further North, as well as seismic reflection profiles
225 from Argnani et al. (2012); Gutscher et al. (2016); Tugend et al. (2019); Gambino et al.
226 (2021, 2022b) (Figure 4c). The structure of the western section is constrained by onshore
227 and offshore geology, well log stratigraphy, geophysics, seismic reflection profiles, and
228 geological cross-sections from the ViDEPI project, Lentini and Carbone (2014), Lipparini
229 et al. (2023), Scarfi et al. (2018), Henriquet et al. (2019) and Finetti et al. (2005).

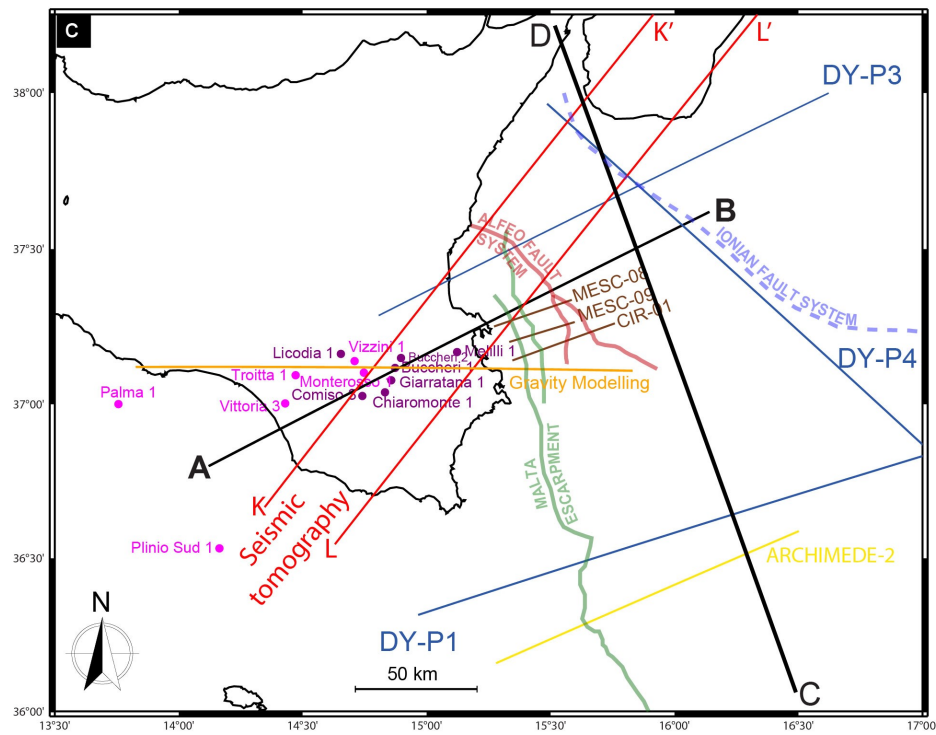

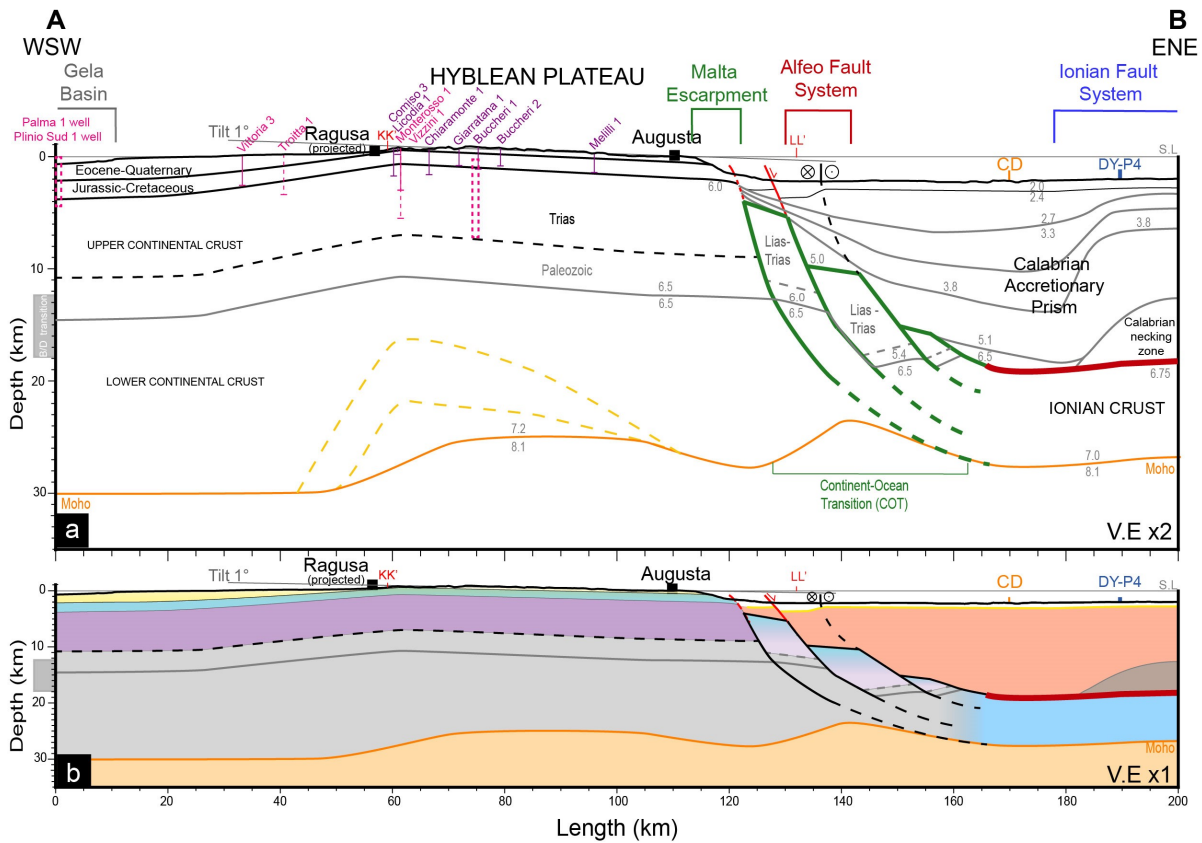

Figure 4 : Simplified crustal cross-section along the $N30^{\circ}E$ AB profile (see Figures 4c and 2 for location). a) Two times vertically exaggerated synthetic structural profile along with seismic velocity data showing the structure and rheology of the Hyblean Plateau and western oceanic domain determined from onshore and offshore geology, wells stratigraphy, geophysics, seismic reflection, and refraction profiles (see Supplementary Figure S9 for references). Note the 1° tilt of the Hyblean Plateau topography toward the East. The red line corresponds to the inferred position of the main subduction décollement, and the green lines, refer to our interpretation of tilted blocks from the Malta Escarpment (M.E). b) The synthetic structural profile shows the potential geological layers and structural deduced by, essentially, wells data for onshore domain and seismic refraction for offshore domain profiles, respectively, without vertical exaggeration (V.E.x1). c) Locations in the map view of the AB profile, wells data, tomography profile, refraction, and reflection seismic profiles.

230 In the Hyblean domain, geophysical data (e.g., SgROI et al., 2012; Milano et al., 2020)
 231 indicate that the crust has an average thickness of ~ 30 -35 km, with a notable difference
 232 in the Hyblean Plateau region, marked by a huge positive Bouguer anomaly. Based on
 233 gravity data modeling, Henriquet et al. (2019) showed that this gravity anomaly can be
 234 explained by a 100 km-large high-density lower crustal body, compatible with a local
 235 Moho uplift to a depth of about 20-25 km. This last interpretation seems also supported
 236 by recent tomographic data (Scarfi et al., 2018). We constrain the geometries of the
 237 Quaternary to Mesozoic sedimentary units of the Hyblean Platform and Gela basin are
 238 constrained using the Monterosso 1, Plinio Sud 1, Troitta 1, Vittoria 3, Vizzini 1 wells from
 239 ViDEPI project (in pink, Figure 4c and Supplementary Figure S9), the Chiaramonte 1 and
 240 Mellili 1 wells from Lentini and Carbone (2014), and Buccheri 1-2, Comiso 3, Giarratana
 241 1 and Licodia 1 wells from Lipparini et al. (2023) (in purple, Figure 4c and Supplementary
 242 Figure S9). We also used the top of the Upper Triassic (Gela formation) isobaths published
 243 by Lipparini et al. (2023).

244 In the DY-P3 seismic refraction profile (Dellong et al., 2018), the 6.0 and 6.5 km/s
 245 velocity contours delimit two main steps deepening eastward at the junction between
 246 the Hyblean continental and Ionian oceanic domains (Figures 4a and 4b). Considering
 247 their locations along the Malta Escarpment that outlines the Continent-Ocean Transition
 248 (COT), we interpret these velocity variations as deepening of the sediment/basement
 249 boundary, potentially related to tilted blocks of thinned continental crust formed during
 250 the Permo-Triassic/Early Jurassic rifting phase (see section 1) (e.g., Scandone et al., 1981;
 251 Minelli and Faccenna, 2010; Dellong et al., 2018; Tugend et al., 2019). Our interpretation
 252 of tilted blocks at the continent-ocean transition is consistent with similar considerations
 253 analyzing seismic reflection/refraction profiles (e.g., Afilhado et al., 2015; Sapin et al.,

254 2021; Klingelhofer et al., 2022).

