## Abstract

This study investigates how lithological changes can affect the strike-slip faults propagation patterns using analogue models. Strike-slip fault zones are long structures that may cut across pre-existing tectonic or lithological steep boundaries. How strike-slip faulting is affected by a laterally heterogeneous upper crust is crucial for understanding the evolution of regional and local fault patterns, stress reorientations, and seismic hazard. Our models undergo sinistral distributed strike-slip shear (simple shear) and have been analyzed by Particle Image Velocimetry (PIV). We use quartz sand and microbeads as brittle analogue materials over a viscous mixture to distribute the deformation through the model. The first models investigate strike-slip faulting in a homogeneous upper crust by using quartz sand or microbeads only. Three further models examine how the presence of a central section which laterally differs in its properties, influences strike-slip faulting. The main observations are the following:

- The homogeneous upper crust shows typical Mohr-Coulomb strike-slip faults, with synthetic fault strikes related to the angle of internal friction of the material used
- The heterogeneity upper crust has a profound effect on synthetic fault propagation, interaction and linkage as well as the kinematic evolution of antithetic faults that rotate around a vertical axis.
- The orientation of the central section determines whether antithetic fault activity concentrates along the entire length of the central contact or not. In the first case, fault activity is segmented or the number of different faults formed is increased in distinct domains. In the second case, the

28 properties of the central material determines fault propagation, interaction and/or linkage across  
29 the central domain.

- 30 • These findings have potential implications for nature have been seen in the NW Iberian Peninsula.  
31 In this area the change of direction of the sinistral faults and the position of the antithetic faults  
32 can be explained due to lithological change.

### 36 **1. Introduction**

37 Strike-slip fault systems in nature extend from a few meters to several hundred kilometers and typically  
38 have complex geometries consisting of separate fault segments offset from each other or comprising  
39 anastomosing, linked faults (e.g., Aydin and Nur, 1982; Barka and Kadinsky-Cade, 1988; Wesnousky,  
40 1988; Stirling et al., 1996; Kim et al., 2004). The evolution of strike-slip fault systems has been studied  
41 in numerous studies focused on the process of offset formation and therefore, basin development,  
42 change of fault polarity and parameters controlling segmentation (e.g., Riedel, 1929; Anderson, 1951;  
43 Deng et al., 1986; Sylvester, 1988; Dooley and Schreurs, 2012; Hatem et al., 2017; Lefevre et al.,  
44 2020a; Visage et al., 2023). Understanding strike-slip fault interaction and linkage is important for its  
45 implications on seismic hazard (Petersen et al., 2011; Bullock et al., 2014), in terms of dynamics, fault  
46 growth and size of earthquakes (e.g. Aki, 1989; Harris and Day, 1999; Scholz, 2002; Wesnousky, 2006;  
47 Shaw and Dieterich, 2007; de Jossineau and Aydin, 2009; Preuss et al., 2019); but also in terms of  
48 regional stress orientations (Kirkland et al., 2008) and in view of the location of geothermal and  
49 hydrocarbon resources (e.g. Sibson, 1985; Martel and Peterson, 1991; Aydin, 2000; Odling et al.,  
50 2004; Cazarin et al., 2021).

51 How faults interact or link is considered to be a function of loading, stress disturbances, rheology and  
52 the geometry of pre-existing structures (e.g., Kim et al., 2004; Myers and Aydin, 2004; Peacock and  
53 Sanderson, 1991, 1992; Burgmann and Pollard, 1994; Sibson, 1985; Gamond, 1983; Rispoli, 1981;  
54 Wesnousky, 1988). Various studies have investigated the influence of vertical changes in upper crustal  
55 strength (e.g. a horizontal sedimentary sequence comprising layers or bodies of different strengths) on

56 strike-slip fault orientation, segmentation, linkage, and displacement. These studies used field  
57 observations, combined with analytical and numerical methods (e.g. Du and Aydin, 1995; Aydin and  
58 Berryman, 2010; De Dontney et al., 2011), or analogue models (Richard, 1991; Richard et al., 1995;  
59 Gomes et al., 2019; Gabrielsen et al., 2023; Venancio and Alves Da Silva, 2023). However, it is also  
60 important to consider the evolution of strike-slip fault systems in a laterally heterogeneous upper crust.  
61 Strike-slip faults often extend laterally over considerable distances and are thus expected to be  
62 influenced by steeply oriented pre-existing tectonic or lithological boundaries having rocks with  
63 contrasting strength on either side. Such (sub)vertical contacts often occur at terrane boundaries or  
64 within crustal blocks comprising rock units with contrasting strengths, e.g. a magmatic body with steep  
65 margins that intruded into a sedimentary sequence. To our knowledge no modelling studies have yet  
66 investigated how strike-slip fault systems are affected by steeply dipping contacts separating different  
67 rock types. Here we use scaled analogue model experiments analysed by Particle Imaging Velocimetry  
68 (PIV) to assess the role of vertically oriented domains of contrasting brittle strength in the upper crust  
69 on fault kinematics in distributed strike-slip shear. The models were inspired by the deformation pattern  
70 of the NW Iberian Peninsula, which has undergone sinistral shearing during the Alpine Orogeny (e.g.  
71 Martínez Catalán, 2011; Vergés et al., 2019). This particular area shows a system of sinistral faults that  
72 cross lithological domains with contrasting properties and part of their segmentation is conditioned by  
73 these domains.

## 74 75 **2. Methods**

### 76 **2.1. Analogue model setup**

77 The experimental set-up for simulating distributed strike-slip shear included a mobile base plate that could  
78 be translated horizontally above a fixed base plate (Fig. 1). An assemblage of 60 individual and moveable  
79 plexiglass bars (each 78 cm long, 5 cm high and 5 mm wide) was positioned on top of two base plates. The  
80 assemblage of plexiglass bars was confined by carbon-fiber sidewalls on the long sides (Fig. 1b) and  
81 wooden bars (c. 5 mm high, 2 cm wide and 40 cm long) on the short sides (Fig. 1b, c), that could pivot  
82 below the longitudinal sidewalls. The model was constructed on top of the plexiglass bars and consisted of  
83 a 2 cm-thick viscous layer, simulating the ductile lower crust, overlain by a 2 cm-thick layer of granular  
84 materials simulating the brittle upper crust. The short sides of the model were confined by vertical rubber

85 sheets. Although our model set-up included both a horizontal viscous layer overlain by a horizontal brittle  
 86 layer, our experiments focus on the influence of vertical domains with brittle strength contrasts on strike-  
 87 slip faulting. The function of the viscous layer, directly overlying the plexiglass bars, is to distribute the  
 88 applied shear deformation over the entire width of the model in the overlying brittle layer (e.g. Schreurs,  
 89 1991, 2003; Dooley and Schreurs, 2012).

90 Each model had an initial rectangular shape in map view, with a length of 78 cm parallel to the shear  
 91 direction and a width of 30 cm perpendicular to it. The movement of the mobile base plate occurred by  
 92 computer-controlled stepper motors at a constant velocity of 40 mm/h, resulting in 80 mm of total  
 93 displacement after two hours. Displacement of the mobile base plate changed the initial rectangular shape  
 94 of the overlying assemblage of plexiglass bars into a parallelogram simulating simple shear.

95

96

97 **Figure 1: Schematic experimental setup.** (a) The base of the model set-up consists of a fixed plate and a mobile  
 98 plate overlain by an assemblage of individual and moveable plexiglass bars. The model is constructed on top of  
 99 the plexiglass bars and is confined by two longitudinal sidewalls and two short sidewalls consisting of rubber  
 100 sheets. (b) upper panel: Initial position of base plates overlain by plexiglass bars confined on the short sides by  
 101 wooden bars that can pivot about a vertical axis; lower panel: Sinistral horizontal displacement of the mobile  
 102 base plate induces a simple shear movement in the overlying assemblage of plexiglass bars as they slide past one  
 103 another.

