26 **Abstract.**

27 Anthropogenic emissions from city clusters can significantly enhance secondary organic
28 aerosol (SOA) formation in the downwind regions, while the mechanism is poorly understood. To
29 investigate the effect of pollutants within urban plumes on organic aerosol (OA) evolution, a field
30 campaign was conducted at a downwind site of the Pearl River Delta region of China in the fall of
31 2019. A time-of-flight chemical ionization mass spectrometer coupled with a Filter Inlet for Gases
32 and Aerosol (FIGAERO-CIMS) was used to probe the gas- and particle-phase molecular
33 composition and thermograms of organic compounds. For air masses influenced by urban pollution,
34 strong daytime SOA formation through gas-particle partitioning was observed, resulting in higher
35 OA volatility. The obvious SOA enhancement was mainly attributed to the gas-particle partitioning
36 of high volatility (SVOC+IVOC+VOC, $C^* > 0.3 \mu\text{g m}^{-3}$) organic vapors. Using the equilibrium
37 equation could underestimate the contribution of high volatility organic vapors, since the volatility
38 of these species in the particle-phase was lower than that in the gas-phase. We speculated that the
39 elevated NO_x concentration could suppress the formation of highly oxidized products, resulting in
40 a smooth increase of low volatility (ELVOC+LVOC, $C^* \leq 0.3 \mu\text{g m}^{-3}$) organic vapors. Evidences
41 showed that urban pollutants (NO_x and VOCs) could enhance the oxidizing capacity, while the
42 elevated VOCs were mainly responsible for promoting daytime SOA formation by increasing the
43 RO_2 production rate. Our results highlight the important role of urban anthropogenic pollutants in
44 SOA control in the suburban region.

54 1. Introduction

55 As a major concern of air pollution, aerosol particles are known to have significant impacts on
56 public health and climate (Apte et al., 2018; Arias et al., In Press). Primary particulate matter (PM)
57 in China has shown a remarkable reduction since 2013, owing to strictly clean air policies
58 implemented by the Chinese government (Zhang et al., 2019). Despite the effective reduction of
59 primary emissions in the past ten years, secondary organic aerosol (SOA) remains at high levels and
60 is mainly responsible for the haze development in China (Huang et al., 2014). SOA is thought to be
61 formed through the oxidation of volatile organic compounds (VOCs) and atmospheric aging
62 processes of primary organic aerosol (POA). However, models are especially challenged in
63 reproducing SOA concentration and properties, since the formation mechanisms and gas precursors
64 of SOA remain poorly characterized (Hodzic et al., 2010).

65 Gas-particle partitioning of organic vapors is found to be the important formation pathway of
66 SOA worldwide (Nie et al., 2022; Hallquist et al., 2009; Lanzafame et al., 2021). Nie et al. (2022)
67 suggested that the contribution of the condensation of organic vapors to the SOA mass growth
68 ranged from about 38%-71% in China megacities. Photochemical produced SOA via gas phase
69 chemistry is usually related to a higher volatility and a lower oxidation degree than that formed in
70 the aqueous phase (Ervens et al., 2011; Saha et al., 2017). The condensation processes of organic
71 vapors are determined by their volatility, which is closely related to oxidation state, functional
72 groups, and the number of atomic carbons. Laboratory studies revealed that high nitrogen oxides
73 (NO_x) concentration can suppress the production of molecules with high oxidation degree by
74 inhibiting autoxidation (Rissanen, 2018; Peng et al., 2019), which is considered to be an important
75 pathway of low volatility vapor formation (Praske et al., 2018). Such compounds have been shown
76 to play a vital role in the SOA formation and growth of newly formed particles (Mutzel et al., 2015;
77 Bianchi et al., 2019; Mohr et al., 2019). On the other hand, it is shown that the increase of oxidant
78 owing to elevated NO_x concentration can offset the decrease of autoxidation efficiency, leading to a
79 higher production of oxygenated organic vapors (Pye et al., 2019), highlighting the complexity of
80 SOA formation. However, the lack of a molecular dataset of SOA and gas precursors hinders the
81 understanding of the SOA formation mechanism.

82 Recently, a chemical ionization time-of-flight mass spectrometer coupled with a Filter Inter for

83 Gases and AEROsols (FIGAERO-CIMS) has been employed to measure gas- and particle-phase
84 oxygenated organic compounds worldwide (Chen et al., 2020; Buchholz et al., 2020; Masoud et
85 al., 2022). Using a FIGAERO-CIMS, Cai et al. (2023) showed that heterogeneous reaction might
86 have an important role in the secondary formation of particle-phase oxidized organic nitrogen. The
87 volatility of OA can provide information about the formation and aging processes of OA, given that
88 it is strongly affected by chemical composition. In past decades, a thermodenuder (TD) coupled
89 with aerosol detection instruments (e.g. aerosol mass spectrometer and condensation particle
90 counter) was widely used in the estimation of OA volatility (Philippin et al., 2004; Lee et al., 2010).
91 Cai et al. (2022) found that the OA volatility was higher at a particle size range of 30 to 200 nm
92 during daytime, suggesting that the SOA formation through gas-particle partitioning could generally
93 occur at all particle sizes. However, this method failed to provide the volatility information of
94 different molecules of OA. In recent years, the FIGAERO-CIMS was developed to characterize the
95 volatility of oxygenated organic molecules in the particle phase. (Ren et al., 2022; Ylisirniö et al.,
96 2020). Wang and Hildebrandt Ruiz (2018) showed that the thermal desorption products of SOA can
97 be separated into different groups on a two-dimensional thermogram measured by the FIGAERO-
98 CIMS. Ren et al. (2022) investigated the relationship between the molecular formulae of OA
99 components and their [volatilities and](#) suggested that the volatility of OA compounds was strongly
100 affected by O to C ratio. These results provide valuable insights into the SOA formation mechanisms.
101 However, as yet few FIGAERO-CIMS field studies are available in the literature in China (Ye et al.,
102 2021; Salvador et al., 2021), especially in urban downwind areas.