255 As documented in Argnani and Bonazzi (2005), Gutscher et al. (2016), and Gambino
256 et al. (2021, 2022b), the seismic reflection profiles (MESC-O6, MESC-11, CIR-01, MESC-
257 08, and MESC-09) show several normal faults bounding and crossing the Turbiditic Valley,
258 extending along the base of the Malta Escarpment (Gutscher et al., 2016). The Turbiditic
259 Valley fault system is constituted by three parallel normal faults, ~ 60 km long, producing
260 a marked morphological offset of the Ionian seafloor from the latitudes of Catania to
261 Siracusa (Figures 4a and 4b). These faults dip $35\text{-}50^\circ$ to the East and most probably
262 merge at depth into a single major fault plane (Argnani and Bonazzi 2005; Argnani 2021;
263 cf. MESC-08 and MESC-09 seismic reflection profiles in Gambino et al. 2021). These
264 offshore normal faults could be linked to the recent re-activation of crustal faults at the
265 Ocean-Continent Transition, inherited from the Early Mesozoic rifting phase (Figures 4a
266 and 4b).

267 On the eastern side of the Hyblean domain, the Moho is constrained by DY-P3
268 and DY-P1 refraction profiles to a depth of ~ 30 km below the Malta Escarpment. To the
269 east, in response to the bending of the Ionian slab, the Moho deepens northward from 20
270 km (DY-P1) to 32 km (DY-P3). Based on these data and the DY-P4 refraction profile
271 (Dellong et al., 2020), we estimate the depth of the Moho below the Ionian oceanic crust
272 to be about 25-30 km in the eastern part of the AB synthetic profile. In this region, the
273 domain delimited by the seismic refraction velocities of 3.8-5.1 km/s has been interpreted
274 as corresponding to the deformed sediments of the Calabrian accretionary prism (CAP)
275 (Dellong et al., 2018). Its thickness increases from 5 km (DY-P1) to 15 km (DY-P3), and
276 it is evaluated to be ~ 15 km along the AB profile (Figures 4a and 4b). Note that a portion
277 of the southern termination of the Calabrian Arc (i.e., Hercynian basement) is probably
278 present in the AB profile according to the seismic refraction DY-P4 profiles (Dellong et al.,
279 2020) (Figures 4a and 4b). The location of the main subduction décollement along the
280 AB profile has been estimated at a depth of ~ 20 km (thick red line in Figure 4a) using
281 the velocity of 6.75 km/s seismic refraction DY-P3 and DY-P4 profiles (Dellong et al.,
282 2018).

3 Mechanical model hypotheses

To explain the long wavelength bending trend evidenced by the PS-InSAR Up component, we model the flexure of the Hyblean Plateau induced by (1) overloading of the continent-ocean transition (COT) domain in response to the SE migration of the very thick Calabrian accretionary prism (CAP), and (2) forced subsidence of the COT due to the local increase of the slab pull force imposed by the southward roll-back of the Ionian subduction. We hypothesize that these crustal/lithospheric deformation mechanisms may be strong enough to bend the adjacent Hyblean domain and induce the large-scale subsidence and tilt evidenced by the geodetic data (PS-InSAR and GNSS) (Figure 2b). In addition, we test interseismic loading models on several onshore and offshore east-dipping normal faults, such as the Augusta-Siracusa fault, the Malta Escarpment, and the active faults documented by Bianca et al. (1999); Argnani and Bonazzi (2005), Gutscher et al. (2016) and Gambino et al. (2021, 2022b), to explain the short wavelength deformation signal (relative uplift) extending along the eastern coast of the Hyblean Plateau (Figure 2b).

3.1 Lithospheric flexure along a NNW-SSE profile

To better constrain key flexural parameters, such as the rigidity of the Hyblean and Ionian crust/lithospheres, the slab-pull force, and to investigate the impact of the Ionian slab roll-back, we first model the bending of the subducting Ionian slab along a NNW-SSE profile (CD profile), trending orthogonal to the AB profile (Figure 5a). We compare the Ionian slab geometries with Hayes et al. (2018) and Maesano et al. (2017) datasets with the depth of the top oceanic crust from Dellong et al. (2018) seismic refraction data (Supplementary Figure S10). In the southern part of the CD profile, the Maesano et al. (2017) dataset indicates shallower depths (~ 5 km), compared to Hayes et al. (2018) and Dellong et al. (2018, 2020) data, because the main décollement jumps away from the top of the Ionian oceanic crust to a higher level in the sedimentary cover (Supplementary Figure S10). Note that in the northern part of the CD profile, the Maesano et al. (2017) dataset indicates also a shallower depth compared to the Hayes et al. (2018) dataset.

Finally, we decided to use, as a structural reference, the isobaths of the top of the Ionian slab published by Hayes et al. (2018) because it correlates with the top of the

313 oceanic crust depths derived from the seismic refraction data (Dellong et al., 2018, 2020)
314 (Figure 5a).

315 The lithosphere flexure models (as well as those in section 3.2) are calculated
316 using the gFlex software (Wickert, 2016). We impose a no-displacement condition at the
317 southern profile boundary and a broken plate with no bending moment and no shear at
318 the northern boundary. The Ionian oceanic lithosphere is modeled assuming an effective
319 elastic thickness (T_e) ranging from 25 to 37 km (Figure 5b and Supplementary Figure S11)
320 compatible with its Triassic to early Jurassic age (e.g., Catalano et al., 2001; Speranza
321 et al., 2012) and consistent with other publications (e.g., Watts and Zhong, 2000; Tesauero
322 et al., 2012; Cloetingh et al., 2015).

323 The flexure of the subducting slab depends on its mechanical properties and the
324 loads induced by the sedimentary cover, the accretionary prism, and the slab pull force
325 (Figure 5b). According to seismic refraction profiles DY-P1 and DY-P4 (Dellong et al.,
326 2018, 2020), the undeformed ante-Messinian sedimentary cover overlying the Ionian crust
327 has a thickness of about 5 km. Thus, taking into account a depth of the Ionian Sea of
328 5-6 km, we consider that the top of the Ionian crust was lying at a uniform depth of
329 10-11 km before the onset of the Calabrian subduction system (Figure 5b). This depth
330 corresponds to the isostatic equilibrium for the Ionian crust. It determines the initial
331 geometry of the flexural model from which we calculate the bending induced by the
332 Calabrian accretionary prism (CAP) load.

