21 **Abstract**

22 Chemical losses of ambient reactive volatile organic compounds (VOCs) is a long-term issue yet to
23 be resolved in VOC source apportionments. These losses substantially reduce the concentrations of
24 highly reactive species in the apportioned factor profiles and result in the underestimation of source
25 contributions. This review assesses the common methods and existing issues in ways to reduce losses
26 and loss impacts in source analyses and suggest research directions for improved VOC source
27 apportionments. Positive Matrix Factorization (PMF) is now the main VOC source analysis method
28 compared to other mathematical models. The issue in using any apportionment tool is the processing
29 of the data to be analyzed to reduce the impacts of reactive losses. Estimating the initial
30 concentrations of ambient VOCs based on photochemical age has become the primary approach to
31 reduce reactive loss effects in PMF except for selecting low reactivity species or nighttime data into
32 the analysis. Currently, the initial concentration method only considers daytime reactions with
33 hydroxyl ($\bullet\text{OH}$) radicals. However, the $\bullet\text{OH}$ rate constants vary with temperature and that has not
34 been considered. Losses from reactions with O_3 and NO_3 radicals especially for alkene species
35 remain to be included. Thus, the accuracy of the photochemical-age estimation is uncertain. Beyond
36 developing accurate quantitative approaches for reactive losses, source analyses methods for the
37 consumed VOCs and the accurate quantification of different source contributions to O_3 and
38 secondary organic aerosols are important additional directions for future research.

42 **Keywords:** Reactive loss; Consumed VOCs; Source analyses; PMF; Initial concentrations

43 **1 Introduction**

44 Ambient VOCs are key precursors of ozone (O₃) and secondary organic aerosols (SOAs)
45 formation (Li et al., 2016; Li et al., 2018a; Wu and Xie, 2018). Accurate apportionment of their
46 sources can be important in developing effective prevention and control measures for atmospheric O₃
47 and secondary organic particulate matter pollution (Carrillo-Torres et al., 2017; Meng et al., 1997;
48 Wang et al., 2022a). Current research on source analyses of atmospheric VOCs has been primarily
49 conducted utilizing the species ratio method (Che et al., 2019; Zhang et al., 2021), the photochemical
50 age-based parameterization method (Huang et al., 2020; Zhu et al., 2021), and receptor models (e.g.,
51 positive matrix factorization (PMF) (Gu et al., 2020; Liu et al., 2016), chemical mass balance (CMB)
52 (Song et al., 2019), and principal component analysis/multiple linear regression (PCA/MLR) (Jia et
53 al., 2016; Sanchez et al., 2008), etc.) based on the measured concentration data. Receptor models,
54 especially PMF, are the most widely used source apportionment methods (Song et al., 2008; Vega et
55 al., 2022; Yang et al., 2022b). However, compared to particulate matter, ambient VOC species can
56 undergo rapid, complex chemical reactions with •OH radicals, NO₃ radicals, O₃, etc. (Atkinson and
57 Arey, 2003), resulting in substantial chemical losses during their transport from their sources to the
58 receptor site (Yang et al., 2022b; Yuan et al., 2012a). Therefore, the source apportioned results based
59 on the measured VOC data have difficulty to reflect the actual impacts of emission sources on air
60 quality (Wu et al., 2023b; Yang et al., 2022a).

61 To reduce the impact of reactive losses, many studies have selected low-reactivity VOC species
62 to conduct source analyses when using PMF source analyses (Guan et al., 2020; Yang et al., 2022a).
63 However, this method cannot fully solve the issues related to reactive losses and provide complete
64 source apportionments since some highly active marker species such as isoprene (Tan et al., 2020)
65 cannot be excluded from the PMF input species without a substantial loss of information (Liu et al.,
66 2023a). Therefore, recent studies estimated the initial concentrations of ambient VOCs (i.e., the VOC
67 concentrations in the fresh emissions before they can undergo chemical reactions) utilizing the
68 photochemical age-based parameterization method and then performed source analyses with PMF
69 (He et al., 2019; Zou et al., 2023). However, there could still be high uncertainties in the estimated
70 photochemical age of VOC species (Parrish et al., 2007; Yuan et al., 2012b).