Deleted: volatilities, and

103 Observational studies have demonstrated that anthropogenic emissions can significantly affect
104 SOA formation in the downwind region. Fry et al. (2018) observed an enhancement of organic
105 nitrate aerosol formed through NO_3 +isoprene in power plant plume during nighttime, which was
106 mainly attributed to NO_x emissions from the power plant. The results from Liu et al. (2018)
107 suggested that the OH concentrations increased by at least 250% under polluted conditions, which
108 might promote the daytime SOA formation. A field measurement in the Amazon forest by De Sá et
109 al. (2018) showed that the enhancement of OA (about 30-171%) in urban plumes was mainly
110 contributed by SOA. A recent study founded that anthropogenic emission of NO_x from urban could
111 enhance oxidant concentration, thereby promoting daytime SOA formation (Shrivastava et al., 2019).

112 In this study, we investigate the SOA formation through photochemical reactions at a typical

114 downwind site in the Pearl River Delta region (PRD) using a FIGAERO-CIMS along with a suite
115 of other online instruments. The volatility of OA and its relationship with identified OA sources
116 during long-range transport, urban air masses, and coastal air masses periods are discussed. The
117 formation mechanisms of daytime SOA formation within the urban plume are investigated based on
118 online measurements of gas- and particle-phase organic compounds, gaseous pollutants, and aerosol
119 physicochemical properties. The impact of urban pollutants on SOA formation will be discussed.

120 **2. Measurement and Method**

121 **2.1 Field measurement**

122 The campaign was conducted at the Heshan supersite in the PRD region during the fall of 2019
123 (29th September to 17th November 2019). The Heshan Supersite, surrounded by farms and villages,
124 is located (at 22°42'39. 1"N, 112°55'35.9"E, with an altitude of about 40 m) at southwest of the
125 PRD region and about 70 km southwest of Guangzhou city (Fig. S1). During the measurement, the
126 sampling site is mainly influenced by the air masses from the center of the PRD region (Fig. S2a).
127 All instruments were placed in an air-conditioned room on the top floor of the supersite. A detailed
128 description of the site and experimental setup can be found in Cai et al. (2021).

129 **2.2 Instrumentation**

130 **2.2.1 FIGAERO-CIMS**

131 A FIGAERO-CIMS coupled with an X-ray source was employed to measure organic
132 compounds in the gas- and particle-phase using I⁻ as the chemical ionization reagent. The particle
133 sampling inlet of the FIGAERO-CIMS was equipped with a PM_{2.5} cyclone and a Nafion dryer
134 (model PD-07018T-12MSS, Perma Pure, Inc., USA). The principle of the instrument can be found
135 in Lopez-Hilfiker et al. (2014) and Le Breton et al. (2018). In general, the operation settings and
136 data processing were the same as Cai et al. (2023) and Ye et al. (2021). Here, only a brief description
137 relevant to the measurement is given. The instrument was worked in a cycle pattern of 1 hour, with
138 24 minutes of gas-phase measurements and particle collection (sampling mode), followed by a 36-
139 minutes particle-phase analysis (desorption mode). In the sampling mode, ambient gas was

140 measured in the first 21 minutes, followed by a 3-min zero air background. At the same time,
141 ambient particles were collected on a PTFE membrane filter. In the desorption mode, the collected
142 particles were desorbed by heated N₂. The temperature of the N₂ was linearly ramped from indoor
143 temperature (~25°C) to ~175 °C in 12 minutes and held for 24 minutes. The data processing steps
144 in this campaign were the same as Ye et al. (2021). A few chemicals were calibrated before and after
145 the measurement. For uncalibrated species, a voltage scanning method was employed to obtain their
146 sensitivities (referred to as semi-quantified species) (Ye et al., 2021; Iyer et al., 2016; Lopez-Hilfiker
147 et al., 2016).

214 compounds of the collected particles. Thus, the volatility information of particles can be obtained
215 by investigating the relationship between the measured signals and desorption temperature. The
216 temperature of the peak desorption signal (T_{max}) has a nearly linear relationship with the natural
217 logarithm of saturation vapor pressure (P_{sat}) of the respective compound (Lopez-Hilfiker et al.,
218 2014):

$$219 \quad \ln(P_{sat}) = aT_{max} + b \quad (1)$$

220 where a and b are fitting coefficients. Thus, saturation vapor concentration (C^* , $\mu\text{g m}^{-3}$) can be
221 obtained:

$$222 \quad C^* = \frac{P_{sat}M_w}{RT} 10^6 \quad (2)$$

223 where M_w is the molecular weight of the compound (determined by the FIGAERO-CIMS), R is the
224 universal gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), and T is the thermodynamic temperature in kelvin (298.15
225 K).