333

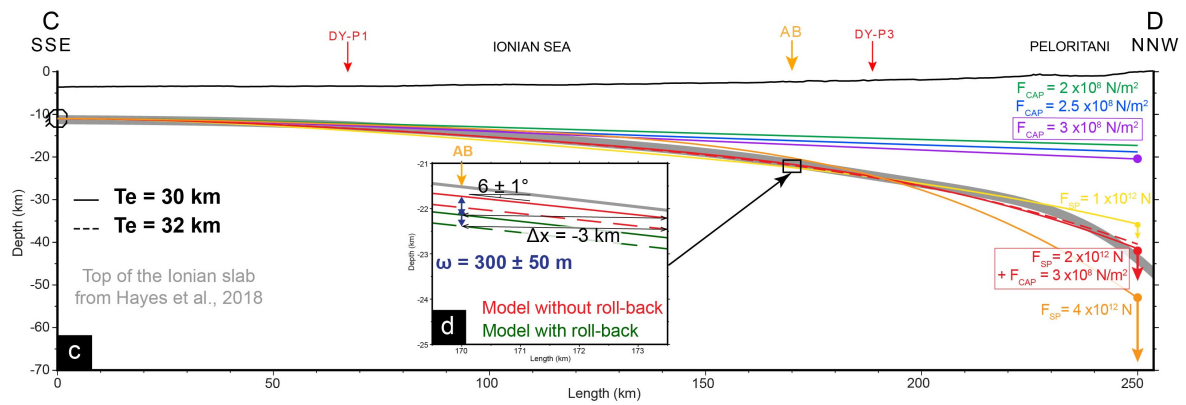

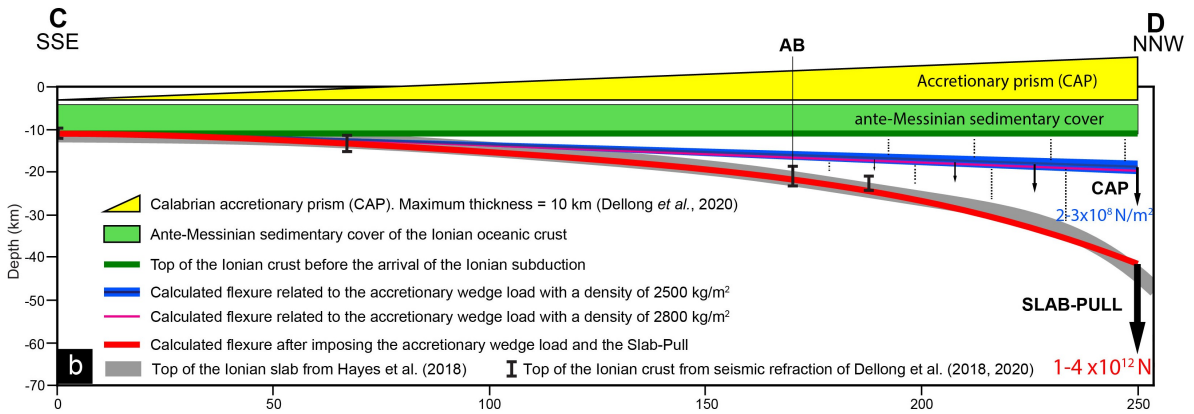

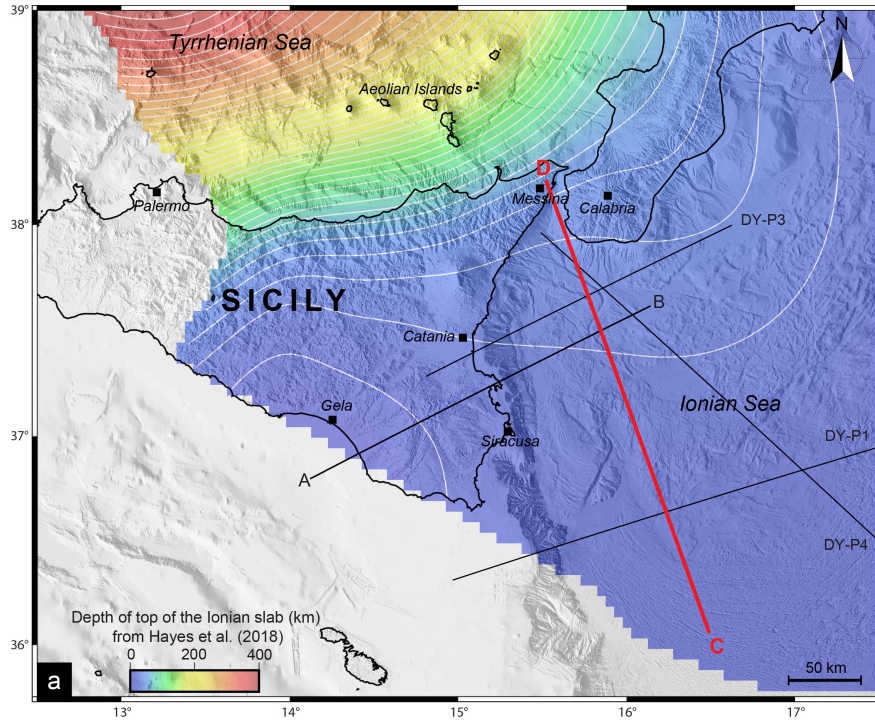

Figure 5 : a) Map and isobaths of the top of the Ionian slab subducting below the Calabrian Arc (Hayes et al., 2018) with seismic refraction profiles from Dellong et al. (2018, 2020), also used to constrain the top of the Ionian oceanic crust. b) NNW-SSE trending CD cross-section (in gray) showing the flat and ramp geometry of the Ionian slab (see location in Figure 5a). *Interval symbols outline the top of the Ionian crust derived from seismic refraction profiles (Supplementary Figure S10).* The Ionian oceanic lithosphere supports a 5 km thick homogeneous Paleogene sedimentary cover (in green). The CAP (in yellow) thickness increases northward up to ~ 15 km (Dellong et al., 2020). The associated flexure (in blue) is calculated with density ranging from 2500 kg/m^2 to 2800 kg/m^2 (in dark blue and pink). The bending of the slab is controlled by the slab pull, represented as a punctual load, ranging from $1\text{-}4 \times 10^{12} \text{ N}$ (in red). c) The Paleogene cover and the CAP load are performed with a maximum CAP load of $2 \times 10^8\text{-}3 \times 10^8 \text{ N/m}^2$. Flexural models are performed with effective elastic thicknesses (T_e) ranging from 25 to 37 km and slab pull forces ranging from 1×10^{12} to $4 \times 10^{12} \text{ N}$ (Supplementary Figure S11). Topographic, slab, and flexural model profiles are presented without vertical exaggeration (V.E.x1). d) Zoom of profiles CD and AB intersection showing the depth difference between favorite models: CAP load of $3 \times 10^8 \text{ N/m}^2$, slab pull of $2 \times 10^{12} \text{ N}$, elastic thickness of 30 (continuous line) and 32 (dashed line) km, without rollback (red line) and with rollback (green line). The local subsidence associated with the 3 km/Myr slab SE retreat is estimated to be about $300 \pm 50 \text{ m}$.

334 Based on seismic refraction profiles DY-P4, DY-P1, and DY-P3 (Dellong et al., 2018,
 335 2020), the Calabrian accretionary prism thickness increases northward from 5 to 15 km.
 336 By removing the initial 5 km-thick Ionian sedimentary cover, the CAP load represents
 337 an increase in sediment thickness from 0 km at the southern end of the CD profile to 10
 338 km at the northern end. The Calabrian backstop, made of Hercynian continental crust,
 339 is not taken into account (Figure 5b).

340 The CAP load is calculated by:

$$F_{CAP} = \rho gh \quad (1)$$

341 with a sediment density (ρ) of $2500\text{-}2800 \text{ kg/m}^2$ (profile 2D) using to Dellong et al. (2020),
 342 a gravity acceleration (g) of 9.81 m/s^2 , and an increase of the CAP thicknesses (h) from 0
 343 to 10 km. We also calculated the CAP load using an end-member density of 2800 kg/m^2
 344 (Figure 5b), which resulted in a variation in flexure amplitude of a few percent, thus not
 345 affecting the results of continental flexural models.

346 The CAP load (F_{CAP}) is applied on the CD profile divided into 1-km-long segments
 347 by imposing a northward linear gradient from 0 to $2.45 \times 10^8 \text{ N/m}^2$ (equation 1) on the
 348 first 250 km of the profile (Figures 5b and 5c). We perform several tests with different
 349 maximum CAP load (F_{CAP}) and elastic thicknesses (T_e) ranging from 2×10^8 to $3 \times$
 350 10^8 N/m^2 and 25 to 37 km, respectively. Models are tested with a constant mantle density
 351 of 3300 kg/m^2 and no filling density for mantle restoration force (Figure 5c). The resulting

352 flexure (~ 8 km maximum), even if significant, is not sufficient to fit the Ionian slab profile
353 (gray line in Figures 5b and 5c).

354 The slab pull force is then added to the northern termination of the Ionian litho-
355 sphere as a point load (Figure 5b). We tested with different slab pull forces ranging from
356 1×10^{12} to 4×10^{12} N, consistent with other publications reviewing slab rollback mechani-
357 cal properties (e.g., Lallemand et al., 2008) and the same range of elastic thicknesses from
358 25 to 37 km (Figure 5c and Supplementary Figure S11). The best fit to the Ionian slab
359 top profile is obtained for elastic thicknesses (T_e) of 30-32 km, a maximum accretionary
360 wedge load (F_{CAP}) of 3×10^8 N/m², and a slab pull force (F_{SP}) of 2×10^{12} N (Figure 5c
361 and Supplementary Figure S11). It's worth noting that including the CAP load signifi-
362 cantly reduces the amplitude of the fore bulge associated with slab bending, resulting in
363 a flat-and-ramp geometry similar to that of the Ionian slab.

364 **3.2 Crustal flexure along a WSW-ENE profile**

365 The impact of the Ionian subduction roll-back on the deformation of the Hyblean
366 Plateau is evaluated along the N30°E trending AB profile (Figure 5a), considering the fol-
367 lowing simplifications: (1) The ongoing roll-back induces incremental changes in the slab
368 profile that can be matched with a southward translation of the slab geometry, inducing a
369 local deepening. (2) This results in a local incremental increase of the accretionary prism
370 thickness. (3) Due to the mechanical coupling of the Ionian slab and Hyblean lithosphere,
371 the slab deepening exerts an incremental downward force on the COT (Figure 6).

372 The effective elastic thickness of the Hyblean lithosphere is less constrainable than
373 that of the Ionian lithosphere but should remain within standard values for a regular
374 undeformed continental crust with an average geotherm. We test elastic thicknesses (T_e)
375 ranging from 25 to 40 km (Figure 6), assuming a uniform thickness, considering that the
376 continent-ocean transition and the oceanic lithosphere have the same elastic rigidity as
377 the Hyblean crust. Finally, we also considered that none of the fault systems offshore
378 SE Sicily are mature enough to significantly affect the mechanical properties of the
379 above-mentioned crustal/lithospheric blocks (e.g., Gambino et al., 2022a).

380

Figure 6 : a) Continental crustal flexure is controlled by the southward retreat of the Ionian slab. We calculated the flexure (*gFlex* from Wickert, 2016) induced by the only CAP load (F_{CAPa}) of $10 \text{ N/m}^2/\text{yr}$ distributed on the Continent-Ocean Transition (in black), and on the adjacent Ionian crust (in white). For an elastic thickness of 30 km , best models have bending forces (F_B) of $1 \times 10^4 \text{ N/m/yr}$ (in green), $1.5 \times 10^4 \text{ N/m/yr}$ (in orange), $2 \times 10^4 \text{ N/m/yr}$ (in purple), $2.5 \times 10^4 \text{ N/m/yr}$ (in brown), and $3 \times 10^4 \text{ N/m/yr}$ (in yellow) distributed on the only adjacent Ionian crust or including also part of the COT (see also Supplementary Figure S12). b) Best models (Supplementary Figure S12) are compatible with a wide range of elastic thicknesses ($25\text{-}40 \text{ km}$). PS-InSAR vertical velocities (in blue) and GNSS vertical velocities with their uncertainties. Topographic and bathymetric profiles are presented without vertical exaggeration ($V.E.x1$).

381 We first evaluate the flexural response due solely to the local incremental increase
 382 of the CAP load induced by its southward migration, using our previous analysis of the
 383 bending of the Ionian slab. Based on the velocities of the GNSS stations situated in
 384 Calabria, we estimate the southward migration to 3 mm/yr , compared to a fixed Hyblean
 385 Plateau (Henriquet et al., 2022). At the intersection between AB and CD profiles, at
 386 the 170 km length mark in the CD profile, the Ionian slab dips $6 \pm 1^\circ$ toward the north
 387 (Hayes et al., 2018) (Figure 5d). Taking into account the CAP geometry, its southward
 388 motion, and the slab geometry, we calculate a local incremental thickening of the CAP
 389 of $3 \times 10^{-4} \text{ m/yr}$ (equivalent to 300 m/Myr) and a resulting load (F_{CAPa}) of about 5-
 390 $10 \text{ N/m}^2/\text{yr}$ (Figure 5d). Applying a linear load gradient starting from zero at the base
 391 of the Malta Escarpment (140 km marks of the AB profile) to $5\text{-}10 \text{ N/m}^2/\text{yr}$ at the end
 392 of the continent-ocean transition (165 km marks of the AB profile), then applying this
 393 constantly load until the end of the AB profile results in a slow onshore subsidence rate of

394 $1.5 \times 10^{-4} \pm 5 \times 10^{-5}$ mm/yr maximum, 20 000 time smaller than the PS-InSAR subsidence
 395 rate measured in the same area (~ 3 mm/yr).