71 There were studies that only used nighttime data for source analyses to reduce the loss impacts

72 (Kim et al., 2005), but the representativeness of the apportioned results was likely limited since there
73 could be daytime only sources that would not be observed at night (Buzcu and Fraser, 2006). Some
74 studies applied decay factors to correct the impact of reactive losses in using CMB for VOC source
75 analyses (Friedlander, 1981; Lin and Milford, 1994; Na and Pyo Kim, 2007). However, there were
76 relatively few studies and the effectiveness of this method still needs to be assessed. In 2023, Liu et
77 al. (2023a) systematically investigated the impact of VOCs photochemical losses on the PMF source
78 apportioned results, and found that photochemical losses reduced the concentrations of highly
79 reactive species in factor profiles resulting in the contributions of biogenic emissions and polymer
80 production-related industrial sources being substantially underestimated. However, there has been
81 little related research to assess the limitations of VOC apportionments.

82 With the substantial increase of O₃ concentrations in many locations worldwide in recent years
83 (Li et al., 2020; Zhang et al., 2018; Zhao et al., 2021), accurate source apportionment approaches of
84 the key precursor VOCs have been acquired increasing attention (Gu et al., 2022). Thus, a related
85 issue is the determination of the VOCs consumed in the formation of the observed O₃ and SOAs (Gu
86 et al., 2023). Although some studies have investigated the underestimated contributions of emission
87 sources by comparing the apportioned results based on the initial and measured data (He et al., 2019;
88 Wu et al., 2023a), there are few publications that conducted source analyses for the consumed VOCs
89 and apportioned the contributions of different sources to the formation of O₃ and SOA. In 2023, Gu
90 et al. (2023) attempted to develop a method for apportioning the emission sources of the consumed
91 VOCs, and Wang et al. (2022b) conducted a similar study. Currently, although some studies have
92 been conducted on these issues of VOC reactive losses and achieved some important results (Gu et
93 al., 2023; Watson et al., 2001; Wu et al., 2023b), there remain unresolved issues. To better promote
94 progress on the development of better VOCs source apportioned methods, the present work
95 systematically investigated the main methods and shortcomings of those methods that are currently
96 applied to resolve these issues by reviewing relevant papers, with the aim of identifying directions
97 for the future developments and improvement of VOCs source apportionment methods.

98

99 **2 Materials and methods**

100 Relevant papers were collected by searching Science Direct (Elsevier), the Web of Science, and

101 the China National Knowledge Infrastructure (CNKI) with keywords: volatile organic compounds
102 (VOCs), oxygenated VOCs (OVOCs), initial concentrations/mixing ratios, chemical/photochemical
103 losses, source apportionment/analysis, positive matrix factorization (PMF), chemical mass balance
104 (CMB), receptor model, and photochemical age-based parameterization method. The information
105 extracted from each publication included methods for reducing the impacts of photochemical losses,
106 the impacts of VOC photochemical losses on source analyses, the source apportioned methods and
107 the results for the consumed VOCs in the atmosphere. This study identified a total of 151 papers, of
108 which 62 were published in the past five years (i.e., 2019-2023), accounting for 41% of the total
109 publications.

110

111 **3 Results and discussion**

112 **3.1 Methods of reducing the impacts of reactive losses**

113 Ambient VOCs can be substantially oxidized by O₃, hydroxyl (•OH), and nitrate (NO₃) radicals
114 (Atkinson and Arey, 2003; Bey et al., 2001; Finlayson-Pitts and Pitts, 1997), especially oxidation by
115 •OH radicals primarily during the daytime (Wang et al., 2013). Therefore, reducing the impacts of
116 VOC reactive losses on source apportionment has long been an important but not easy issue to
117 resolve in VOC source apportionments (Liu et al., 2023a). Ambient VOCs primarily include alkanes,
118 alkenes, aromatic hydrocarbons, alkynes, OVOCs, and halogenated hydrocarbons, etc. Studies
119 suggested that the Photochemical Assessment Monitoring Stations (PAMS) VOCs (i.e., alkanes,
120 alkenes, aromatic hydrocarbons, and alkynes) accounted for ~58% of total VOCs (TVOCs), while
121 OVOCs and halogenated hydrocarbons contributed ~8.5%-63% and ~0.1%-14% to the TVOCs,
122 respectively (Table S1) (Li et al., 2016; Wu et al., 2023a; Zhu et al., 2021). The reported number of
123 measured species ranged from 13 to 116, including 0-32 alkanes, 2-16 alkenes, 1 alkyne (only
124 acetylene), 3-18 aromatic hydrocarbons, 4-21 OVOCs, and 28-35 halogenated hydrocarbons. There
125 were substantial differences in the identified emission sources for the different types of VOCs (Mo et
126 al., 2016). For example, PAMS VOCs mainly originate from primary anthropogenic sources (Chen et
127 al., 2010), while OVOCs can also be formed by oxidation of PAMS VOCs in addition to primary
128 source emissions (Chen et al., 2014; Seinfeld and Pandis, 1986). The contributions of secondary
129 formation to some OVOC species (e.g., acetaldehyde and propionaldehyde) can exceed 50% (de