226 We used a series of polyethylene glycol (PEG 5-8) compounds to calibrate the T_{max} and
227 obtained the fitting parameters a and b . The PEG standards were prepared in a mixture of
228 acetonitrile and then atomized with a homemade atomizer. The atomized particles are classified by
229 a differential mobility analyzer (DMA, model 3081 L, TSI Inc., USA) at two diameters (100 nm
230 and 200 nm). The selected particles were then split into two paths: one to a condensation particle
231 counter (CPC, model 3775, TSI Inc., USA) for measuring the particle concentration and another
232 one to the particle inlet of the FIGAERO-CIMS. The collected concentration can be calculated based
233 on the selected particle diameter, particle number concentration, flow rate of the particle inlet of
234 FIGAERO-CIMS, and collection time. The calibration results and corresponding fitting parameters

235 can be found in Fig. S5 and Table. S1. Note that the T_{max} can vary with mass loading, and it is
236 necessary to consider for estimation the relationship between T_{max} and C^* (Wang and Hildebrandt
237 Ruiz, 2018). Our calibration results demonstrated that the correlation between T_{max} shift and mass
238 loading was not linear, which may be attributed to matrix or saturation effects (Huang et al., 2018).
239 During the measurement, the collected mass loading centered at about 620 ng and the particle
240 volume size distribution (PVSD) centered at about 400 nm (Fig. S6). Thus, the fitting parameters
241 ($a=-0.206$ and $a=3.732$) of the calibration experiment with a diameter of 200 nm and mass loading
242 of 407 ng were adopted in the C^* calculation, since the mass loading and diameter are the closest to

Deleted: assumed to be 200 g mol⁻¹

Deleted: S4

245 [the ambient samples.](#)

246 For gas-phase organic compounds (organic vapors), we first divided them into two groups
247 based on their oxidation pathways ([multi-generation OH oxidation and autoxidation, solid line in](#)
248 [Fig. S7](#)) and then used different parameters in their volatility estimation. [The classification of](#)
249 [pathways was based on the molecular characteristics of oxidation products of aromatics and](#)
250 [monoterpene, respectively \(Wang et al., 2020\).](#) In general, their saturation vapor concentration (C^* ,
251 at 300 K) can be estimated as follows:

$$\log_{10}(C^*(300K)) = (25 - n_c) \cdot b_c - (n_o - 3n_N) \cdot b_o - \frac{2(n_o - 3n_N)n_c}{(n_c + n_o - 3n_N)} \cdot b_{CO} - n_N \cdot b_N \quad (3)$$

253 where n_c , n_o , and n_N are the numbers of carbon, oxygen, and nitrogen atoms in each compound.

254 For oxidation products formed from multi-generation OH oxidation (aging) pathway, the volatility
255 parameters b_c , b_o , b_{CO} , and b_N were assumed to be 0.475, 2.3, -0.3, and 2.5, respectively (Donahue
256 et al., 2011). For oxidation products formed from autoxidation pathway, the modified
257 parameterization is used, with $b_c=0.475$, $b_o=0.2$, $b_{CO}=0.9$, and $b_N=2.5$ (Bianchi et al., 2019). [It](#)
258 [should be noted that this method can only roughly distinguish the formation pathways of ambient](#)
259 [organic vapors, since it is based on the oxidation products of specific species in a laboratory study.](#)

260 2.3.2 Calculation of oxidation state (\overline{OS}_C) of $C_xH_yO_z$ and $C_xH_yN_{1,2}O_z$ compounds

261 For $C_xH_yO_z$ compounds, the \overline{OS}_C can be estimated as:

$$\overline{OS}_C = 2 \times \frac{o}{c} - \frac{H}{c} \quad (4)$$

263 For $C_xH_yN_{1,2}O_z$ compounds, the \overline{OS}_C can be calculated from following equation:

$$\overline{OS}_C = 2 \times \frac{o}{c} - \frac{H}{c} - x \times \frac{N}{c} \quad (5)$$

265 where x is the valence state of N atoms, which is dependent on functional groups. Several
266 assumptions were adopted to classify them. (1)N-containing functional groups were nitro (-NO₂,
267 $x=+3$) or nitrate (-NO₃, $x=+5$) in our measurement; (2)N-containing aromatics contain nitro
268 moieties while N-containing aliphatic hydrocarbons contain nitrate moieties; (3)N-containing
269 aromatics have 6-9 carbon atoms and fewer hydrogen atoms than aliphatic hydrocarbons with the
270 same number of carbon atoms.

Deleted: Note that the T_{max} can increase vary with mass loading increase and it is necessary to consider for estimation the relationship between T_{max} and C^* (Wang and Hildebrandt Ruiz, 2018). During the measurement, the collected mass loading centered at about 620 ng (Fig. S5S6). Thus, the fitting parameters ($a=-0.206$ and $a=3.732$) of the calibration experiment with a diameter of 200 nm and mass loading of 407 ng were adopted in the C^* calculation.