396 We then investigate the effect of the southward Ionian slab roll-back and associ-
 397 ated downward pull on the COT. We first calculate the flexural rigidity of the oceanic
 398 lithosphere (Turcotte and Schubert, 2014):

$$D = \frac{ETe^3}{12(1 - \nu^2)} \quad (2)$$

399 with a Young modulus (E) of 1×10^{11} Pa, a Poisson's ratio (ν) of 0.25, and effective
 400 elastic thicknesses (Te) of 30-32 km (see 3.1). We obtain a flexural rigidity (D) of the
 401 Ionian lithosphere of $2.4\text{-}2.9 \times 10^{23}$ Pa m³.

402

403 To simulate the Ionian slab retreat, we translate the slab profile southward, as-
 404 suming a slab retreat velocity of ~ 3 mm/yr (D'Agostino et al., 2011) (Figure 5d). At
 405 the intersection of profiles AB and CD, this induces an incremental deepening of the Io-
 406 nian slab of about 3×10^{-4} m/yr (equivalent to 300 m/Myr), which defines the equivalent
 407 downward force at the same location along the CD flexure profile (Turcotte and Schubert,
 408 2014):

$$F_B = \frac{\omega 2D}{x^2(L - \frac{x}{3})} \quad (3)$$

409 with an incremental deflection (ω) of 3×10^{-4} m/yr (Figure 5d) and a flexural rigidity
 410 (D) of $2.4\text{-}2.9 \times 10^{23}$ Pa m³. The total profile length L corresponds to the point of the
 411 Hyblean lithosphere where the deflection (ω) is null, ~ 200 km based on the PS-InSAR and
 412 structural data (Figure 6). The distance x corresponds to the point where the deflection
 413 (ω) is estimated (intersection with profile CD). Considering $L = 250 \pm 50$ km and $x =$
 414 150 km, the equivalent incremental downward force is about $1\text{-}6.5 \times 10^4$ N/m/yr.

415 This equivalent force (F_B) is then applied on the AB profile to model, with gFlex,
 416 the resulting flexure of the Hyblean crust/lithosphere. Flexural models are calculated
 417 with a no-displacement boundary condition at the southwestern end of the profile (20 km
 418 west of Gela) and a free displacement of a horizontally clamped boundary condition at
 419 its northeastern end (80 km East of Malta Escarpment). Flexural models are run with
 420 a fill density of 2500 kg/m² (2D profile) solely for the CAP load. The downward force

421 (F_B) and CAP load (F_{CAPa}) are applied as constant loads (on 1-km-long segments) over
422 the 35 or 60-km-long portion of the AB profile corresponding to the only adjacent Ionian
423 crustal domain, and from the base of the Malta Escarpment to the end of the COT, as a
424 linear load gradient evolving from zero to the maximum calculated load. We test different
425 elastic thicknesses (T_e) and bending force (F_B) ranging from 25 to 40 km and 1×10^4 to
426 6.5×10^4 N/m/yr, respectively (Figure 6b and Supplementary Figure S12).

427 To determine the best Hyblean crustal flexure models, we first filter the PS-InSAR
428 vertical velocities (5 km stacked of the AB profile) using a 5 km width median filter with a
429 step of 1 km. Comparing the resulting long-wavelength trend of the PS-InSAR data with
430 all flexural models shows maximum misfits of about 12 mm/yr. The comparison between
431 the GNSS data (20 km stacked of the AB profile and 5 km large median filter with a step
432 of 1 km) shows a little bit higher maximum misfit of about 13 mm/yr due to a variable
433 spatial density and quality of GNSS stations over the Hyblean Plateau (Supplementary
434 Figure S12c). The best models (0.5 mm/yr RMS PS-InSAR) have a CAP load plus a
435 bending force ranging from 1×10^4 to 3×10^4 N/m/yr distributed on a 35 km long portion
436 of the AB profile, and also between 1×10^4 to 1.5×10^4 N/m/yr distributed on a 60 km
437 long portion of the AB profile, with effective elastic thicknesses ranging from 25 to 40
438 km (Figure 6b, and Supplementary Figures S12b, S12c). None of the tested continental
439 crustal flexure models reproduce the short wavelength deformations observed in the Gela
440 region (slow uplift of ~ 0.5 mm/yr) or along the Augusta-Siracusa coastal area (relative
441 uplift of 1-2 mm/yr).

442 **3.3 Interseismic loading and aseismic creep on coastal and off-** 443 **shore faults**

444 Along the coast, from Augusta to Siracusa, PS-InSAR vertical velocities vary at
445 a kilometer scale and appear 1-3 mm/yr slower than the general trend of subsidence
446 affecting the Eastern Hyblean Plateau (Figures 2a and 6b). Interestingly, these short
447 wavelength signals show triangular patterns similar to those produced by shallow faulting
448 in an elastic domain. To investigate the sources of these surface deformations, we test
449 several scenarios involving interseismic loading and aseismic creep on coastal and offshore
450 faults.

451 Offshore, several active normal faults, outcropping along the base of the Malta Es-
452 carpment, have been identified, imaged, and documented in detail by Argnani and Bonazzi
453 (2005); Gutscher et al. (2016); Gambino et al. (2021, 2022b). Close to the coastline, **the**
454 **offshore** Augusta-Siracusa fault (Figure 7) has also been considered a potentially active
455 fault (e.g., Bianca et al., 1999; Azzaro and Barbano, 2000). We use the Coulomb 3.4
456 software (Toda et al., 2011) to impose different fault slip rates and geometric boundary
457 conditions on these fault systems, assuming standard elastic properties (Poisson’s ratio of
458 0.25, Young modulus of 80 GPa).

459 The fault plane geometries tested (strike, dip) are based on published field-trip
460 observations and measurements (Gambino et al., 2021). Fault locations are based on
461 published geological/structural maps (Adam et al., 2000) and on the presence of sharp
462 gradients in the PS-InSAR velocity pattern. The imposed fault slip velocities result from
463 a trial-and-error empirical approach. The objective, essentially, is to evaluate if aseismic
464 slip on known and unknown faults could generate sufficient surface deformation to explain
465 the measured surface deformation pattern.

466 The model predictions are compared to the PS-InSAR short wave-length signals
467 (Figure 7b) obtained by removing the mean of best-fitting flexural models (see section
468 3.2) from the original geodetic dataset. Two patterns of relative uplifts of about $2.5 \pm$
469 0.5 mm/yr, gently tapering westward, can be identified near and to the SE of Augusta
470 with a zone of relative subsidence of about -2 ± 1 mm/yr in between them (Figure 7a).
471 We hypothesized that these surface deformations could be induced by fault slip along
472 ENE-dipping normal fault systems (Figure 7).