130 Gouw et al., 2005). In addition to local emissions, the ambient concentrations of halogenated
131 hydrocarbons can also be affected by the long-distance transport (Mintz and McWhinney, 2008).
132 Therefore, utilizing only the same source analyses approach for multiple VOC species from different
133 sources might produce results with high uncertainties in the apportionments.

134 Source analyses methods for ambient VOCs mainly included PMF, CMB, and photochemical
135 age-based parameterization method (Table S2). PMF was the most commonly method used for
136 source analyses (Yang et al., 2022b). Approximately 61% of the reviewed publications focused on
137 source analyses of PAMS species using PMF, while OVOCs primarily used photochemical age-based
138 parameterization for source apportionment but with only relatively few studies (only 7 papers) (Table
139 S3). Additionally, the studies on data from simultaneous measurement of both PAMS and OVOC
140 species utilized two methods to conduct source analyses: one method was to simultaneously input
141 PAMS and some OVOC species into the receptor model (e.g., PMF) for source analyses and only
142 separated primary and secondary source contributions of ambient VOCs (Li et al., 2023; Liu et al.,
143 2023b; Tan et al., 2021) (Table S2). Another approach was to use the PMF and photochemical age-
144 based parameterization to obtain the source apportioned results for ambient PAMS and OVOCs,
145 respectively, and then combined the two apportioned results to obtain finally source resolution results
146 for the ambient VOCs (Zhu et al., 2021). However, the utilization of this method has been limited.