Deleted: (multi-generation OH oxidation and autoxidation, Fig. S6)...

Deleted:

282 2.3.3 Estimation of condensation sink

283 The condensation sink (CS) represents the condensing vapor captured by pre-existing particles
284 and can be calculated from the following equation:

$$285 \quad CS = 2\pi D \sum_{D_p} \beta_{m,D_p} D_p N_{D_p} \quad (6)$$

286 where D is the diffusion coefficient of the H_2SO_4 vapor ($0.8 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$), β_{m,D_p} is the
287 transitional regime correction factor which can be calculated from the Knudsen number (Fuchs and
288 Sutugin, 1971), and N_{D_p} represents the particle number concentration at D_p .

289 2.3.4 Estimation of OA contributed by high volatility organic vapors

290 Organic vapors with higher volatility (SVOC+IVOC+VOC, $C^* > 0.3 \mu\text{g m}^{-3}$) can easily reach
291 an equilibrium between the gas and particle phase. Thus, the contribution of high volatility organic
292 vapors to OA concentration (OA_{HVgas}) through gas-particle partitioning can be estimated as
293 following:

$$294 \quad OA_{HVgas} = \sum_i C_{i,g} f_i \quad (7)$$

295 where $C_{i,g}$ is the gas-phase concentration of species i , f_i is the fraction of species i in the particle
296 phase and is defined as:

$$297 \quad f_i = \frac{C_{OA}}{C_{OA} + C_i^*(T)} \quad (8)$$

298 where C_{OA} is the concentration of OA measured by the SP-AMS, and $C_i^*(T)$ is the saturation
299 concentration of species i at temperature (T). The temperature-dependent $C_i^*(T)$ was obtained by
300 (Nie et al., 2022):

$$301 \quad \log_{10} C_i^*(T) = \log_{10} C_i^*(300K) + \frac{\Delta H_{vap,i}}{R \ln(10)} \left(\frac{1}{300} - \frac{1}{T} \right) \quad (9)$$

$$302 \quad \Delta H_{vap,i} = -5.7 \log_{10} C_i^*(300K) + 129 \quad (10)$$

303 where $\Delta H_{vap,i}$ is the enthalpy of vaporization and can be estimated based on $\log_{10} C_i^*(300K)$.

304 2.3.4 Estimation of the production rate of RO_2 and OH

305 A zero-dimensional box model (0-D Atmospheric Modeling, FOAM(Wolfe et al., 2016)) based
306 on Master Chemical Mechanism (MCM v3.1.1, <https://mcm.york.ac.uk/MCM>) was used to simulate
307 the production rate of OH in this study. The FOAM box model has been widely used in investigating

308 chemical reactions of VOCs, NO_x, and RO_x radicals (including OH, HO₂, and RO₂) in field and
309 laboratory researches (Baublitz et al., 2023; Yang et al., 2022; D'ambro et al., 2017). The simulation
310 was constrained with the observation data of non-methane hydrocarbons (NMHC), HCHO,
311 CH₃CHO, NO, CO, HONO, and meteorological parameters (RH, temperature, photolysis rates, and
312 pressure). The background concentration of CH₄ was set as 1.8 ppm (Wang et al., 2011). The
313 simulation time step was set to be 5 minutes. With respect to the integrity and temporal coverage of
314 the observation data, the simulation period was from 16 October to 16 November 2019. Further
315 details on model settings can be found in Yang et al. (2022)

316 The empirical kinetic modeling approach (EKMA) is applied to investigate the sensitivity of
317 the production rate of RO₂ and OH to the variation of NO_x and VOCs. The base case was simulated
318 based on the observation of average conditions. Sensitivity tests are performed by adjusting NO_x or
319 VOCs by a ratio ranging from 0.1 to 2.0 without changing other parameters.

320 3. Results and discussion

321 3.1 Overview

322 Figure 1 shows the temporal profile of particle number size distribution (PNSD) and
323 condensation sink (CS) during the measurement (a), one-dimensional thermograms and T_{max}
324 measured by the FIGAERO-CIMS (b), bulk PM₁ chemical composition measured by the SP-AMS
325 and PM₁ concentration (c), deconvolved OA factors from PMF analysis (d), and wind speed and
326 direction (e). Note that all measurements started on 2 October. As shown in Fig. 1a, new particle
327 formation (NPF) events occurred frequently along with relatively low CS values during the
328 measurement period (44.4%, 20 out of 45 days). The T_{max} mainly varied in two temperature ranges,
329 80-95 °C and 110-120°C (Fig. 1b). The lower T_{max} was usually accompanied by high desorption
330 signals peaked at 80-95 °C (Fig. 1b), a higher fraction of LOOA (Fig. 1d), and an obvious wide
331 accumulation mode in PNSD (Fig. 1a).

332 The evening peak of hydrocarbon-like OA (HOA) and biomass burning OA (BBOA) was
333 related to local anthropogenic activities (e.g., biomass burning, cooking, and traffic, Fig. 2). The
334 less oxygenated OA (LOOA) and biomass burning SOA (BBSOA) showed afternoon peaks (Fig.