104

105 We performed four series of simple shear experiments, referred to as Series A, B, C and D (Fig. 2). Series  
 106 A involved two models with only one brittle material (Fig. 2a), quartz sand or microbeads, to investigate  
 107 strike-slip fault kinematics in a homogeneous upper crust, without any lateral variations in mechanical  
 108 strength. In the other three series (Fig. 2b-d), we introduced vertical domain boundaries across which the

109 mechanical strength varied laterally. Each model had three domains with a 5-cm-wide central domain  
 110 consisting of a different material than the domains on either side. The difference between Series B, C and  
 111 D is the orientation of the central domain with respect to the shear direction. To achieve such a model set-  
 112 up, two vertical thin sheets of cardboard ( $< 1$  mm) were first placed as provisional walls, spaced 5 cm apart,  
 113 on top of the viscous layer in the central domain of the model, parallel to the required orientation of the  
 114 vertical domain boundaries. Subsequently, the different granular materials were sieved on top of the viscous  
 115 layer and once the desired model thickness was reached, the cardboard sheets were carefully removed.  
 116 Although removal of the cardboard produced increased dilation along a narrow zone, it hardly affects the  
 117 de facto function of this vertical boundary as a primary surface with materials of contrasting brittle strength  
 118 on either side. For descriptive purposes, we defined a North direction, which is perpendicular to the applied  
 119 shear direction and parallel to the short sides of the undeformed model (Fig. 2a). In models with a brittle  
 120 strength contrast, we can distinguish two outer domains, a western and an eastern one, and a central domain  
 121 (Fig. 2b-d).

 125  
 126  
 127  
 128

Figure 2: Schematic drawing of the materials used and their surface distribution at the initial stage. All models have a length of 78 and a width of 30 cm. The references about the patterns observed have been given by using the long side of the edge of the models as “north”. In the series of models referred as A, only one type of material (quartz sand or microbeads) has been used. The diagrams of series B, C and D show the position and orientation of the vertical domain boundaries in plan view and which materials were used.

129 **2.2. Analogue materials**

130 We used two different types of granular materials in our analogue models to assess the role of vertical zones  
 131 of contrasting mechanical strength in the upper crust: quartz sand and microbeads grains. The quartz sand  
 132 (distributor Carlo Bernasconi AG; [www.carloag.ch](http://www.carloag.ch)) has a grain size between 60 and 250  $\mu\text{m}$  with a bulk  
 133 density of  $1560 \text{ kg m}^{-3}$ , whereas the grain size of the microbeads (distributor: Worf Glasskugeln, Germany)  
 134 lies between 150 and 210  $\mu\text{m}$  with a bulk density of  $1400 \text{ kg m}^{-3}$ . These density values were achieved by  
 135 sieving the granular material into the model box from a height of 30 cm. Both, quartz sand and microbeads  
 136 deform according to the Coulomb failure criterion and have internal peak friction angles of  $36^\circ$  and  $22^\circ$  and  
 137 cohesion values of  $50 \pm 26 \text{ Pa}$  and  $25 \pm 4 \text{ Pa}$ , respectively (Panien et al., 2016; Schmid et al., 2020). The  
 138 considerable difference in the internal peak friction angle between the two materials makes them suitable  
 139 for simulating contrasting upper crustal rocks. According to their difference in the internal friction angle,  
 140 we consider the microbeads and quartz sand as weak and strong materials, respectively.

141 The viscous layer in our models had a density of  $1600 \text{ kgm}^{-3}$  and consisted of a mixture of SGM-36  
 142 polydimethylsiloxane (PDMS) and corundum sand (weight ratio of 0.965: 1.000). The mixture has a quasi-  
 143 linear viscosity of  $1.5 \times 10^5 \text{ Pa s}$  and a stress exponent of 1.05 (Zwaan et al., 2018). The properties of all  
 144 analogue materials are summarized in Table 1.

145

146

Granular materials	Quartz sand	Microbeads	Viscous material	PDMS/corundum mixture
Density ( $\text{kg/m}^3$ )	1560	1400	Density ( $\text{kg/m}^3$ )	1600
Grain size ( $\mu\text{m}$ )	60-250	150-210	Viscosity ( $\text{Pa s}$ )	$1.5 \times 10^5$
Peak friction coefficient $\mu$ and angle, $\phi$	$0.72 - 36^\circ$	$0.41 - 22^\circ$	Stress exponent n	1.05
Cohesion (Pa)	$50 \pm 26$	$25 \pm 4$		

147 **Table 1:** Materials properties of used granular and viscous materials (after Panien et al., 2006; Schmid et al., 2020).

148

149        **2.3.    Scaling**

150    For brittle Mohr-Coulomb type materials, dynamic similarity is given by the equation for stress ratios

$$\sigma^* = \rho^* g^* h^* \quad (1),$$

151    where  $\rho^*$ ,  $g^*$  and  $h^*$  are the ratios of model to nature for density, gravity and length, respectively. Note,  
152    that our two used granular materials have different densities, cohesions and internal friction coefficients.  
153    However, the resulting scaling factors are nearly identical and therefore we provide only the scaling factors  
154    for quartz sand. Where scaling factors substantially differ, we denote them with subscripts “qtz” and “mb”  
155    for quartz sand and microbeads, respectively. Our model setup yields a length scaling factor of  $h^* =$   
156     $2 \times 10^{-6}$  and a gravity scaling factor of 1. For quartz sand, the density scaling factor is  $\rho_{qtz}^* \sim 0.6$  and the  
157    cohesion factor is  $C_{qtz}^* = 1 \times 10^{-6}$  (using a cohesion of  $\sim 50$  Pa and 50 MPa for our quartz sand and upper  
158    crustal rocks, respectively; Byerlee, 1978). Additionally, for microbeads the density scaling factor and  
159    cohesion scaling factor are  $\rho_{mb}^* \sim 0.5$  and  $C_{mb}^* = 1 \times 10^{-6}$  (assuming a weakened natural rock type with a  
160    cohesion of c. 25 MPa), respectively. Using these scaling factors yields a stress scaling factor of  $\sigma^* =$   
161     $1 \times 10^{-6}$  for both quartz sand and microbeads.

162    Assuming a lower crustal viscosity of  $\eta = 10^{22}$  Pa s (Moore and Parsons, 2015; Zhang and Sagiya, 2017)  
163    yields a viscosity ratio  $\eta^* = 1 * 10^{-17}$  (using the viscosity of  $1.5 * 10^5$  Pa s for the viscous analogue  
164    material).

165    The strain rate ratio is obtained from the stress ratio and the viscosity ratio by (Weijermars and Schmeling,  
166    1986):

$$\dot{\epsilon}^* = \frac{\sigma^*}{\eta^*} \quad (2).$$

167    Note that due to the simple shear setup, we substitute the strain rate scaling factor  $\dot{\epsilon}^*$  with the shear strain  
168    rate scaling factor  $\dot{\gamma}^* = 1 \times 10^{11}$ . Next, the velocity scaling factor  $v^*$  and a time scaling factor  $t^*$  are  
169    calculated with

$$\dot{\gamma}^* = \frac{v^*}{h^*} = \frac{1}{t^*} \quad (3)$$

170 yielding a velocity scaling factor  $v^* = 2 \times 10^5$  and a time scaling factor  $t^* = 1 \times 10^{-11}$ .