147

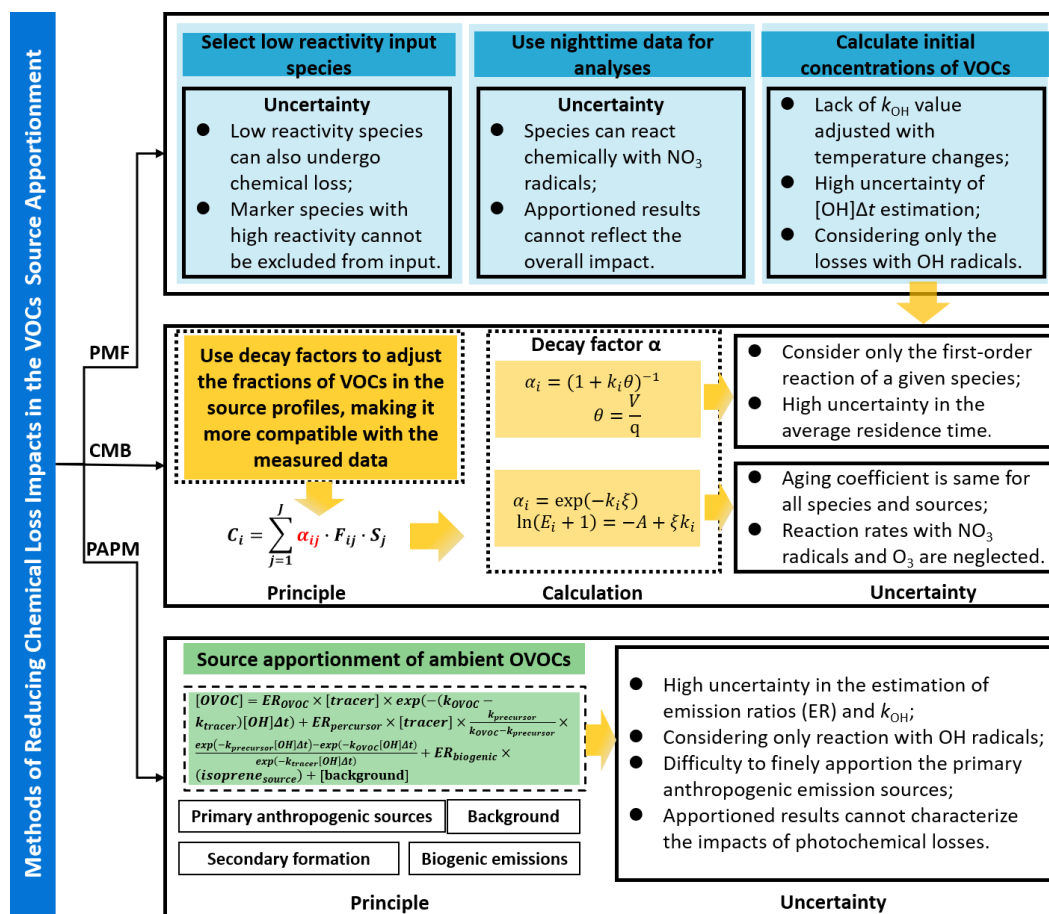

148 **3.1.1 Methods for reducing reactive loss in PMF source analyses**

149 **3.1.1.1 Selecting low activity species or incorporating night only data into PMF**

150 The methods of reducing effects of reactive losses for source apportionments utilizing different
151 models are shown in Fig. 1. At present, selecting the VOC species with lower reactivity to be input in
152 PMF for apportionment is the most commonly used approach (Chen et al., 2019; Tan et al., 2020;
153 Yang et al., 2022b). Many highly active alkene and aromatic hydrocarbon species were not included
154 in the PMF calculations (Gu et al., 2023; Liu et al., 2023a). For example, Liu et al. (2023a) excluded
155 highly active species such as 1-hexene, trans-2-butene, trans-2-pentene, cis-2-pentene, and cis-2-
156 butene. In addition, some studies have utilized nighttime only data for source analyses (Buzcu-
157 Guven and Fraser, 2008; Buzcu and Fraser, 2006; Kim et al., 2005; Xie and Berkowitz, 2006).
158 However, the volatile emission sources commonly contribute substantially to VOCs during the

159 daytime (Gu et al., 2023). For example, Buzcu and Fraser (2006) used nighttime and all-day data to
 160 conduct VOC source apportionment in Houston, respectively. They found that the night only data did
 161 not identify biogenic or gasoline sources due to minimal emissions at night. Thus, the contributions
 162 of the nighttime emission sources substantially increased compared to the all-day results because of
 163 the missing source types. Meanwhile, the all-day VOC source analysis conducted by Zhao et al.
 164 (2004) in Houston during the same period also showed substantial differences from the results
 165 reported by Buzcu and Fraser (2006) utilizing night-only data. An additional consideration is that
 166 VOCs can react with NO₃ radicals at night causing reactive losses. Thus, this approach does not
 167 eliminate the effects of all possible loss mechanisms.
 168

169

173

174 **3.1.1.2 Incorporating VOC initial concentration estimated by photochemical age-based** 175 **parameterization method into PMF**

176 The photochemical age-based parameterization method is an approach to estimate the initial
177 concentrations of ambient VOCs (Shao et al., 2011; Wang et al., 2013; Yuan et al., 2012b). This
178 method assumes that the chemical loss of ambient VOCs mainly originates only from reactions of
179 the VOCs with •OH radicals (Parrish et al., 1992; Sun et al., 2016; Wang et al., 2013). The
180 photochemical ages (Δt) of VOC species are estimated, and then combined with the rate constants
181 for reaction for •OH radicals with the VOC species (k_{OH}) to calculate their initial concentrations and
182 quantified the VOC photochemical losses (Shao et al., 2011; Wang et al., 2013; Zhan et al., 2021).
183 The equation for the initial concentration calculation is shown in Eq. (1), where k_{OH} and Δt are the
184 key parameters in this approach.

$$185 [VOC]_t = [VOC]_0 \times \exp(-k_{\text{OH}} \times [\bullet\text{OH}]\Delta t) \quad (1)$$

186 where $[VOC]_0$ and $[VOC]_t$ are the initial and measured concentrations of VOC at time t, $[\bullet\text{OH}]$
187 represents the concentration of •OH radical. However, many studies estimated $[\bullet\text{OH}]\Delta t$ because of
188 the lack of •OH radical concentration data and defined the product as the •OH exposure (Shao et al.,
189 2011; Wei et al., 2022; Yuan et al., 2012b).