Deleted: CH₄,

Formatted: Font: 五号, Font color: Auto

Formatted: Font: 五号, Font color: Auto

Formatted: Font: 五号, Font color: Auto

Deleted: aged

Deleted: aBBOA

338 2), which could be attributed to secondary organic aerosol (SOA) formation through daytime
339 photochemical reactions. LOOA showed a noticeable increase corresponding to the particle surface
340 area (Fig. S8), while we did not observe such correlation for other SOA factors (MOOA and
341 BBSOA). Furthermore, LOOA exhibited a stronger positive correlation with organic vapors
342 measured by the FIGAERO-CIMS compared to other OA factors (Fig. S9). These results suggested
343 that the daytime formation of LOOA was attributed to gas-particle partitioning. The O_x ($O_x=O_3+NO_2$)
344 had a strong correlation with organic vapors in the afternoon (10:00-16:00 LT, Fig. S10),
345 highlighting an important role of photochemical reaction on the formation of LOOA.

346 The high desorption signal at a lower temperature range suggested that the volatility of OA
347 could be higher, which could be associated with the formation of LOOA. Coincidentally, either NPF
348 events or a higher fraction of LOOA could only be observed during the period prevalent with north
349 wind direction (Fig. 1e), when the measurement site was affected by the pollutant from the city
350 cluster around Guangzhou city. It indicates that the urban pollutants might promote particle
351 formation and growth and daytime SOA formation by increasing oxidants and acting as precursor
352 gases. Xiao et al. (2023) suggested that fresh urban emissions could enhance NPF, while NPF was
353 suppressed in aged urban plumes. Shrivastava et al. (2019) found that urban emissions, including
354 NO_x and oxidants, could significantly enhance the SOA formation in the Amazon rainforest. Three
355 periods were classified based on the combination of wind direction and the analysis of backward
356 trajectories to further investigate the impact of urban pollutants on this downwind site, which were
357 long-range transport, urban air masses, and coastal air masses periods (Fig. S2 and Table. S2). The
358 long-range transport period was related to long-range transport masses from northeast inland. The
359 urban air masses period was mainly affected by regional urban air masses from the PRD region. The
360 coastal air masses period was associated with air masses from the South China Sea and the northeast
361 coast.

362 A significant daytime peak of LOOA ($10.4 \mu g m^{-3}$) was shown during the urban air masses
363 period (Fig. 2c), while the enhancement of BBSOA was inapparent. It suggests that the contribution
364 of gas-particle reactions on SOA formation was enhanced when the site was affected by urban
365 plumes. The O_x concentration in the afternoon during the urban air masses period was higher than
366 that during the long-range transport period (Fig. S11), which might be able to explain the significant
367 enhancement of LOOA for the urban air masses period. These results imply that urban pollution

Formatted: Font: 五号, Font color: Auto

Deleted: The daytime formation of LOOA was attributed to gas-particle reactions, confirmed by the positive relationship between LOOA and particle surface area as well as organic vapors measured by the FIGAERO-CIMS (Fig. S7 and S8).

376 plumes could promote the formation of SOA in the downwind region by increasing the oxidant
377 concentration.

378 3.2 The daytime formation of FIGAERO OA

379 As aforementioned, the increase of LOOA was usually along with the significant desorption
380 signals measured by the FIGAERO-CIMS at a low temperature range (80-95°C), suggesting that
381 OA volatility could be higher. The average two-dimensional thermograms of all calibrated and semi-
382 quantified species and an example of a one-dimensional thermogram of levoglucosan can be found
383 in Fig. 3 a and b, respectively. According to Eqs. (1) and (2), we calculated the C^* value of all
384 calibrated and semi-quantified species based on their T_{max} and constructed volatility distribution as
385 volatility basis set (VBS, Fig. 3c). The T_{max} of each species is obtained based on their average
386 thermogram. These 12 VBS bins were classified into three groups (Donahue et al., 2012): semi-
387 volatile organic compounds (SVOC, $0.3 < C^* \leq 3 \times 10^2 \mu\text{g m}^{-3}$), less-volatile organic compounds
388 (LVOC, $3 \times 10^{-4} < C^* \leq 0.3 \mu\text{g m}^{-3}$), and extremely low-volatility organic compounds (ELVOC,
389 $C^* \leq 3 \times 10^{-4} \mu\text{g m}^{-3}$). In general, most species measured by FIGAERO-CIMS fall into LVOC groups
390 (Fig. S12). Note that the decomposition of organic compounds was ignored in this method, which
391 could affect thermogram peaks in some cases and the measurement of low volatility compounds
392 (Wang and Hildebrandt Ruiz, 2018). Furthermore, the fraction of SVOC might be underestimated
393 owing to its high volatility, as a result fast evaporation could occur during the collection on the filter
394 and shifting from sampling mode to desorption mode.