171 Based on our scaling, 1 cm in our experiments corresponds to 5 km in nature and the applied velocity of 40  
 172 mm h<sup>-1</sup> converts to a velocity of ~2 mm a<sup>-1</sup> in nature. Using the shear strain rate scaling factor  $\dot{\gamma}^*$ , the bulk  
 173 shear strain rate  $\dot{\gamma} = 3.7 \times 10^{-5} \text{ s}^{-1}$  in our models translates to a shear strain rate of  $\dot{\gamma} = 3.7 \times 10^{-16} \text{ s}^{-1}$   
 174 in nature and 1 h in our analogue experiments translates to ~12.5 Myr in nature.

175 In order to verify dynamic similarity of brittle natural and experimental material we calculate the  
 176 Smoluchowski number  $S_m$ , which is the ratio between gravitational stress and cohesive strength (Ramberg,  
 177 1981):

$$S_m = \frac{\rho gh}{C + \mu \rho gh} \quad (4),$$

178 where  $\rho$ ,  $h$ ,  $C$  and  $\mu$  are the density, thickness, cohesion, and friction coefficient, respectively of the brittle  
 179 material. With a cohesion of 50 MPa and a friction coefficient of ~0.6 (Byerlee, 1978) for upper crustal  
 180 rocks, this yields values of  $S_m \sim 1$  for our models as well as for nature. We further calculate the Ramberg  
 181 number  $R_m$  to ensure dynamic and kinematic similarities between the viscous layers.

$$R_m = \frac{\rho gh^2}{\eta v} \quad (5)$$

182 For our velocity of 40 mm h<sup>-1</sup>, this yields a Ramberg number of 6 for both, our models and nature. The  
 183 Reynolds number  $R_e$  is defined as the ratio between inertial forces and viscous forces and is for all our  
 184 models as well as for the natural prototype  $\ll 1$ :

$$R_e = \frac{\rho v h}{\eta} \quad (6)$$

185 Based on the applied scaling laws, the material properties and the similar non-dimensional numbers for  
 186 model and nature, we consider our models to be properly dynamically scaled. Model parameters and  
 187 dynamic numbers of the used materials are specified in Table 2.

188

	General parameters			Brittle upper crust		Ductile lower crust		Dimensionless numbers

191

192

193

#### 194 **2.4. Deformation monitoring and quantification**

195 Since the experiments were conducted using a simple shear setup, vertical motions during deformation  
 196 were negligible, with nearly all movement located within the horizontal plane. The different experiments  
 197 were monitored by an automated Nikon D810 (36 MPx) DSLR camera positioned above the experimental  
 198 model. Images were taken at fixed intervals of 60 s during two hours, resulting in 121 subsequent top view  
 199 images of the model surface. For a quantitative 2D analysis of the surface deformation, we used the  
 200 StrainMaster module of the LaVision© DaVis image correlation software. Using a calibration plate, the  
 201 software corrects the top view images for lens distortion effects (i.e., unwarping), applies image  
 202 rectification and provides a scaling function that maps coordinates from the camera sensor to physical  
 203 coordinates with a resolution of ~9 px/mm. The digital image correlation calculates local displacement  
 204 vectors on subsequent images using a square matching algorithm with adaptive multi-pass cross-  
 205 correlation. To properly track the grain movement patterns, we sprinkled coffee grains on the model surface  
 206 prior to the model run. For each image, the analyzed area is subdivided into small interrogation window for  
 207 which a local displacement vector is determined by cross-correlation. We used subsets (i.e., interrogation  
 208 windows) of 31 by 31 pixels with a 75% overlap for the local displacement calculations that, assembled

209 result in incremental (60 s interval) displacement fields for the horizontal x- and y-components  $u_x$  and  $u_y$ ,  
210 respectively with a vector resolution of  $\sim 1.3$  vectors/mm.

211 Postprocessing included an outlier filter to fill gaps of pixels within a 3 by 3 neighborhood (Westerweel  
212 and Scarano, 2005). Discarded vectors in the displacement fields were replaced by an iterative interpolation  
213 requiring at least two neighboring vectors. For quantifying deformation at the model surface, we calculate  
214 the z-vorticity  $\omega_z$  (i.e., a rotation measure in the xy plane ) as a proxy for shear movement along strike-slip  
215 faults. In our models the X-axis corresponds to the long side of the rectangle; and the Y-axis corresponds  
216 to the short side of the model. In contrast to the shear strain  $\epsilon_{xy}$ , vorticity is not dependent on the orientation  
217 of the coordinate system, which is crucial when quantifying deformation along faults that strike obliquely  
218 with respect to the coordinate system (e.g., Cooke et al., 2020).  $\omega_z$  can be derived from local displacement  
219 gradients according to equation 1:

$$\omega_z = \frac{\partial u_y}{\partial x} - \frac{\partial u_x}{\partial y} \quad (7)$$

220 With  $u_x$  and  $u_y$  being the horizontal displacement components in the x, and y direction, respectively. Positive  
221 and negative  $\omega_z$  values refer to sinistral and dextral relative displacement, respectively. Within the  
222 predefined increment of 60 s,  $\omega_z$  values are consistently within the range [-2%, 2%] and we set a threshold  
223 of -0.5% and 0.5% to distinguish between active deformation and background noise for dextral and sinistral  
224 shear sense, respectively. In the results section we present  $\omega_z$  at deformation stages every 30 min (i.e., after  
225 30, 60, 90, and 120 min). Finite deformation after 120 min for each model is illustrated with a surface  
226 photograph and enhanced with superposed line drawings of the fault pattern. For the statistical analysis of  
227 fault orientations, we traced active fault segments (i.e.,  $\omega_z \leq -0.5\%$  or  $\omega_z \geq 0.5\%$ ) in MATLAB using  
228 polylines, where each fault segment is defined by two consecutive vertices. At each time step, segment  
229 length and azimuth were calculated and visualized in length-weighted rose diagrams.