190 The k_{OH} of VOC species are substantially affected by atmospheric temperature (Atkinson and
191 Arey, 2003), which could be commonly measured in laboratory (or chamber) experiments or through
192 the use of detailed chemical computer models (Atkinson and Arey, 2003). According to the reviewed
193 papers regarding the estimation of photochemical age, it was found that approximately 46% of the
194 publications used the Atkinson and Arey's 2003 summary of k_{OH} values at 298° K (Atkinson and
195 Arey, 2003), and approximately 9% used Carter's 2010 summary of k_{OH} values at 300° K (Carter,
196 2010). The detailed k_{OH} values for different VOC species summarized in these two publications are
197 provided in Table S4. However, other relevant studies cited k_{OH} values from other papers by
198 Atkinson and/or Carter (Atkinson, 1991, 2007; Atkinson et al., 2006; Talukdar et al., 1994). The rate
199 constant for a bimolecular reaction between a hydroxyl radical and a VOC molecule has a roughly
200 exponential dependence on temperature in the Arrhenius equation (Liu et al., 2023a). Therefore,

201 these published papers only used k_{OH} values at specific temperatures, which made it difficult to
202 characterize the actual reaction rates at the actual temperatures in the atmosphere. To address this
203 issue, Wang et al. (2022b) and Wang et al. (2023) utilized the Arrhenius expression to locally
204 optimize the k_{OH} values of VOC species based on the actual temperature conditions to further
205 improve the accuracy of estimating the VOC initial data. In addition, some studies used the k_{OH} of
206 m,p-xylene instead of values of more reactive species to reduce high-outliers when estimating the
207 initial concentration (Wang et al., 2013). However, the validity of this method was difficult to assess.

208 There are two main methods (as shown in Table S5) for estimating Δt , namely, the species ratio
209 method (Roberts et al., 1984; Shao et al., 2011; Wan et al., 2022) and the sequential reaction model
210 (Gong et al., 2018; Shao et al., 2011; Xie et al., 2008). The specific details are as follows:

211 (1) Estimation of Δt based on the species ratio method

$$212 \Delta t = \frac{1}{(k_A - k_B) \times [OH]} \times \left[\ln \left(\frac{[A]_0}{[B]_0} \right) - \ln \left(\frac{[A]_t}{[B]_t} \right) \right] \quad (2)$$

213 where k_A and k_B are the reaction rate constants with $\bullet OH$ radicals for species A and B of highly
214 homologous species with substantial differences in reaction activity, respectively, $\frac{[A]_0}{[B]_0}$ is the initial
215 concentration ratio of A to B in fresh emissions, $\frac{[A]_t}{[B]_t}$ is the measured concentration ratio of A to B at
216 time t . The determination of initial concentration ratio of A to B was extremely critical for estimating
217 the Δt . The Δt is used to then calculate the initial concentrations of the VOCs of interest using Eq. (1).
218 The initial concentrations can then be the input variables to PMF (Liu et al., 2023a).

219 This ratio method was first proposed by Roberts et al. (1984). The method has been
220 commonly applied to PAMS species emitted by anthropogenic sources. There have been differences
221 in the species used to calculate the initial ratio in different papers (Table S6). Generally aromatic
222 hydrocarbons (e.g., benzene, toluene, ethylbenzene, or m,p-xylene) were used as the selected species.
223 The substantial differences in activity and high homology are generally the main basis for selecting
224 species-ratio types (Lin et al., 2011; Shao et al., 2009; Zou et al., 2021; Zou et al., 2023). Most
225 publications used the initial ratios of ethylbenzene/m,p-xylene (E/X) or m,p-xylene/ethylbenzene
226 (X/E) to calculate Δt . These two species accounted for ~36.8% of the total reviewed publications in
227 this study (Table S6), respectively. Approximately 15.8% of the papers used toluene/benzene (T/B),
228 while m,p-xylene/benzene (X/B) and ethylbenzene/o-xylene (E/O) had limited use, accounting for

229 ~5.3% and ~10.5% of the reviewed publications.