473

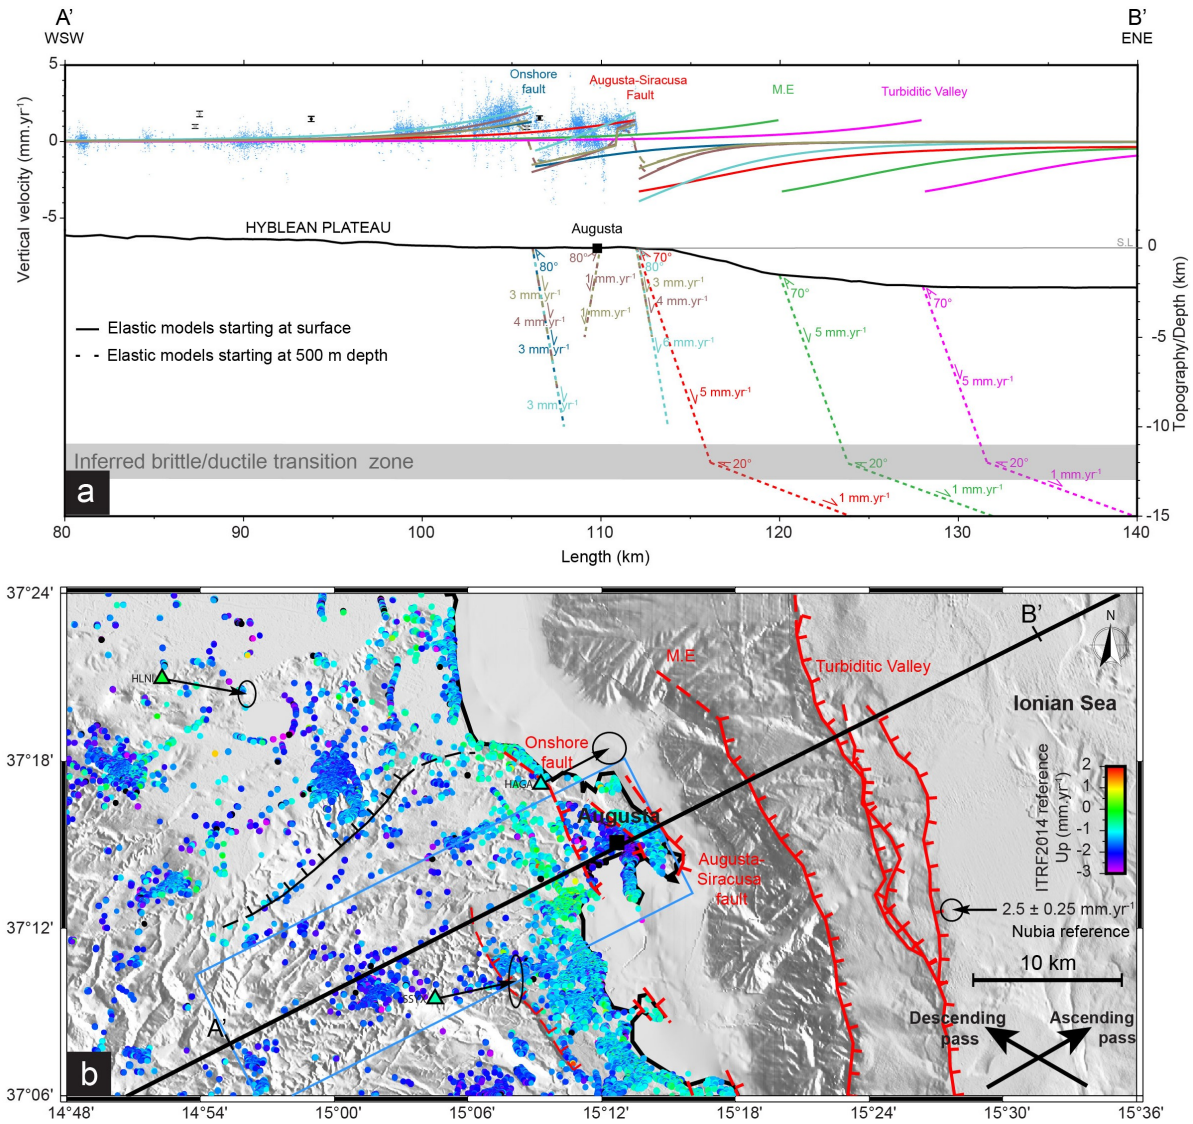

Figure 7 : a) Coulomb 3.4 (Toda et al., 2011) numerical models of interseismic elastic loading on offshore and coastal inferred active faults along the eastern Hyblean Platform. PS-InSAR Up velocities (in blue) are stacked across a 5 km width on both sides of the AB profile. Modeled interseismic deformations related to: the Turbiditic Valley normal fault (in magenta), the Malta Escarpment (in green), the Augusta-Siracusa coastal fault (in red), onshore inferred active faults in Augusta (in dark blue). Modeled elastic loading of the Augusta-Siracusa coastal fault plus onshore inferred active faults in Augusta are represented in light blue, light, and dark brown lines. Topography/depth is represented without vertical exaggeration (V.E.x1). b) Map view of geodetic data in the northeastern part of the Hyblean Plateau. Major faults of the Hyblean Plateau containing the Augusta-Siracusa coastal fault and the inferred onshore active fault, and Malta Escarpment (M.E) including the Turbiditic Valley faults (red: active fault; red dashed: inferred active fault; black: inferred aseismic slip).

474 The first set of models corresponds to interseismic locking of the shallow (0 to
 475 10-15 km depth) sections of the main normal faults identified in the study area (Figure
 476 7b) and elastic loading by deep (> 15 km depth) creeping sections. Regardless of the
 477 deep fault geometry or slip rates, all these models generate generalized long-wavelength
 478 subsidence rates incompatible with the geodetic data (green dotted line, Supplementary
 479 Figure S13). Thus, we dismiss interseismic loading as a potential mechanism to explain

480 the short wavelength surface deformation patterns.

481 The second set of models corresponds to shallow aseismic slip imposed on three
482 offshore normal faults: the Augusta-Siracusa fault (Bianca et al., 1999), the Malta Es-
483 carpment fault, and the Turbiditic Valley fault (Gutscher et al., 2016; Gambino et al.,
484 2021, 2022b) (Figure 7a and Supplementary Figure S13). We decided to test the Malta Es-
485 carpment fault because it lies between the Turbiditic Valley active fault and the Augusta-
486 Siracusa fault, for which evidence of activity has been documented by as yet unpublished
487 sparker lines acquired in the Augusta Bay (G. Barreca, C. Monaco, personal commu-
488 nication). The modeled faults (Figure 7a) share a similar listric geometry with a first
489 fault plane dipping 70° NE and extending from the surface to 12 km depth (inferred brit-
490 tle/ductile transition zone) and a second one dipping 20° NE and extending from 12 to
491 50 km depth (to limit boundary effects). We imposed slip rates of 5 mm/yr on the first
492 fault plane, based on [the](#) Meschis et al. (2020) model (Supplementary Figure S13), and 1
493 mm/yr on the second plane to dampen the elastic deformation produced by slip on the
494 shallow fault (Figure 7a). Aseismic slip on these various faults produces coastal uplift
495 rates, reaching at most ~ 1 mm/yr for the Augusta-Siracusa fault, consistent with the
496 PS-InSAR measurements east of Augusta (Figure 7a). However, all the modeled offshore
497 faults failed to reproduce the ~ 2 -3 mm/yr relative uplift rates measured west of Augusta
498 (Figures 7a and 7b).

499 The third set of models focuses on surface deformation generated by aseismic creep
500 on 70 - 80° ENE-dipping shallow coastal and onshore fault planes. We first simulate slip on
501 the upper portion of the Augusta-Siracusa fault, but if this model succeeds in producing
502 sufficient uplift east of Augusta, it fails to reproduce the relative uplift west of Augusta.
503 Based on PS-InSAR data and structural evidence of regional onshore normal faulting (e.g.,
504 Adam et al., 2000; Gambino et al., 2021), we added to the previous Augusta-Siracusa fault
505 model an 80° dipping onshore normal fault outcropping at the 106 km mark of the AB
506 profile (sharp velocity gradient in the PS-InSAR data), with a slip rate of 3 mm/yr down
507 to 10 km depth (light blue lines in Figure 7a). The surface deformation generated by this
508 dual creeping fault can explain the observed PS-InSAR relative uplift between the 103
509 and 106 km profile marks and 110 and 112 km. Note that imposing aseismic slip on the
510 onshore normal fault alone fails to reproduce the subsidence east of Augusta (dark blue
511 line in Figure 7a).

512 The triangular patterns of sharp steps and associated lows in the PS-InSAR data
513 could be also fitted by a three-fault model, involving shallower aseismic creep (up to 5 to
514 8 km depth) and combining the onshore ENE-dipping fault (106 km mark), creeping at
515 3-4 mm/yr, with an antithetic onshore WSW-dipping fault (110 km mark), creeping at
516 1 mm/yr, and the Augusta-Siracusa coastal fault (112 km mark), creeping at 3-4 mm/yr
517 (brown lines in Figure 7a). We test the same configuration (two onshore faults and the
518 Augusta-Siracusa coastal fault) with a fault plane propagating to the surface up to 500
519 m depth (Figure 7a). This model, equivalent to a blind fault, induces vertical surface
520 deformation (between the 106 and 110 km marks) about 0.2 mm/yr slower than the
521 model starting to creep from the surface but remains consistent with the PS-InSAR data.

522 **At present, however, there is no evidence of the existence of faults matching the**
523 **ones used in the third set of models.** All **these** ad-hoc models, illustrate that the short
524 wavelength geodetic signal along the Eastern Hyblean Plateau coast could be explained
525 by ongoing extension tectonics and creep on coastal normal faults.

526 **3.4 Alternative hypothesis**

527 To explore if other natural processes could explain part of the observed geodetic
528 velocity patterns, we briefly investigate three alternative models:

529 **Mantle flow upwelling**

530
531
532 Seismic tomography and volcanic data identify a slab window extending along
533 most of the northern coast of Sicily, with a slab break-off recently propagating from
534 west to east and potentially triggering toroidal and upwelling mantle flows (Trua et al.,
535 2003; Civello and Margheriti, 2004; Faccenna et al., 2005; Scarfi et al., 2018). This
536 process could induce long wavelength surface motions (so-called dynamic topography)
537 over the whole of Sicily. However, mantle flow numerical modeling mainly predicts
538 areas of uplift and subsidence restricted to Mount Etna and the southern Peloritani
539 region (Faccenna et al., 2011; Gallen et al., 2023). Thus, SE Sicily appears to be
540 situated too far from the Ionian slab edge to be affected by upwelling mantle flow. There-
541 fore, it is unlikely that this hypothesis explains the observed vertical surface deformations.

543 **Volcanic deflation**

544

545 The last volcanic activity documented on the Hyblean Plateau dates back 1.4
546 Myr (Schmincke et al., 1997; Behncke, 2004), but **post-volcanic deep tectono-magmatic**
547 activity, not recorded at the surface, cannot be ruled out. In such a case, volcanic material
548 deflation located below the central Hyblean Plateau could induce local subsidence rates
549 affecting a large region. We tested this hypothesis numerically with deflating spheres, 6
550 to 14 km in diameter (Mogi model, Supplementary Figure S14), situated at a depth of 8
551 km, at the top of the Paleozoic basement and possible location of magma accumulation
552 (Henriquet et al., 2019). Our first-order tests show that even using extreme deflations of
553 50-75%, the PS-InSAR subsidence rates cannot be reproduced (Supplementary Figure
554 S14), rendering the volcanic deflation hypothesis extremely unlikely.