230

231

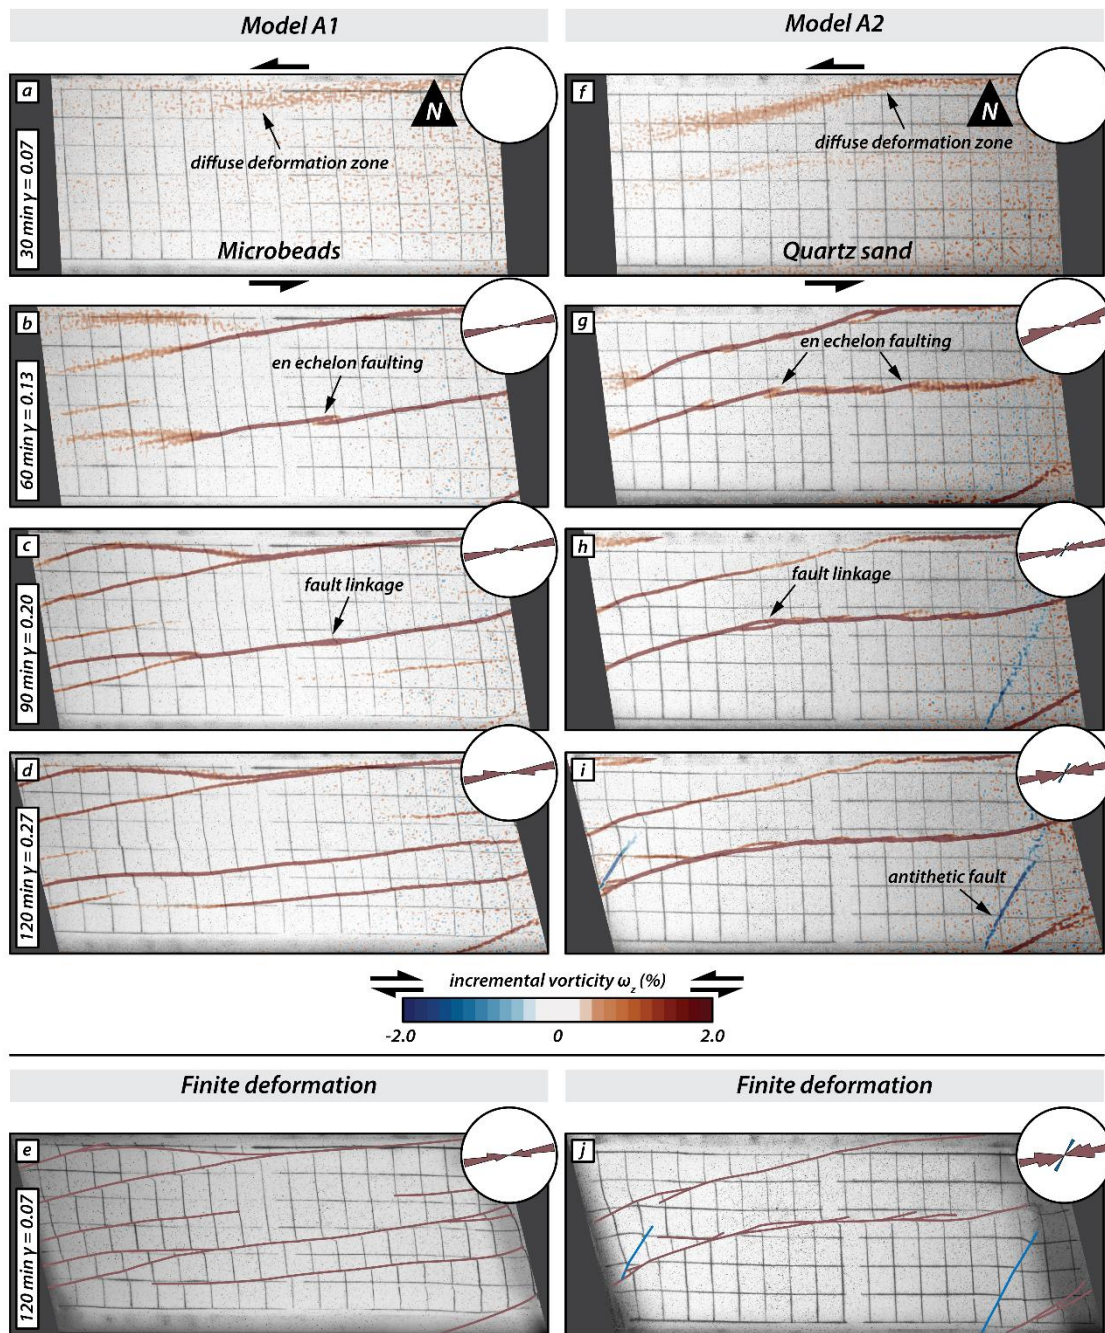

232

233        **3. Results**

234        **3.1. Series A: Fault evolution in a homogeneous upper crust**

235        The Series A models consisted of a homogeneous upper crustal layer composed of either microbeads (Fig.  
236        3; Model A1) or quartz sand (Fig. 3; Model A2). The incremental strain panels document that strain  
237        localized first in the model with quartz sand, while deformation was still diffuse in the model with  
238        microbeads (Fig. 3a and f), i.e. strain localization occurs at lower amounts of applied simple shear in quartz  
239        sand than in microbeads. With progressive sinistral simple shear deformation, slightly overlapping right-  
240        stepping *en echelon* strike-slip faults with a sinistral displacement formed (Fig. 3b and g). These faults were  
241        synthetic with respect to the bulk simple shear. In the model with microbeads (Model A1) the first synthetic  
242        faults had an orientation of N79°E (Fig. 3b), whereas in the model with quartz sand (Model A2) their  
243        orientation was N72°E (Fig. 3g). Initial deformation in both models is accommodated by synthetic  
244        (sinistral) strike-slip faults (Fig. 3a, b and f, g). As deformation progressed, individual fault segments linked-  
245        up forming major sinistral strike-slip faults (Fig 3c and h). Antithetic faults only developed in Model A2  
246        (quartz sand only; Fig. 3h and i) at later stages of deformation. These faults were confined in between  
247        previously formed synthetic faults. The final deformation stage (Fig. 3e and j) shows that most deformation  
248        was taken up by major synthetic faults that crossed the entire length of the model. At the final stage, the  
249        initial *en echelon* pattern of faulting was better preserved in the quartz sand model than in the microbeads  
250        model, resulting in a wider damage zone in the former.

251

252

253 Figure 3: Overview of Series A models: Simple shear deformation of two models with a homogenous upper  
 254 brittle layer. The first four panels of each series show surface photographs with the incremental vorticity after  
 255 30 minutes (20 mm displacement of mobile base plate), 60 minutes (or 40 mm displacement), 90 minutes (or 60  
 256 mm displacement) and 120 minutes (or 80 mm displacement). Incremental positive and negative values indicate  
 257 sinistral (synthetic, red) and dextral (antithetic, blue) relative movement, respectively. The last panel for each  
 258 series shows a surface photograph of the final stage overlain with the interpreted fault pattern; red lines are  
 259 sinistral faults, blue lines are dextral faults.

260

261

262

263           **3.2.     Series B: Fault evolution in models with N20°E vertical domain boundaries**

264     The vertical domain boundaries in the Series B models were oriented N20°E. Model B1 had a central  
265     domain consisting of strong quartz sand with weak microbeads in the adjacent, western and eastern domains  
266     (Fig. 4; Model B1), whereas in Model B2 it was the other way around. (Fig. 4; Model B2). Both models  
267     showed the development of dextral strike-slip (antithetic, with respect to sinistral simple shearing) faults  
268     along the vertical boundaries of the central domain (Fig. 4a, f). Later, sinistral strike-slip faults (synthetic)  
269     formed in the western and eastern domains (4b, g). Although these faults propagated laterally with time,  
270     none of the synthetic faults crossed the central domain. Instead, they halted at or close to the boundary  
271     faults along the central domain (Fig. 4c, h). In Model B1 a few antithetic faults formed in between pre-  
272     existing synthetic faults in the western and eastern domains, striking at c. N60°E (Fig. 4d, e). Antithetic  
273     faults developed also in the western and eastern domains of Model B2, almost coevally with the synthetic  
274     faults. They strike at higher angles to the shear direction than those antithetic faults confined between  
275     overlapping synthetic faults in Model B2. With increasing deformation, the central domain and its bordering  
276     antithetic faults rotated counterclockwise in both models (Fig. 4a-e, f-j), as did the antithetic faults in the  
277     western and eastern domains, which acquired a slight sigmoidal shape form (e.g. Fig. 4j)

278

### 3.3. Series C: Fault evolution in models with N-S vertical domain boundaries

291

During the early stages of simple shear, dextral (antithetic) faults formed along the N-S striking borders of

292

the central domain (Fig. 5b, g) in both models, but earlier and more pronounced in Model C1. With

293

progressive shearing, both synthetic and antithetic faults formed in the outer domains of both models (Fig.

294

5c and h). In Model C2, activity along the antithetic faults bordering the central domain ceased, and

295

synthetic faults propagated from the outer domains into the central weak domain (Fig. 5h-j). In contrast, in

296

Model C1, the antithetic faults along the borders of the central domain remained active, and no synthetic

297

faults crossed the central strong domain (Fig. 5d). In the eastern domain of Model C2, a few antithetic faults

298

formed in between major synthetic faults, striking at a lower angle to the shear direction than earlier formed

299

antithetic faults in the western domain. With progressive simple shear the central domain showed

300

counterclockwise rotation around a vertical axis in both models and antithetic faults obtained a sigmoidal

301

shape in top view (Fig. 5i). As the initial N-S antithetic faults bordering the central domain rotated

302

counterclockwise, activity along these faults stopped and new fault segments parallel to earlier antithetic

303

faults formed in the western and eastern domains (Fig. 5d, e). At the final stage of Model C2, antithetic

304

faults dominated in the western domain and synthetic faults in the eastern domain. In contrast, in Model

305

C1, antithetic and synthetic faults were present in both the western and eastern domain.