395 During the urban air masses period, the FIGAERO-CIMS measured significant signals at a
396 desorption temperature range of SVOC and LVOC (Fig. S13) in the afternoon (12:00-16:00 LT),
397 indicating that the OA volatility could be higher. The SVOC+LVOC in the FIGAERO OA increased
398 from $5.2 \mu\text{g m}^{-3}$ (8:00 LT) to $16.29 \mu\text{g m}^{-3}$ (15:00 LT) during the urban air masses period (Fig. 4a),
399 which was coincident with an enhancement of LOOA (Fig. 2c). It suggested that daytime
400 enhancement of the SVOC+LVOC in the FIGAERO OA was closely related to the obvious LOOA
401 formation. The FIGAERO OA during the urban air masses period was systemically higher than that
402 during the long-range transport period, with a significantly higher concentration of LVOC group
403 (Fig. 4b), especially the portion with a volatility $\log_{10}C^*$ of -1. Table 1 investigated the relationship

Deleted: S11

Deleted: S12

406 between SVOC+LVOC and six OA factors. The SVOC+LVOC in FIGAERO OA had a significant
407 positive correlation ($R=0.72-0.85$) with the LOOA, especially during the urban air masses period
408 ($R=0.85$, Fig. S14 and Table 1), suggesting that the LOOA formation was mainly responsible for
409 the increase of OA volatility.

410 Interestingly, the high volatility organic vapors (SVOC+IVOC+VOC, $C^* > 0.3 \mu\text{g m}^{-3}$)
411 dramatically increased in the afternoon during the urban air masses period, while we did not observe
412 such phenomenon for low volatility (ELVOC+LVOC, $C^* \leq 0.3 \mu\text{g m}^{-3}$) organic vapors (Fig. 4c).
413 The concentration of low volatility organic vapors in the afternoon (12:00-16:00 LT) did not show
414 a significant difference (1.76 and $1.84 \mu\text{g m}^{-3}$) between the long-range transport and urban air masses
415 periods, indicating that the irreversible condensation of low volatility organic vapors could not fully
416 explain the enhancement of LOOA during the urban air masses period (Wang et al., 2022). However,
417 the high volatility organic vapors had a notably higher concentration ($51.69 \mu\text{g m}^{-3}$) during the urban
418 air masses period than that ($41.70 \mu\text{g m}^{-3}$) during the long-range transport period. It implies that the
419 significant enhancement of LOOA during the urban air masses period might be mainly attributed to
420 the equilibrium partitioning of high volatility organic vapors, which could also increase the volatility
421 of total OA.

422 Here we selected a typical day (2 November 2019) of the urban air masses period for further
423 investigation. The measurement site was affected by the urban plume from the city cluster in the
424 PRD region on this day (Fig. S15). A wide accumulation mode centered at about 180 nm in PNSD
425 was observed, with a significant desorption signal measured by the FIGAERO-CIMS in the
426 afternoon and weak north wind (Fig. S16). As shown in Fig. 5a, the desorption signals of organic
427 compounds increased from 9:00 LT and reached their peak at 14:00 LT, suggesting a significant
428 daytime SOA formation. The variation of OA volatility distribution and mean $C^*(\bar{C}^*)$ is shown in
429 Fig. 5b. The \bar{C}^* shown an afternoon peak ($0.021 \mu\text{g m}^{-3}$) at 15:00 LT, suggesting a higher OA
430 volatility in the afternoon. An evident enhancement of OA with a volatility $\log_{10}C^*$ of -1 was
431 observed in the afternoon, aligning with the formation of LOOA (Fig. 5c), which primarily
432 contributes to higher OA volatility. Combined with the volatility distribution analysis in Fig. 4b, it
433 indicated that the main components of LOOA have a volatility $\log_{10}C^*$ of -1. Interestingly, the
434 T_{max} value of the sum thermogram (Fig. 5a) increased from 81°C at 9:00 to 96°C at 17:00, implying
435 that the OA volatility decreased during the daytime owing to the daytime aging processes. However,

448 the $\overline{C^*}$ value consistently increased from 6:00 LT until 15:00 LT and then began to decrease, which
449 was conflict with the increasing T_{max} . One possible reason is that species in the FIGAERO OA fell
450 into a specific T_{max} range (about 11°C) were categorized into different C^* bins by a factor of 10.
451 Thus, the slight variation of T_{max} might not affect the estimated volatility distribution of FIGAERO
452 OA. The other possible reason is that the volatility distribution of FIGAERO OA was estimated
453 based on the T_{max} value of calibrated and semi-quantified species, while the sum thermograms
454 contained all organic compounds containing C, H, and O atoms. There could be some organic
455 compounds formed through aging processes that were not included in the C^* estimation.

456 3.3 The contribution of high volatility organic vapors to SOA formations

457 In the previous section, we found that the significant enhancements in LOOA during the urban
458 air masses period might be attributed to the high volatility organic vapors through gas-particle
459 partitioning. The contribution of high volatility organic vapors to the OA concentration via
460 equilibrium partitioning can be estimated based on eq. (7). Our results show that the estimated
461 contribution of high volatility organic vapors (estimated $OA_{HV,gas}$) was higher (peaked at about 1.17
462 $\mu g m^{-3}$) during the urban air masses period (Fig. 6a). Correspondingly, we observed an enhancement
463 in the measured concentration of these species in the particle-phase (measured $OA_{HV,gas}$, peaked at
464 about 10.32 $\mu g m^{-3}$, Fig. 6b). This implies that the increase in high volatility organic vapors might
465 significantly contribute to the daytime SOA formation during the urban air masses period. However,
466 the estimated contribution was much lower than the measured value. It suggests that using the
467 equilibrium equation might not be able to fully explain the increase of LOOA contributed by the
468 high volatility organic vapors during the urban air masses period. Nie et al. (2022) indicated that the
469 estimation of OA contribution through the equilibrium equation can be easily disturbed by varied
470 meteorological processes, which would lead to uncertainties in the calculations.