230 The methods for obtaining the initial species ratio in the reviewed papers mainly included
231 referring to other similar studies (Wang et al., 2016), source emission inventory values (Wang et al.,
232 2013), and estimation based on the observed concentration data at the receptor sites at times when
233 low reactivity was expected (Fang et al., 2021; Han et al., 2019; Wu et al., 2023b). There were
234 several papers using the first two methods to obtain the initial species ratios (Table S6). The initial
235 species ratios obtained by these methods had difficulty to accurately characterize the comprehensive
236 impacts of multiple sources in the study area. Most studies were based on the observed data of low
237 photochemical reaction periods at night (~ 19:00 to 07:00 LT) to calculate the initial species ratios
238 (Table S6). This method assumes that VOC species emitted by different sources during the certain
239 periods of night would not undergo oxidative reaction, and the concentration ratio of two
240 homologous species had no the change during the transport process from source emissions to the
241 receptor sites (Liu et al., 2023a; Sun et al., 2016; Yuan et al., 2012b). Since there could be residual
242 reactions with nitrate radical and multiple sources of the indicator species, there remains uncertainty
243 in the results. For example, McKeen and Liu (1993) and McKeen et al. (1996) found that the species
244 ratios can be substantially influenced by the oxidative chemistry and atmospheric mixing.
245 Comparing one species versus another, both the model results and the observations were consistent
246 with an average rate of dilution roughly equivalent to n-butane oxidation (McKeen et al., 1996). This
247 result has negative implications for the use of hydrocarbon ratios as chemical reaction clocks
248 (McKeen et al., 1996). Parrish et al. (2007) also suggested that there were uncertainties in the
249 determination of Δt by the initial species ratios because of influence of fresh emissions along the
250 transport path that perturb the results. However, this approach can still provide a useful measure of
251 chemical processing in the atmosphere (Parrish et al., 2007).

252 There were differences in the estimation details of the initial species ratio in different reports
253 (Liu et al., 2023a; Shao et al., 2011; Yuan et al., 2012b). For example, Yuan et al. (2012b) utilized the
254 m,p-xylene and benzene data measured between 0:00 and 5:00 LT to conduct a linear fit. The
255 regression line was then extrapolated to the highest benzene concentration during this period so that
256 the initial ratio could be estimated from the m,p-xylene to benzene concentration ratios at this point.
257 Wu et al. (2023b) and Yang et al. (2022a) used time periods (00:00-04:00 LT and 20:00-05:00 LT,

258 respectively) with the lowest and the highest E/X and T/B ratios at night to calculate the average
259 values of corresponding E/X ratios less than various percentiles or the corresponding T/B values
260 above various percentiles, and then determined the initial ratio by the minimum average ratio (i.e.,
261 E/X) or the maximum average ratio (i.e., T/B) of the two species with the highest homology (i.e.,
262 highest correlation) below different percentiles. Wu et al. (2023a) reported that the maximum value
263 of X/E at 01:00-06:00 LT was considered as the initial species ratio. In addition, Liu et al. (2023a)
264 utilized the slope of the linear fit of the scatterplots of corresponding ethylbenzene and m,p-xylene
265 below the 10th percentile of E/X ratios during 00:00-05:00 LT to determine the initial ratio. Overall,
266 the E/X range in the reviewed papers was between 0.22 and 0.75, T/B was between 3.14 and 4.25,
267 X/E was between 0.39 and 2.47, E/O was between 1.30 and 1.32, and X/B was 2.2 (Table S6).

268 Zhang et al. (2020) attempted to confirm the feasibility and rationality of estimating Δt based on
269 T/B utilizing the regressions of benzene and toluene versus CO and Δt . Zou et al. (2023)
270 demonstrated the rationality of selecting the ratio of E and X to estimate the Δt through high
271 correlation of these two species having substantial activity differences. However, there were few
272 studies to systematically assess how to choose the most suitable species ratios and the calculated
273 method.

274 Multiple types of initial species ratios were used for estimating Δt of VOCs (Table S6), and the
275 results estimated by the different ratios could vary substantially. Shao et al. (2011) suggested that the
276 differences between the initial concentrations calculated using the ratios of three pairs of compound
277 ratios (i.e., T/B, X/E, and i-butene/propene (iB/P)) were generally within 50%, and the X/E and iB/P
278 results were in good agreement. Zou et al. (2021) examined the sensitivity of estimating initial
279 concentration based on E/X and E/O initial ratios. They found that the relative variation range of the
280 initial concentrations of PAMS species was between 0.41% and 68.06% for an initial E/O of 1.3
281 when compared with an initial E/X of 0.5.