306

 313

314

315

316           **3.4.     Series D: Fault evolution in models with N20°W striking vertical domain boundaries**

317     In contrast to the Model C series, no faults formed along the boundaries of the central domain in both  
318     Models D1 and D2 (Fig. 6a and f). Model D1 is dominated by synthetic faults crosscutting the central strong  
319     domain (6c-e). As these faults traversed the central domain, they slightly changed their strike. In contrast,  
320     in Model D2 the weak microbeads of the central domain were internally deformed and oblique-slip reverse  
321     faults formed, which propagated laterally and parallel to the domain boundaries (Fig. 6g-j). Synthetic faults  
322     formed both in the western and eastern domain of Model D2, while antithetic faults formed later and in  
323     between overlapping synthetic faults (Fig. 6g-j). With progressive deformation synthetic faults from the  
324     western and eastern domain in Model D2 propagated partially into the central, weak central domain, but  
325     halted at the previously formed oblique-slip reverse faults (Fig. 6h and i). During late stages of deformation  
326     a few antithetic faults formed in Model D1 in between earlier formed synthetic faults, striking at larger  
327     angles to the shear direction than in Model D2.

328

329 **Figure 6: Overview of Series D models: Simple shear deformation of two models with N20°W striking vertical**

338

339

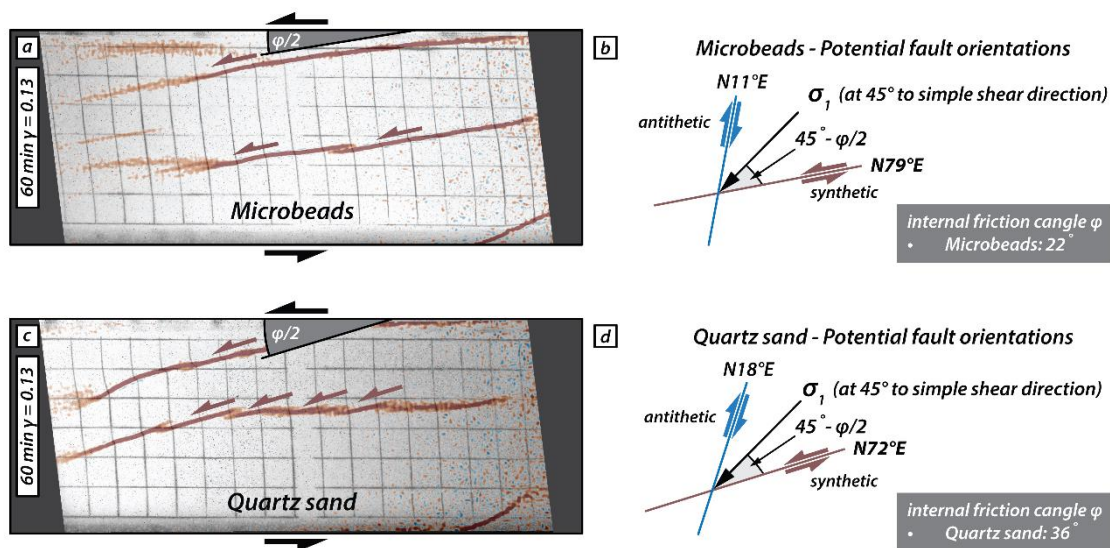

340 **4. Discussion**

341 **4.1. Series A: Strike-slip faulting in models with a homogeneous upper crust model**

342 In our models simulating homogeneous crust the structures display an *en echelon* pattern, as should be  
343 expected (Bartlett et al., 1981; Sylvester, 1988; Misra et al., 2009). Initial bulk simple shear is  
344 accommodated in both models by zones of diffuse deformation and is followed by localized deformation  
345 along narrow fault zones. It is interesting to note that localization requires a higher shear deformation in  
346 the model with the weak material than in the model with strong material. This difference in localization  
347 behaviour is attributed to the difference in dilatancy between the two analogue materials, which is closely  
348 related to grain shape and grain size distribution. The weak material, represented by the microbeads, are  
349 well-rounded and have a narrow grain size distribution (150-210  $\mu\text{m}$ ), whereas the strong material (quartz  
350 sand grains) is angular and have a wider grain size distribution (60-250  $\mu\text{m}$ ). The more uniform the grain  
351 shape and grain size, the more applied shear deformation is needed to localize the strain along a narrow  
352 fault zone (Antonellini et al., 1995; Mair et al., 2002). Therefore, the shape and grain-size characteristics  
353 will influence the time that a fault may take to reactivate depending on the lithology that comprises its fault  
354 zone (e.g. Sammis et al., 1987; Mair et al., 2002).

355 In these two models sinistral (synthetic) strike-slip faults form first. The initial strike of these faults differs  
356 between the model with the weaker material and the one with strong material, striking at N79°E and N72°E,  
357 respectively. The internal friction angle of each type of material will be adjusted to a certain orientation of  
358 rupture according to the Mohr-Coulomb criterion. (Fig. 7). At the beginning of the experiment, the main  
359 principal stress ( $\sigma_1$ ) is oriented at 45° to the shear direction, and the two potential fault orientations strike  
360 at  $45^\circ - \phi/2$  and at  $45^\circ + \phi/2$  to  $\sigma_1$ , respectively with  $\phi$  the angle of internal peak friction, which is 22°  
361 for the microbeads and 36° for quartz sand (Fig. 7). Hence, the synthetic and antithetic faults strike at N79°E  
362 and N11°E, respectively in the model with microbeads and at N72°E and N18°E in the model with quartz  
363 sand respectively. The fact that nearly all deformation is accommodated by synthetic faults is typical of  
364 simple shear models with an initial rectangular shape, i.e. a large aspect ratio of length (parallel to shear  
365 direction) divided by width (Schreurs, 2003; Dooley & Schreurs, 2012). A comparison of previous simple  
366 shear experiments shows that the shape of the initial model has an influence on the relative proportion of  
367 synthetic and antithetic faults (Gapais et al., 1991; Schreurs, 2003). With decreasing aspect ratio, the  
368 number of antithetic faults will increase, and in case of an initially square-shaped model, (i.e., aspect ratio

369 is 1) antithetic faults will dominate (Gapais et al., 1991; Dooley & Schreurs, 2012). In the model with  
 370 quartz sand, a few antithetic faults form in between previously formed major synthetic faults (Fig. 3i).  
 371 These late antithetic faults, however, form in response to local stress field modifications between  
 372 overlapping synthetic faults, causing  $\sigma_1$  to rotate clockwise from  $45^\circ$  to the bulk shear direction towards an  
 373 orientation that is subparallel to the previously formed synthetic faults. As a consequence, these late  
 374 antithetic faults are not in the “conjugate” position with respect to the synthetic major faults, but strike at  
 375 lower angles with respect to the long borders of the model (these are the lower-angle antithetic faults of  
 376 Schreurs, 2003).