471 Moreover, the gas-particle equilibrium theory assumes that particles are droplets and that the
472 high volatility species in the particle-phase could reach a reversible equilibrium with the gas-phase
473 concentration. However, some studies indicate that this assumption significantly overestimates the
474 volatility of these species in the particle-phase and underestimate the contribution of high volatility
475 organic vapors to the SOA concentration (Kolesar et al., 2015; Cappa and Wilson, 2011). This is

Deleted: s

Deleted: (peaked at about 10.32 $\mu g m^{-3}$)

Deleted: (

479 because particles might exist in a glassy state rather than a liquid state. It was consistent with the
480 difference of the volatility distribution of these species between the particle- and gas-phase (Fig.
481 7a). The volatility in the particle-phase was centered at a $\log_{10}C^*$ of -1, while that in the gas-phase
482 showed a higher concentration of $\log_{10}C^*=6-8 \text{ } \mu\text{g m}^{-3}$, implying that the volatility of these
483 compounds in the particle-phase could lower than that in the gas-phase.

Deleted: higher

484 Another possible explanation is that the corresponding species in the particle-phase could be
485 the decomposition products of low volatility compounds, leading to a higher concentration than
486 expected. We further investigate the difference between the measured and estimated concentration
487 of different high volatility species (Fig. 7b). The measured concentration was systematically higher
488 than the estimated value. The higher measured concentration of $\text{C}_2\text{H}_2\text{O}_4\text{I}^-$ could be owing to the
489 decomposition of low volatility species, as the desorption signal peaked at the ELVOC region (Fig.
490 7c). However, for higher molecular weight compounds, the corresponding T_{max} values were in the
491 LVOC region, suggesting that these species might not be the decomposition products. This implies
492 that the decomposition products might play a minor effect in the difference between the measured
493 and estimated concentration.

494 Taken together, these results suggest the increase in high volatility organic vapors could
495 promote the daytime enhancement of SOA during urban air masses period. However, this
496 contribution might be underestimated using gas-particle equilibrium theory, since the volatility of
497 organic aerosol may differ significantly from the volatility determined by the equilibrium theory.

Deleted: might lead to

498 3.4 Enhancement of SOA formation by urban pollutants

499 As aforementioned, the significant enhancement of high volatility organic vapors were
500 observed during the urban air masses period. Figure 8 compares the difference of organic vapors in
501 the carbon oxidation state (\overline{OS}_c) in the afternoon (12:00-16:00 LT) between the long-range transport
502 and urban air masses periods. A higher concentration of organic vapors with a low \overline{OS}_c ($\overline{OS}_c \leq 0$)
503 was observed during the urban air masses period, while this trend became to overturn for high \overline{OS}_c
504 ($\overline{OS}_c > 0$) organic vapors. It suggests that the oxidation degree of organic vapors was lower during
505 the urban air masses period, even though the O_x concentration was higher (Fig. S11). This trend was
506 more significant for carbon number between 2 and 5, indicating a higher concentration of small

Deleted: non-condensable

Deleted: was

Deleted: 6

Deleted: S10

513 molecules with low \overline{OS}_c during urban air masses period. The \overline{OS}_c of major C_8 compounds was
514 about -1.33, which was mainly contributed by $C_8H_8NOI_2$, highlighting the role of NO_x chemistry.

515 The oxygenated organic vapors production rates depend on oxidant and precursor concentration,
516 and the mechanism of significant enhancement of high volatility organic vapors remain unclear. We
517 speculated that it could be partly attributed to the elevated NO_x concentration in the afternoon during
518 the urban air masses period (Fig. S17). NO_x was found to have a detrimental effect on the production
519 of highly oxidized products, and thus the formation of low volatility vapors (Rissanen, 2018), which
520 might be responsible for the smooth increase of low volatility organic vapors. Previous studies found
521 that the increase of NO_x could lead to higher OH production, which would offset decreases in the
522 autoxidation efficiency and further result in enhanced SOA formation (Liu et al., 2021; Pye et al.,
523 2019). During the urban air masses period, both low volatility and high volatility CHON compounds
524 increased in the afternoon, implying the effect of NO_x on the photochemical reactions (Fig. S18 a
525 and b). That was further evidenced by the higher fraction of CHON compounds in the FIGAERO
526 OA (Fig. S18f). This result was consistent with Schwantes et al. (2019), who reported that low
527 volatility organic nitrates might have a significant contribution to SOA under high NO_x conditions.
528 Interestingly, in contrast with the higher fraction of low volatility CHON compounds in the
529 afternoon, the fraction of high volatility CHON compounds was lower at the same time (Fig. S18 d
530 and e), indicating that the effect of high NO_x concentration on photochemical oxidation goes beyond
531 the formation of CHON compounds for high volatility species.