555

556 **Hydrological loading**

557

558 The geology of the Hyblean Platform is mainly composed of limestones and
559 dolomites in a karstic environment. Long-term recharge or discharge of karst aquifers
560 is known to induce transient elastic deformation, measurable geodesically (e.g., Grillo
561 et al., 2011; Silverii et al., 2016; D'Agostino et al., 2018). Hydrological loading/unloading
562 cycles can have a significant impact on vertical deformation, up to a few tens of mil-
563 limeters on an annual cycle (White et al., 2022). The effects of hydrological variation on
564 pluri-annual trends are more difficult to assess. Here, we consider velocities over **five** years
565 from PS-InSAR and GNSS. The regional subsidence rate of 1-3 mm/yr and associated
566 east-side-down tilt would require an average increase of the water level by $\sim 10-20$ cm over
567 **five** years at the scale of the whole Southeastern Sicily reservoir. This seems incompatible
568 with the absence of similar observable effects over Central and Western Sicily and with
569 the drought periods that have affected Sicily in recent decades. Hydrological loading, as
570 a source of large-scale surface subsidence, is then unproved.

571 4 Discussions

572 4.1 Short-term and long-term model limits

573 We explain the eastward tilt and subsidence rates of the Hyblean Plateau as the
574 flexure of the Hyblean continental crust/lithosphere induced by the southward migra-
575 tion of the Calabrian Accretionary Prism (CAP) and retreat of the Ionian subducting
576 slab (sections 3.1 and 3.2). This model is based on the assumption that the geodetic
577 data (GNSS and PS-InSAR), measured over a short period (5-15 years), are represen-
578 tative of the kinematic evolution of the studied region at the scale of a few hundred
579 to a thousand years. In the absence of significant seismic events during the period of
580 geodetic data acquisition, and considering that major earthquakes ($M > 7$) in SE Sicily
581 probably have a return period of more than 500 years, geodetic data are mainly recording
582 interseismic elastic deformation and possibly, minor permanent one (fault creep, fold-
583 ing, human-related surface deformation). Flexural modeling indicated that the increasing
584 loading of the COT, induced by the southward propagation of the CAP, is not suffi-
585 cient (Figure 6b). The increase in bending force, imposed by a ~ 3 mm/yr southward
586 retreat of the Ionian slab, gives interesting positive results. This process could be strong
587 enough to pull down the Eastern termination of the Hyblean crust at velocities compat-
588 ible with PS-InSAR measurements. However, we obtained this result considering that
589 the Hyblean crust/lithosphere, the Continent-Ocean Transition (COT), and the Ionian
590 crust/lithosphere have similar mechanical properties. **The role of the nearby Alfeo-Etna**
591 **Fault system (AEF) is still under debate: even though it cuts the entire lithosphere start-**
592 **ing in recent times (probably middle-late Pleistocene), it has probably not reached yet the**
593 **stage of a slab tear (STEP) (Polonia et al., 2016; Gambino et al., 2022a). We, therefore,**
594 **considered the AEF** not mature enough offshore SE Sicily to **significantly** alter the me-
595 chanical properties of the above-mentioned crustal/lithospheric blocks. This assumption
596 implies that the COT has a significantly rigid and potentially too strong rheology (Figure
597 8), as discussed hereafter (section 4.2).

598 We used simple 2D elastic models based on parameters determined through ana-
599 lytical modeling of the Ionian oceanic lithosphere flexure using, as a reference, the Ionian
600 slab geometry determined by Hayes et al. (2018), and data (depth of the top of the Io-
601 nian crust) extracted from the refraction profiles published in Dellong et al. (2018). The

602 use of more advanced numerical models (FEM), including 3D modeling methods, would
 603 likely improve our first-order estimates. Similarly, the lateral variations of the Hyblean
 604 continental crust thickness and elastic properties are not accurately known. We used the
 605 available geophysical data (Scarfi et al., 2018; Henriquet et al., 2019), but it was not possible
 606 to constrain the Hyblean crust/lithosphere rheology with better confidence (Figure
 607 8). Should such parameters become available in the future, they could be used to refine
 608 our Hyblean crust/lithosphere flexure calculations.

609 One of the other assumptions we made concerns the rate of increase in the slab
 610 bending force due to the southward propagation of the Ionian slab roll-back. The
 611 calculated increase in slab bending force east of the HP is based on the estimated rate of
 612 southward retreat of the Ionian slab defined by the mean of the GNSS NS horizontal ve-
 613 locities in southwest Calabria (using as a reference Malta Island). However, this estimate
 614 may be understated if the Calabrian Arc migrates southward more slowly than the Ionian
 615 slab retreat, due to lateral mechanical interactions with the Apulian and African margins.

616

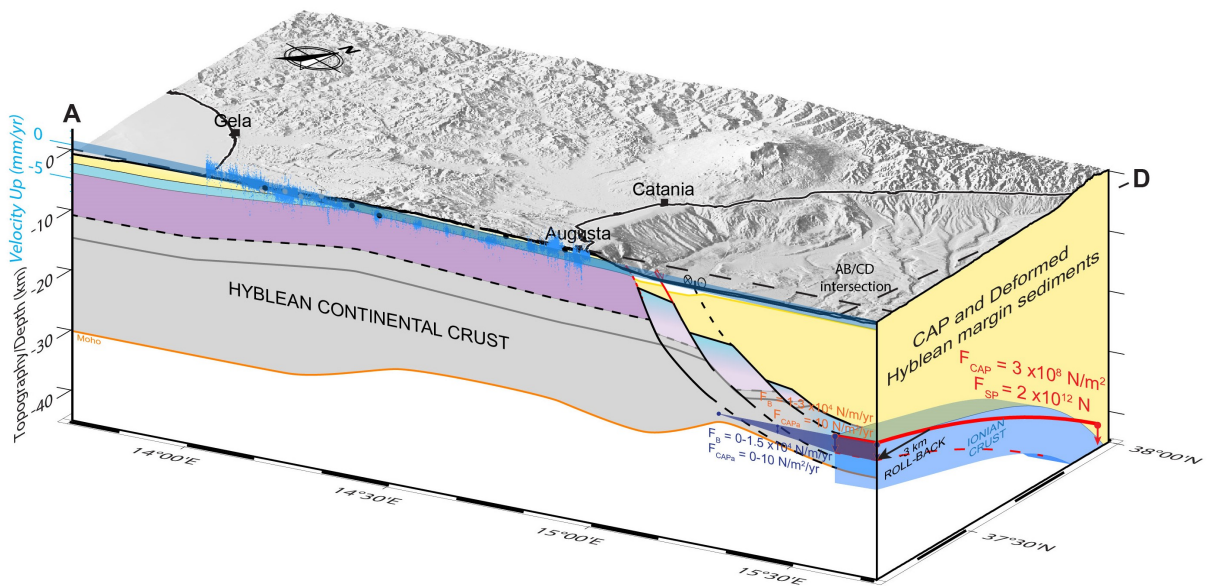

Figure 8 : Schematic 3D deformation model of Southeastern Sicily bounded by profiles AB and CD and controlled by Ionian slab roll-back. The 3 km southward retreat of the Ionian crust flexure model (red dashed line) has a horizontal exaggeration of 6 times. The Moho of the Hyblean continental crust determined by geophysical data (Scarfi et al., 2018; Henriquet et al., 2019) is in orange. The Calabrian accretionary prism (CAP) and deformed Hyblean margin sediments are in yellow. The synthetic structural profile in the AB profile has no vertical exaggeration (V.E x1).

617 The short-wavelength relative uplift signal, observed in the geodetic data along
 618 the Southeastern Sicily coast, must be driven by more shallow deformation mechanisms
 619 than those responsible for the long-wavelength eastward flexure of the HP (Figure 6b).

620 Kilometer-long surface deformations are typically related to upper crustal deformation
621 processes (e.g., Burgmann and Thatcher, 2013), so we test interseismic loading models on
622 the inferred and identified onshore and offshore fault systems.

623 Slip on the Malta Escarpment and Turbiditic Valley normal fault cannot explain
624 the observed deformation of the eastern coast of the Hyblean Plateau. Only creep on the
625 Augusta-Siracusa coastal fault and antithetic structure (Bianca et al., 1999; Azzaro and
626 Barbano, 2000) induces onshore vertical deformation compatible with the geodetic data
627 near Augusta. Interseismic slip (creep) on two onshore ENE and WSW 80°-dipping faults
628 and the Augusta-Siracusa coastal fault fits with the PS-InSAR data in the Eastern of the
629 AB profile. These faults could re-activate inherited Permo-Triassic to Early Jurassic NW-
630 SE extensional structures, leading to the formation of the Augusta Graben, extending
631 up to Siracusa (e.g., Grasso and Lentini, 1982). Even if some seismic activity affects
632 this region (e.g., Adam et al., 2000; Azzaro and Barbano, 2000), field evidence of recent
633 (Holocene) tectonic activity has yet to be demonstrated.

634 Our results suggest that these faults should creep up to the surface or the near-
635 surface (blind fault) to produce sufficient interseismic surface deformation in the footwall.
636 In that later case, their surface expressions could correspond to gentle surface folding or
637 to fold scarp morphologies (e.g., Chen et al., 2007; Li et al., 2015) rather than localized
638 cumulated fault scarps.

639 High precision leveling data acquired between 1970-1991 and analyzed by Spamp-
640 inato et al. (2013), reveals a remarkable ~ 4 mm/yr velocity offset between benchmarks
641 107 and 113, both situated near the coast 5 km west of Augusta (Figure 9c). This sharp
642 vertical velocity gradient is correlated with a marked topographic step, trending NS,
643 and descending toward the sea. Northwest of Augusta, the leveling dataset also shows a
644 ~ 2 mm/yr offset between benchmarks 119 and 120, associated with a topographic step,
645 oriented E-W, and facing north (Figures 9b and 9c).