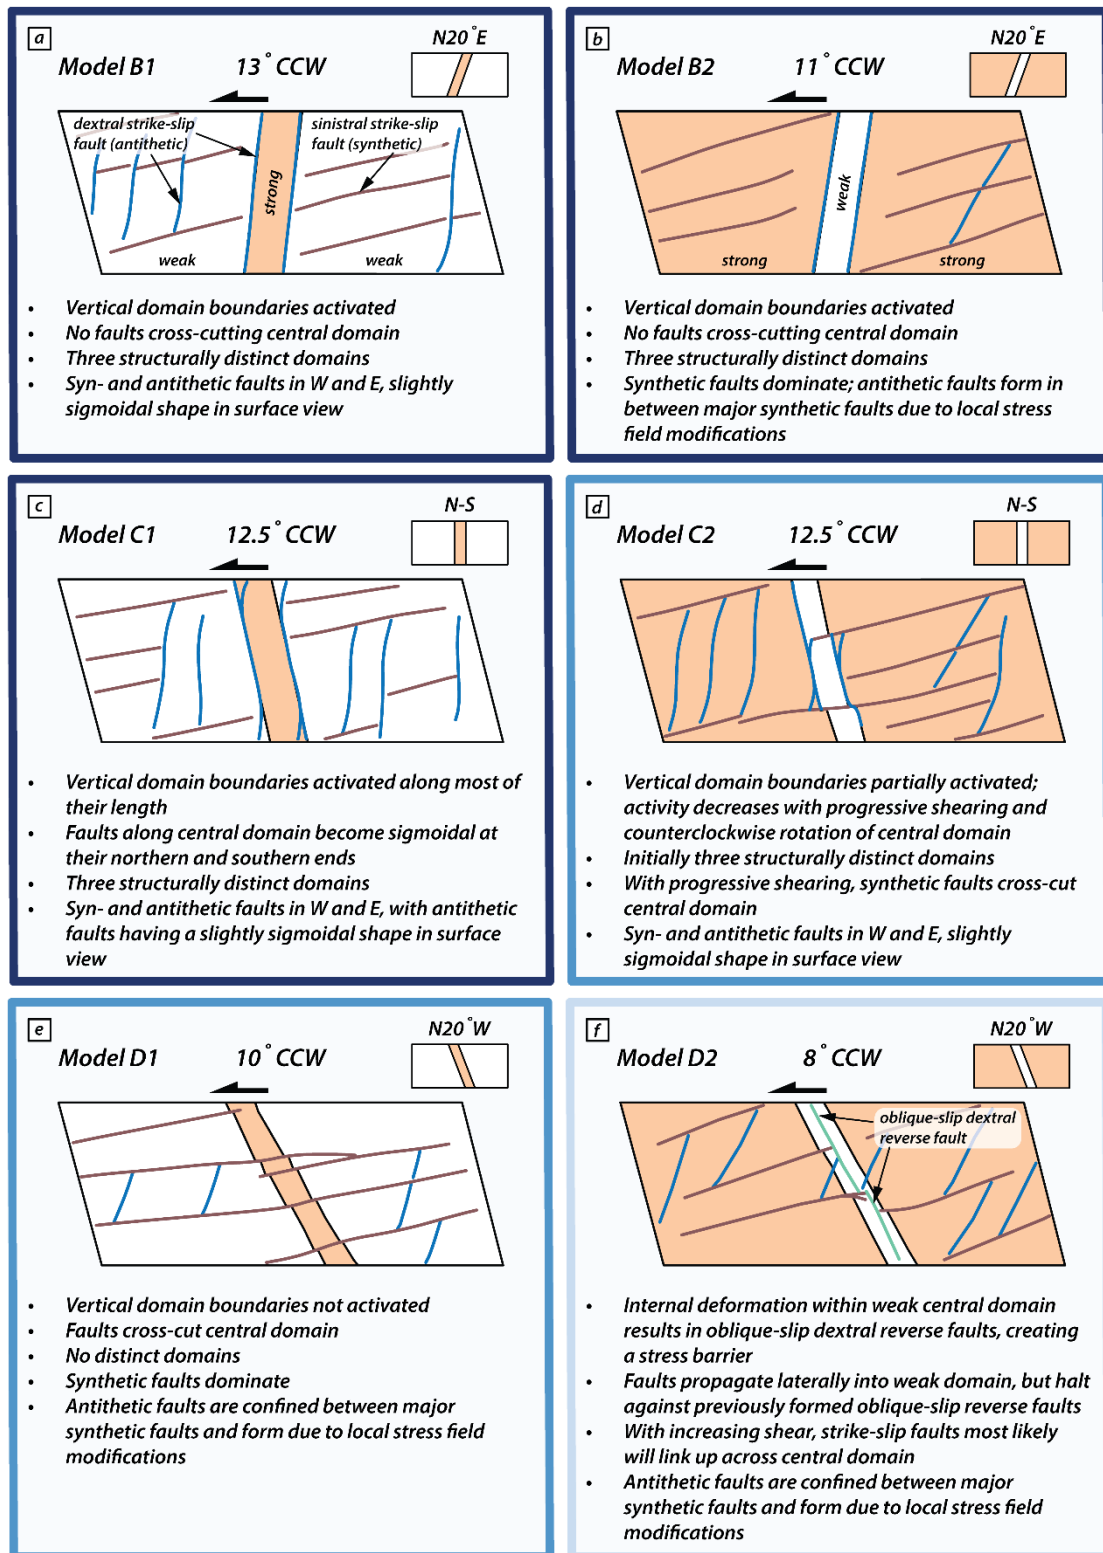

377

 379 **for the experiments with only one type of material (homogeneous upper crust). a) and c) Surface photographs**  
 380 **of the model with microbeads only (a) and quartz sand only (c), with the incremental vorticity after 60 minutes**  
 381 **(40 mm displacement). b) and d) Schematic explanation for the expected orientation of the synthetic and**  
 382 **antithetic faults considering the simple shear orientation along with the Mohr-Coulomb failure criteria, for the**  
 383 **models with microbeads and quartz sand only respectively.**

384

385 **4.2. Series B, C and D: The influence of the orientation lateral heterogeneities on strike-slip**  
 386 **faulting**

387 Introducing a vertical domain with different properties than the surrounding material results in different  
 388 fault patterns and timing of the structures (Segall and Pollard, 1983; Peacock, 1991; Peacock and  
 389 Sanderson, 1992; Schellart and Strak, 2016; Lefevre et al., 2020; Livio et al., 2019; Venancio and Alves Da  
 390 Silva, 2023). The degree of difference in the fault pattern is a function of the orientation and the strength  
 391 of the domains.

392

393 Figure 8: Schematic surface views summarizing the main results from the models with vertical domains of  
 394 contrasting brittle strength.

395

396 The first thing noticed is that the faults do not follow the *en echelon* pattern and the antithetic faults are the  
397 first one to be form (Figs. 4 and 5). The domain boundaries in Series B and C models initially strike N20°E  
398 and N-S respectively (Fig. 8a, b, c and d), which is close to the antithetic fault orientation predicted by the  
399 Mohr-Coulomb failure criterion (i.e. N11°E for microbeads and N18°E for quartz sand, see section 4.1).  
400 As a result, the domain boundaries in both models are activated along their entire length, and the antithetic  
401 faults are formed along the borders of the central domains (Fig. 8a, b and c). With progressive sinistral  
402 simple shear, the central domain bounded by the fault rotates counterclockwise about a vertical axis and, at  
403 the end of the experiment has rotated about 12° striking N08°E. The faults of the domain boundaries remain  
404 active throughout the model run, because their strike is favorably oriented respect the main stress (Fig 8a,  
405 b). As a result the sinistral faults in the series B and in model C1 cannot propagate along the entire model,  
406 regardless of the composition of the central domain, and two possibilities are shown: the faults are  
407 segmented (Fig 8a and b) or more new faults are generated in the eastern and western domains (Fig. 8c).  
408 However, if the central domain is composed of the weak material and is not fully surrounded by antithetical  
409 faults, the synthetic fault can crosscut the entire model (Fig. 8d). This may offer the possibility that strike-  
410 slip fault stepping may also be due to the action of lithology, which is able to induce fault segmentation.  
411 Hence, the presence laterally heterogeneous upper crust with steep boundaries and suitable oriented for  
412 activation by antithetic faults, can prevent the synthetic strike-slip faults from crossing certain domains.