532 To further understand how the urban plumes affect the SOA formation, we used an observation-
533 constrained box model to simulate the production rate of organic peroxy radicals (RO_2) and OH
534 with different NO_x and VOCs concentrations (Fig. 9). The detailed description of the box model is
535 described in Sect. 2.3.4. In general, the production rates of OH ($P(OH)$) were close to the transition
536 regime during three selected periods (Fig. 9a), where the $P(OH)$ is sensitive to both VOCs and NO_x
537 variation. Further, the $P(OH)$ tended to be in the NO_x -limited regime during the coastal air masses
538 period. The emission of NO_x might enhance the atmospheric oxidation capacity, consistent with the
539 results from other observations (Shrivastava et al., 2019; Pye et al., 2019). Interestingly, the
540 sensitivity regime of $P(OH)$ changed to the VOCs-limited during the urban air masses period,
541 suggesting that the production of OH would be suppressed with continued increases in NO_x . During
542 the urban air masses period, the concentration of NO_x and VOCs was noticeably increased compared

563 to the coastal air masses period, leading to a significant increase of P(OH).

564 Recent studies show that autooxidation of RO₂ can result in highly oxygenated molecules
565 (O:C≥0.7) and promote SOA formation(Pye et al., 2019; Pye et al., 2015). In general, the production
566 rate of RO₂ (P(RO₂)) was in the VOCs-limited regime during three selected periods (Fig. 9b), where
567 the P(RO₂) increased with the increase of VOCs. It suggests that the production of RO₂ was
568 suppressed with the increase in NO_x. During the urban air masses period, the concentration of VOCs
569 was noticeably increased compared to the coastal air masses period, leading to a significant increase
570 of P(RO₂). The model results indicate that urban pollutants, including NO_x and VOCs, could
571 enhance the oxidizing capacity, while the increase of VOCs was mainly responsible for significant
572 daytime SOA formation.

Deleted: 7b

573 4. Conclusions

574 In this study, we demonstrated that daytime SOA formation could be enhanced when the rural
575 site was affected by the pollutant from the city region, which could be partly attributed to the high
576 concentration of oxidant in the urban pollution. A higher volatility of OA was observed during the
577 urban air masses period, which was mainly contributed by the component with a volatility $\log_{10}C^*$
578 of -1. The significant increase of SVOC+LVOC in FIGAERO OA in the afternoon was associated
579 with enhanced LOOA formation. Similar to other measurements, the daytime formation of LOOA
580 was mainly through gas-to-particle partitioning of organic vapors, supported by a significant
581 positive relationship between the LOOA and organic vapors. We observed a dramatic increase in
582 the high volatility organic vapors in the afternoon during the urban air masses period, while low
583 volatility organic vapors did not exhibit a similar growth trend. It indicated that the rapid increase
584 of LOOA during the urban air masses period was mainly contributed by the gas-particle partitioning
585 of high volatility organic vapors. However, this contribution was underestimated using equilibrium
586 theory, since the volatility of high organic vapors in the particle phase was significantly lower than
587 that in the gas-phase.

588 The high NO_x might also suppress the formation of highly oxidized products. Thus, the
589 elevated NO_x in the urban plume might be able to explain the smooth increase in low volatility
590 organic vapors and a higher concentration of organic vapors with a low \overline{OS}_C . Box model simulation

Deleted: condensable

598 showed that the P(OH) were close to the transition regime during three selected periods, indicating
599 that the elevated NO_x and VOCs in urban plumes can increase the oxidizing capacity. However, the
600 P(RO₂) was in the VOCs-limited regime, suggesting that the increase in VOCs was mainly
601 responsible for the daytime enhancement of SOA. Further investigations on the effect of urban
602 pollutants on SOA formation on the regional scale are still needed for formulating air pollution
603 control strategies.

918 **Figure 1.** Temporal profile of the measured variables during the campaign. (a) particle number size
 919 distribution and condensation sink (black line); (b) one-dimensional thermograms of organic
 920 compounds (ions containing C, H, and O atoms, referred to as sum thermogram) and the T_{max}
 921 values (white dots) measured by the FIGAERO-CIMS; (c) bulk PM₁ chemical composition
 922 measured by SP-AMS and PM₁ concentration; (d) mass fraction of six OA factors from PMF
 923 analysis of SP-AMS data; (e) wind speed and wind direction. The color in (b) represents the
 924 normalized count per second (ncps) of oxygenated organic compounds calculated based on total
 925 count per second (cps) of oxygenated organic compounds at all m/z (*total cps*), m/z 127 (*cps*₁₂₇),
 926 and m/z 145 (*cps*₁₄₅) measured by FIGAERO-I-CIMS, $ncps = \frac{total\ cps}{(cps_{127} + cps_{145}) \cdot 10^6}$. The OA factors
 927 included more oxygenated OA (MOOA), less oxygenated OA (LOOA), aged biomass burning OA
 928 (BBSOA), hydrocarbon-like OA (HOA), biomass burning OA (BBOA), and nighttime OA (night-
 929 OA).