646

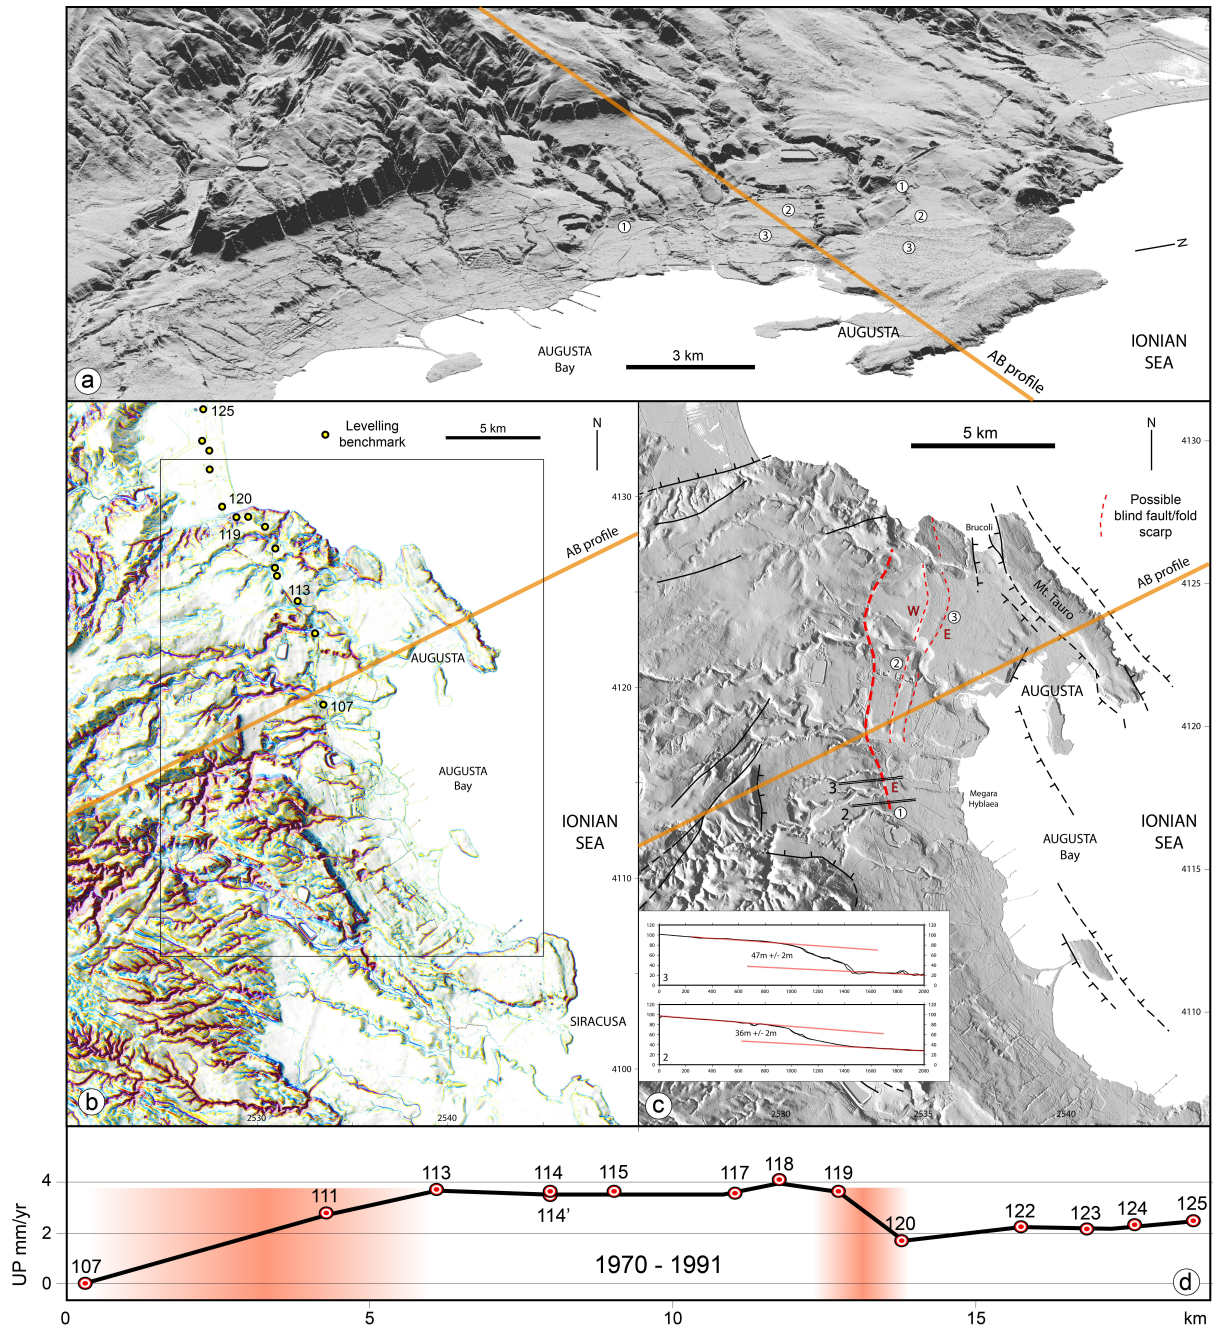

Figure 9 : a) 3D view of a shaded DEM of 2 m resolution from S.I.T.R. regione Siciliana (2013) showing the morphology of the NE part of the Hyblean Plateau. b) Morphological map of the Augusta-Siracusa region showing fluvial incision networks and morphological scarps. The location of leveling benchmarks appears in yellow circles. c) Simplified morpho-structural map highlighting the location of potential tectonic fault/fold scarps in red, and the known fault in thick red dashed line with cross-sections (Supplementary Figure S15). d) 1970-1991 leveling profile (Spampinato et al., 2013) showing a first velocity step (~ 4 mm/yr) between benchmark 107 and 113, and a second one (~ 2 mm/yr), between benchmark 119 and 120 (potential fault zone locations appear in the background in red).

647 A morpho-structural analysis of this region, using a 2 m resolution DEM, outlines
 648 sharp drainage incision anomalies oriented perpendicular to the identified topographic
 649 steps, potentially related to tectonic surface uplift (Figure 9b). The topographic step
 650 between benchmarks 119 and 120 (Figures 9a and 9d) could correspond to the Scordia-
 651 Lentini Graben border (e.g., Barreca, 2014; Cultrera et al., 2015). The topographic

652 anomaly between benchmarks 113 and 107, extending to the north up to the Ionian
 653 Sea and to the South toward Siracusa, was not previously identified as a tectonic feature.
 654 It could correspond to the implemented creeping fault used to match the PS-InSAR data.
 655 Uplifted late Quaternary marine terraces have been evidenced in this region (Bianca et al.,
 656 1999; Monaco and Tortorici, 2000; Meschis et al., 2020), but the authors **did not** mention
 657 a tectonic origin for the measured coastal uplift. Finally, the measured fast surface uplift
 658 (1-2 mm/yr) could be considered inconsistent with the low amplitude of the topographic
 659 scarp measurable in the field (a few tens of meters). This point is discussed hereafter
 660 (section 4.2).

661 4.2 Combined long-term tectonics and seismic cycle model

662 The subsidence and tilt patterns observed in the geodetic data can be explained
 663 by the combination of (1) the flexure of the Hyblean continental crust induced by the
 664 bending forces generated by the Ionian subduction roll-back (slab-pull) and the CAP
 665 overload, explaining the long-wavelength deformation affecting the HP, and (2) the
 666 aseismic activity of the Augusta-Siracusa fault system, potentially extending onshore an
 667 inferred tectonic structures, explaining the short-wavelength deformation signal affecting
 668 the Augusta/Siracusa region (Figure 10). In this section, we discuss how this short-term
 669 (geodetic) model could be combined with long-term geological and tectonic observations.

Figure 10 : *The final model combining the possible range of the Hyblean continental crust flexural models and the surface deformation (step of 1 km) induced by fault creep (from surface, continuous lines) or active folding in the Augusta-Siracusa coastal domain (from 500 m, dashed lines). In this model, the flexure of the Hyblean continental crust is essentially controlled by the bending force associated with the Ionian slab roll-back (F_B) and, to a lesser extent, by the Calabrian accretionary prism load (F_{CAPa}). The synthetic structural profile and topography have no vertical exaggeration (V.E.x1).*

671 Interestingly, along the N30°E trending AB synthetic profile, a \sim 1-degree gen-
672 eralized eastward tilting of the HP topography can be evidenced (Figure 4a). The
673 origin of this tilt, in apparent agreement with the geodetic data, could be linked to
674 the Plio-Quaternary formation of the HP (Henriquet et al., 2019). Indeed, geological
675 analyses suggest that the eastern coast of SE Sicily has been relatively stable over
676 the last million years, with maximal subsidence and uplift amplitudes of ± 0.2 mm/yr
677 (Ferranti et al., 2006). More recently, dating of Late Quaternary marine terraces along
678 the Siracusa-Augusta coastal domain indicates that the eastern coast of the Hyblean
679 Plateau has experienced a slow constant uplift during the last 500 Kyr, increasing
680 northward from 0.1 to 0.4 mm/yr (Meschis et al., 2020). On a shorter historical time
681 scale based on Roman archaeological site studies, Scicchitano et al. (2008) propose that
682 the Siracusa coast has been slowly uplifting during the last 4 Kyr, albeit with significant
683 uncertainties. These long-term observations, extending from the Quaternary to historic
684 time, point to slow regional uplift, apparently at odds with geodetic data. However, it
685 should be remembered that we have considered that PS-InSAR measurements primarily
686 document the interseismic phase. At this stage, the part of the seismic cycle that
687 generates uplift has not yet been taken into account. Previous calculations (Meschis
688 et al., 2020) show that a Mw=7 earthquake on the active fault system at the base of
689 the Malta Escarpment generates little coastal uplift but early and late post-seismic
690 deformation was not considered. In addition, a 500-yr seismic cycle contains other
691 earthquakes contributing to surface deformation than a single M=7 event. To reconcile
692 long and short-time scale surface motions, we propose an original seismic cycle model
693 driven by the southward roll-back of the Ionian oceanic slab (Figure 11).