413 The antithetic faults that form in the outer domains of our models are of two types: (i) those that form  
414 relatively early in as yet largely unfaulted domains and strike at large angles to the shear direction (Fig. 8a,  
415 c and d) and (ii) those confined between earlier formed and overlapping synthetic faults that strike at lower  
416 angles to the shear direction (Fig. 8b, e and f). In the first case, the early-formed antithetic faults reflect the  
417 orientation predicted by the Mohr-Coulomb failure criterion; striking N18°E if the outer domains consist  
418 of the strong material and N11°E if the outer domains consist of the weak material. Due to lateral fault  
419 propagation and coeval rotation of the central fault segments, these antithetic faults obtain a slightly  
420 sigmoidal shape form in map view during progressive simple shear (see also Schreurs, 1994, 2003; Dooley  
421 and Schreurs, 2012). In th second case, the antithetic faults confined in between closely spaced, earlier  
422 formed, synthetic faults have an initial different strike (N15°-N20°E in the weak material, e.g. Model C1)  
423 and N25°- N30°E in the strong material, (e.g. Model C2). The antithetic faults confined between major  
424 synthetic faults result from local stress field modifications governed by relative movement of material in  
425 between previously formed synthetic faults with large overlap (Schreurs, 2003; Dooley and Schreurs, 2012;

426 their  $R'_L$  faults). Both types of antithetic faults rotate counterclockwise with progressive sinistral simple  
427 shear. Rotation of faults and blocks in strike-slip fault systems is not only observed in analogue models  
428 (Schreurs, 1994, 2003; Dooley and Schreurs, 2012), but has also been documented in nature (e.g., Ron et  
429 al., 1986; Nicholson et al., 1986). It is thus important to keep in mind that antithetic faults (and blocks in  
430 between) can undergo considerable rotation about a vertical axis during simple shear deformation, implying  
431 that present-day antithetic fault orientations in strike-slip fault systems do not necessarily reflect the  
432 orientations in which they initially formed.

433 In comparison with the Series B and Series C models, the initial  $N20^\circ W$  striking central domain boundaries  
434 in the Series D models are the least favorably oriented for antithetical fault activation. Consequently, the  
435 fault development pattern follows an echelon type, but in both cases the size of the segments is affected by  
436 the lateral variation of the material properties. In the weak-strong-weak Model D1 (Fig. 8e and f), the  
437 domain boundaries are not activated at all and the synthetic faults forming in the outer domains propagate  
438 across the central domain. Apart from a slight re-orientation of the fault strike, reflecting the difference in  
439 material strength between central and outer domains (difference in internal friction angles), the fault pattern  
440 in Model D1 is similar to the one in Model A1, which had no vertical brittle strength contrasts. The strong-  
441 weak-strong Model D2 shows a different deformation behaviour. Although the domain boundaries at the  
442 surface are not activated, the presence of a weak material surrounded by strong material results in internal  
443 deformation within the central domain and dextral oblique-slip reverse faults form striking parallel to the  
444 domain boundaries. These faults prevent synthetic faults from crossing the central domain, and they halt  
445 against the oblique-slip reverse faults.

446

### 447 **4.3. Fault linkage across central domain**

448 In models where synthetic faults from the eastern and western domain cross-cut the central domain, the  
449 entire model behaves as one domain. As shown in the section above, this is the case for models C2, D1,  
450 and D2 where the vertical boundaries of the central domain are not or only partially activated, depending  
451 on the orientation of the central domain (section 4.2). However, all three models show distinct differences  
452 in how laterally propagating synthetic strike-slip faults link across the central domain (Fig. 9). For model  
453 D1 (Fig. 9a, b), faults cross-cut the stronger central domain from the eastern and western domains (Fig. 9a)

454 linking up in a new segment. This new segment shows different orientation resulting in a step-like linkage  
 455 pattern in surface view (i.e., flat-steep-flat; Fig. 9a, b). When segmentation occurs and the faults cross the  
 456 central domain, the orientation of the faults is different, probably related to the internal friction angles  
 457 between the quartz sand and the microbeads (Du and Aydin, 1995; de Doney et al., 2011).

458

459 **Figure 9: Surface detailed photographs of the central domain of the models with the contrasting brittle**  
 460 **mechanical strength, showing the fault linkage across the central domain at 90 minutes (60 mm displacement)**  
 461 **and 120 minutes (80 mm displacement). a) and b) model D1 with the central domain striking N20°W and**  
 462 **composed by the strong material (quartz). c) and d) model C2 with the central domain striking N-S and**  
 463 **composed by the weak material (microbeads). e) model D2 with the central domain striking N20°W and**  
 464 **composed by the weak material (microbeads). f) Schematic drawing for the fault linkage at the last stage.**

465

466 For models C2 and D2, however, the domain configuration strong-weak-strong has implications for fault  
 467 linkage. As synthetic strike-slip faults propagate from the western and eastern domains towards the weaker  
 468 central domain, early deformation patterns are characterized by a zone of diffuse deformation across the  
 469 central domain (Fig. 9c, e). In model C2, the fault from the W domain cross-cuts the weak central domain  
 470 and eventually links with the fault in the E domain in a straight fashion after 120 min (Fig. 9d), abandoning  
 471 earlier active fault strands striking N18°E (i.e., the predicted orientation for Mohr-Coulomb failure  
 472 criterion). Similar fault kinematics should be expected for model D2 (Fig. 9e, f). However, laterally  
 473 propagating faults in the western and eastern domain do not link during the duration of the model run.  
 474 Instead, the two fault segments halt at the domain boundary resulting in ongoing diffuse deformation  
 475 without strain localization in the central domain. This behavior may be explained by the presence of the  
 476 N20°W-striking reverse faults within the central model domain. Due to the misalignment between central  
 477 domain boundaries and the expected orientation of antithetic faults, the domain boundaries do not activate  
 478 and domain-internal deformation is taken up by oblique-slip dextral reverse faults. Such faults (i.e., nearly  
 479 orthogonally striking with respect to synthetic faults) accommodate bulk shear deformation hindering the

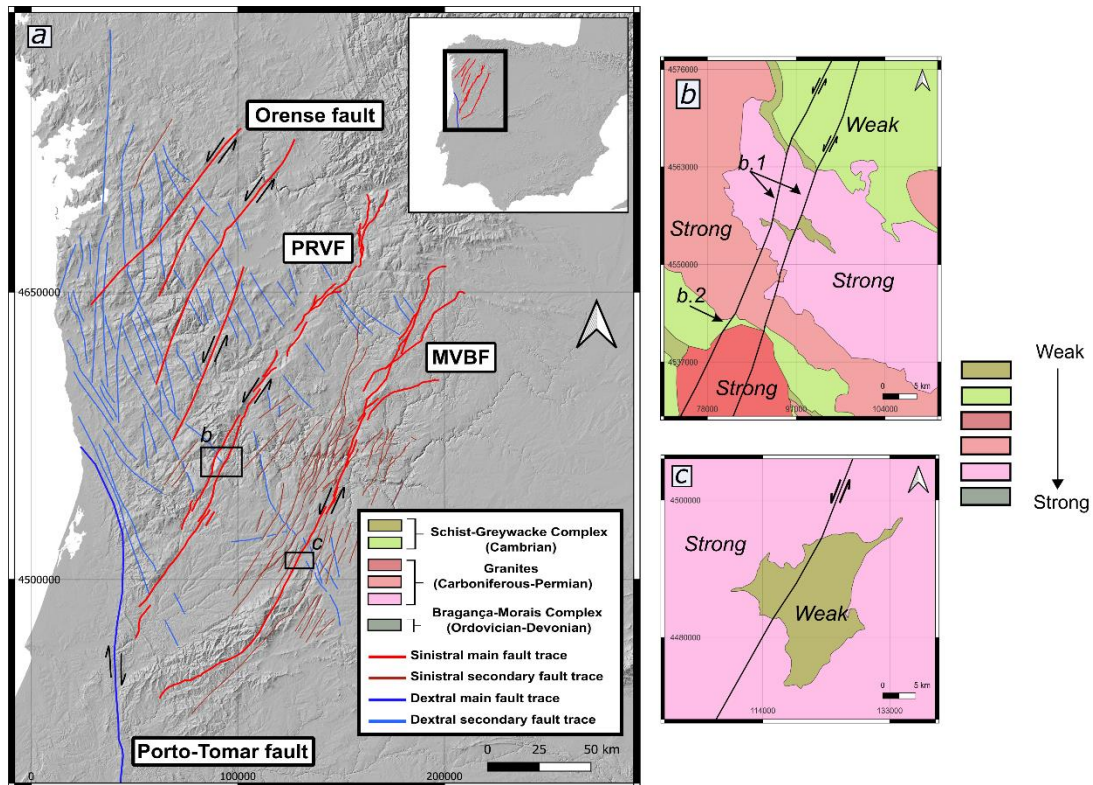

480 synthetic faults to propagate. In that sense, the oblique-slip reverse faults act as an impenetrable barrier  
481 inhibiting linkage of synthetic faults across the weak central domain (Fig. 9f). Oblique-slip reverse faults  
482 in the central domain, therefore, influence fault interaction across the central domain in a similar way as do  
483 the activated domain boundaries in models B1, B2, and C1 (Fig. 8).

484

#### 485 **4.4. Comparison with strike-slip fault zones in Iberia**

486 The NW Iberian Peninsula contains major sinistral and dextral strike-slip intraplate fault systems (Fig. 10a).  
487 These intraplate fault systems are located in an old basement developed during Variscan Orogeny  
488 (Devonian-Carboniferous, e.g., Matte, 1991; Martínez Catalán et al., 1997; Fernández et al., 2004), during  
489 this stage a set of lithologic units with contrasting properties such as granites, quartzites, slates and high-  
490 grade metamorphic rocks were emplaced and deformed. During the Alpine Compression (Late Cretaceous  
491 to the present), the present fault pattern was obtained due to the collision between the Iberian microplate  
492 and the northern edge of Africa in the middle Miocene (e. g., Alonso et al., 1996; Vegas et al., 2004; Martín-  
493 González and Heredia, 2011, Martín-González et al., 2012). This collision caused the Iberian Peninsula to  
494 undergo a counterclockwise twist, resulting in slight shearing (e.g. Martínez Catalán, 2011; Vergés et al.,  
495 2019). In the study area, intraplate deformation led to a fault pattern primarily composed of sinistral faults,  
496 such as the Penacova-Régua-Verin (PRVF), Manteigas-Vilariça-Bragança (MVBF), and Orense faults (see  
497 Fig. 10a). Additionally, antithetic dextral faults were also generated (see Fig. 10a).

498  
 499 **Figure 10: a) Digital elevation model of the northwest section of the Iberian Peninsula where the main faults**  
 500 **are drawn, with the location of Figures b and c. The faults are essentially sinistral and there is a dextral fault on**  
 501 **the southern edge that delimits the study area. In blue and light red, the secondary antithetic (dextral) and**  
 502 **synthetic (sinistral) faults have been marked respectively. b) Schematic representation of the southern section**  
 503 **of the Verin fault showing patterns of directional changes similar to models D1 and D2. c) Schematic**  
 504 **representation of the southern section of the Vilariça fault showing a similar deformation pattern to model C2.**

505

506 Among the traces of these faults, we can observe antithetic faults that do not connect with each other and,  
 507 in some cases, acquire a sigmoidal as observed in Models C1 and C2 models (Fig. 8e and f). These antithetic  
 508 faults are not in a conjugate position and mostly confined between major sinistral faults. At the end of the  
 509 sinistral faults is the Porto-Tomar fault, which delimits the study area. The Porto-Tomar fault shows dextral  
 510 displacement and tectonically delimits the area to the north and south of Portugal (Veludo et al., 2017). The  
 511 main traces of the sinistral faults are not completely straight, but show slight changes in strike. For example,  
 512 along the PRVF, the fault undergoes a counterclockwise refraction when crossing from weak into strong  
 513 lithologies (b.1 in Fig. 10b), similar to Model D1 with strong quartz sand in the central domain (Fig. 10b).  
 514 On the other hand, the same fault undergoes a clockwise refraction as it crosses from strong lithologies  
 515 (granites) in shaly units (b.2 in Fig. 10b), similar to Model D2 with weak microbeads in the central domain.  
 516 The same phenomenon is also observed along the Vilariça fault when the fault intersects granites and slate  
 517 units (Fig. 10c).

518 Although on a local scale, similarities are observed in the behaviour of individual faults crossing contrasting  
519 lithologies in nature and faults crossing vertical domain boundaries in our analogue models, the NW Iberian  
520 Peninsula strike-slip fault system as a whole does show little resemblance with the overall fault patterns in  
521 homogeneous or laterally heterogeneous upper crustal models. This may indicate that the NW Iberian crust  
522 is much more heterogeneous and complex than the one modelled in our experiments.

523

## 524 **5. Conclusions**

525 We performed a series of analogue models to investigate faulting in the upper, brittle crust as a result of  
526 sinistral simple shear. In a first series of models, the upper crust was homogeneous and consisted of a single  
527 analogue material, either weak microbeads or strong quartz sand. In three further series of models, the upper  
528 crust is laterally heterogeneous and consisted of three domains with vertical boundaries and contrasting  
529 strength (i.e. a weak-strong-weak or a strong-weak-strong configuration).

530 - The fault pattern in a homogeneous upper crust is dominated by sinistral (synthetic) strike-slip faulting,  
531 whose orientations are readily explained by the Mohr-Coulomb failure criterion, with fault strikes  
532 being a function of the internal friction angles. In models with heterogeneous upper crust, the  
533 development of the faults does not follow an *en echelon* pattern. The sinistral faults are developed in  
534 the outer domains, in the expected orientations according to the Mohr-Coulomb failure criterion.

535 - The heterogeneity of the upper crust, as lateral variations of the lithology, could affect the expected  
536 sequence of strike-slip faults with antithetic faults being the first to form. If the initial strike of the  
537 boundaries of the domains is subparallel to the predicted Mohr-Coulomb, the development of antithetic  
538 faults is promoted. As a consequence, faulting may occur in distinct structural domains and faults may  
539 be segmented. If the orientation is less favorable, the development of antithetic faults is not promoted,  
540 allowing synthetic faults to form without distinct structural domains.

541 - The properties of the lithology that intersect the sinistral faults, influences how their segments are  
542 connected. In the case of weak-strong-weak, the synthetic faults from the outer domains cross-cut the  
543 central domain with a slight change in strike orientation, whereas in the case of strong-weak-strong,  
544 the weak central domain show internal oblique-slip reverse faulting, which inhibits faults from the  
545 outer domain to fully cross the central domain.

546 - Although we only tested sinistral simple shear, our results can also be applied to dextral simple shear  
547 by mirroring the fault patterns around a N-S axis.

548 - There are similarities between the behaviour of individual faults in natural systems and our  
549 heterogeneous upper crustal models, i.e. the slight change in strike orientation when crossing a  
550 boundary with contrasting strength.