694

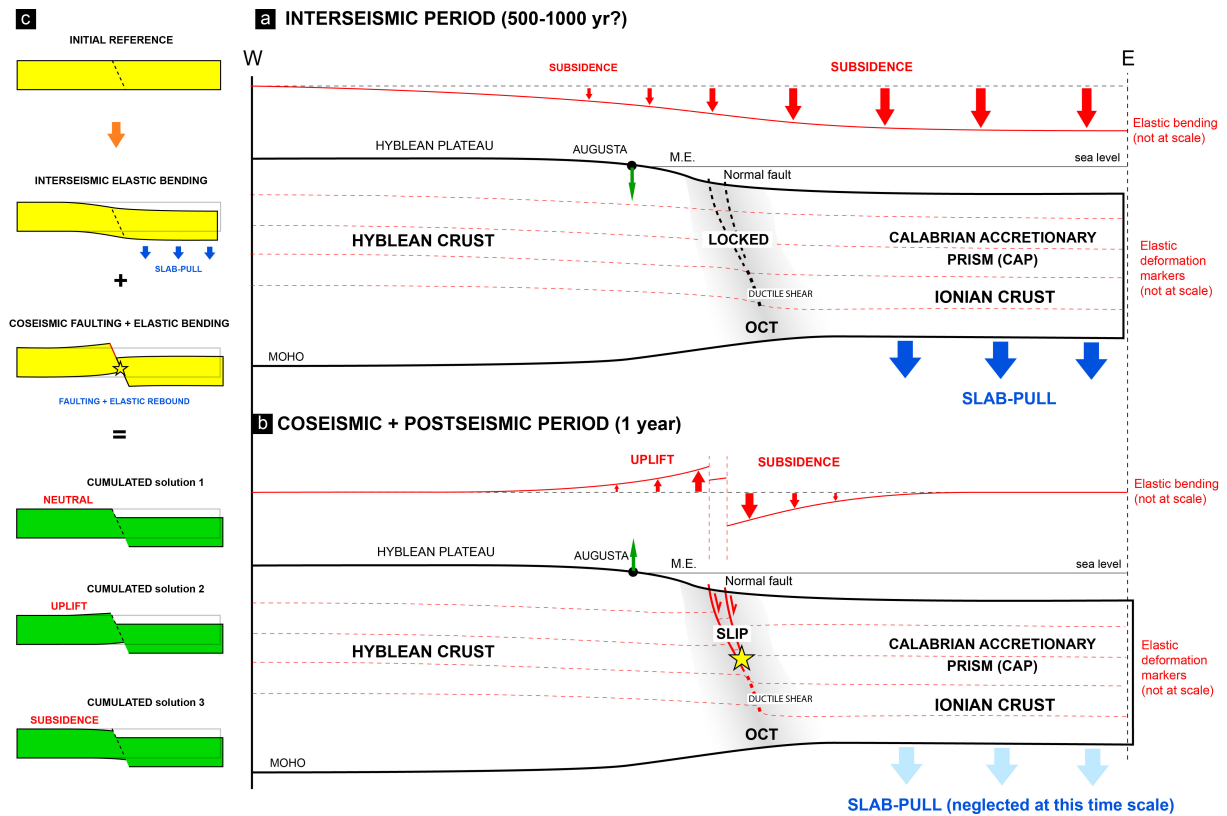

Figure 11 : Schematic model of the seismic cycle for south-eastern Sicily, integrating crustal elastic bending, aseismic, and seismic faulting controlled by slab-pull. a) Interseismic period, b) coseismic and postseismic period, c) different scenarios of the cumulated interseismic, postseismic, and coseismic. This model could reconcile short and long-term observations.

695 During the interseismic phase, the active offshore normal faults affecting the eastern
 696 HP and Malta Escarpment are locked. The Hyblean and Ionian crusts are coupled and can
 697 be compared to an elastic beam, bending eastward in response to an increasing downward
 698 vertical force: the slab pull induced by the Ionian slab roll-back (Figure 11a). Considering
 699 a minimum 500-yr return period for major earthquakes such as the 1693 Val-di-Noto event
 700 (Bianca et al., 1999; Meschis et al., 2020) and extrapolating the PS-InSAR measurements
 701 over this period, coastal subsidence along the Siracusa-Augusta region could reach 1-2 m.
 702 This subsidence could be dampened to 0.5-1 m if, at the same time, the onshore faults,
 703 potentially related to extrados deformation, creep aseismically. During the coseismic
 704 phase, the offshore fault unlocks, and seismic slip induces (for a $M_w > 7$ earthquake) multi-
 705 metric subsidence of the hanging wall and an associated decimetric to metric uplift of the
 706 footwall (e.g., Wells and Coppersmith, 1994) (Figure 11b).

707 The cumulated succession of interseismic coastal subsidence and coseismic uplift
 708 could result in three scenarios (Figure 11c). If the coseismic coastal uplift equals the
 709 cumulated interseismic subsidence, the coastal domain remains stable in the long term.

710 If the former is lower than the latter, as predicted by elastic modeling (Figure 7a), the
711 coast subsides. Conversely, long-term coastal uplift occurs if coseismic uplift surpasses
712 interseismic subsidence. Considering that geological data suggest a slow coastal uplift,
713 this last scenario should be preferred, but additional sources of foot-wall uplift should be
714 identified (Ferranti et al., 2006; Meschis et al., 2020). At this stage, we can only evoke
715 raw hypothesis:

- 716 • The buoyancy of the flexed Hyblean crust could significantly increase post-seismic
717 slip after major earthquakes and thus increase footwall uplift in the coastal region.
- 718 • Further north along the coast, the Ionian slab plunges to great depth and is certainly
719 detached from the Hyblean continental margin owing to a tear-fault propagation
720 southward (e.g., Gutscher et al., 2016; Maesano et al., 2020), which could generate
721 additional stress affecting the surface deformation of the studied region.
- 722 • The inferred interseismic extrado deformation, affecting the coastal domain, could
723 explain the slow long-term uplift (0.1-0.4 mm/yr) off the eastern coast of the HP
724 (e.g., Meschis et al., 2020). In that case, extrado deformation activity should be
725 intermittent, alternating between aseismic fault slip/folding (as presently) and long
726 periods of quiescence. Such a scenario remains speculative and needs to be mechan-
727 ically tested.
- 728 • Finally, the potential impact of a major subduction earthquake [occurring](#) along the
729 Calabrian Arc on SE Sicily could [also be](#) considered (e.g., Gutscher et al., 2016;
730 Carafa et al., 2018).

731 5 Conclusion

732 Present-day deformation of Southeastern Sicily (Hyblean Plateau) reveals specific
733 long and short-wavelength signals indicating a generalized eastward tilting, reversing a
734 few kilometers before reaching the eastern coast of the Hyblean Plateau.

735 We propose that the long-wavelength tilt and subsidence [result from](#) the flexure of
736 the Hyblean continental crust in response to the bending force induced by the southward
737 retreat of the Ionian subduction. Simple flexural modeling, using standard parameters
738 (elastic thickness of 25-40 km, accretionary prism loading of 5-10 N/m²/yr, and a local
739 increase of bending force of 1-3 × 10⁴ N/m/yr or gradually of 0 to 1-1.5 × 10⁴ N/m/yr)

740 support this interpretation.

741 We show that the short wavelength relative to the coastal uplift, measured geodeti-
742 cally, could be explained by shallow creep (at 1-4 mm/yr) on ENE steeply dipping normal
743 faults, related to extrado deformation. Some morphologic evidence of surface deforma-
744 tion, correlated with leveling data indicating differential surface uplift, could corroborate
745 this hypothesis. However, at this stage, the extrado deformation hypothesis has yet to
746 be validated. We investigated other hypotheses, such as upwelling mantle flow, volcanic
747 deflation, and hydrological loading, and found them much less plausible.

748 Finally, we propose an original seismic cycle model in which the surface deforma-
749 tion of Southeastern Sicily is mainly controlled by bending force induced by the Ionian
750 slab roll-back, tilting the Hyblean Plateau eastward. During the interseismic period, the
751 bending of the continental crust causes subsidence and aseismic extrados deformation
752 along the eastern coast of the Hyblean Plateau. Meanwhile, the offshore normal faults of
753 the continent-ocean transition, potentially sources of the origin of the 1693 earthquake,
754 remain locked and elastic strain accumulates. During a major earthquake, the coastal
755 domain uplifts and compensates for the interseismic subsidence.

756 To further develop the formulated hypotheses, additional data are required, such
757 as new high-resolution bathymetric data, onshore and offshore high-resolution seismic
758 data (CHIRP), and on-site analysis to investigate inferred coastal active faults along
759 the Augusta-Siracusa region. Besides, acquiring new PS-InSAR data would improve
760 distinguishing geological processes from human activities. It will be also of interest to
761 perform more advanced flexural models using 3D finite element modeling techniques.