282 Additionally, in the ratio method, the same Δt was calculated for different VOCs for each
283 sample, and the paired species for estimating the ratio were aromatic hydrocarbons (Table S6), which
284 are mainly emitted from anthropogenic emission sources such as solvent use and petrochemical
285 enterprises (Mo et al., 2015; Na et al., 2004; Yuan et al., 2010; Zhang et al., 2016). Therefore, the Δt
286 obtained based on these ratios may only reflect the chemical aging of VOC species emitted from

287 these specific sources. It is difficult to accurately characterize the Δt for these species from other
288 sources. In the future, different types of species ratios (not just aromatic hydrocarbons) need to be
289 selected based on VOC species from different sources. The Δt derived from different types of VOC
290 species should be calculated to improve traditional ratio methods.

291 An additional issue is that this method only considers the reactions between VOCs and $\bullet\text{OH}$
292 radicals, while chemical reactions with O_3 during the day or NO_3 radicals at night were generally
293 excluded. Liu et al. (2023a) attempted to estimate the reactive losses between 19:00 and 23:00 LT,
294 but they considered the gradual loss of $\bullet\text{OH}$ radicals after sunset and did not consider the losses
295 caused by NO_3 radicals reactions that may be present at night since they are not photolyzed as occurs
296 in the daylight. Additionally, alkenes can directly react with O_3 in the atmosphere causing losses.
297 However, there are currently no reports on estimation methods for these reactive losses. In future
298 studies, the ratio of two alkene species with substantial differences in reaction rates with O_3 could be
299 used as the base ratio as in Eq. (2), and combined with measured O_3 reaction rate constants
300 (Atkinson and Arey, 2003) to estimate the chemical reaction time (Δt) of alkene species with O_3 .
301 Then, chemical losses of alkene species in the reaction with O_3 could be estimated using Eqs. (1) and
302 (9) and the combined effects of O_3 and $\bullet\text{OH}$ could be estimated.

303

304 (2) Estimation of Δt based on the sequential reaction model

305 It has been found that using the ratio method to calculate the Δt of isoprene could result in
306 overestimation (Wu et al., 2023a; Yang et al., 2022b). An alternative is the sequential reaction
307 method. It is based on measurements of the reaction products of these reactions.

$$311 \frac{[\text{MACR}]_t}{[\text{Isoprene}]_t} = \frac{0.23k_1}{k_2 - k_1} (1 - e^{(k_1 - k_2)[\bullet\text{OH}]\Delta t}) \quad (6)$$

$$312 \frac{[\text{MVK}]_t}{[\text{Isoprene}]_t} = \frac{0.32k_1}{k_3 - k_1} (1 - e^{(k_1 - k_3)[\bullet\text{OH}]\Delta t}) \quad (7)$$

313 where MVK is methyl vinyl ketone, MACR is methacrolein; k_1 , k_2 , and k_3 are the rate constants

314 reacting with $\bullet\text{OH}$ of isoprene, MACR, and MVK, respectively; $[\text{MVK}]_t$, $[\text{MACR}]_t$, and $[\text{isoprene}]_t$
315 are the measured ambient concentrations at time t .

316 This sequential reaction method was first proposed by Bertman et al. (1995) and was commonly
317 used to estimate the Δt of isoprene emitted primarily from biogenic emissions (Gong et al., 2018;
318 Roberts et al., 2006; Wu et al., 2023a). Assuming the $\bullet\text{OH}$ -driven isoprene oxidation mechanism
319 (Eqs. (3)-(5)) from the laboratory chamber studies of Carter and Atkinson (1996), Stroud et al. (2001)
320 quantified the Δt of isoprene by the reaction relationship between isoprene and its oxidation products
321 (Eqs. (6)-(7)) (de Gouw et al., 2005; Wu et al., 2023a; Xie et al., 2008). The synchronous
322 measurement of MVK and MACR is critical to obtain Δt utilizing this method. Numerous studies
323 failed in estimating the isoprene Δt due to the lack of MVK and MACR (Gu et al., 2023; Liu et al.,
324 2023a; Wang et al., 2023). Although some studies have used the average of Δt obtained from both
325 MVK and MACR as the final Δt (Xie et al., 2008), there has been little assessment of which method
326 was more suitable.

327 Additionally, there were studies using the isotopic hydrocarbon clock method (Kornilova et al.,
328 2016; Rudolph and Czuba, 2000; Saito et al., 2009) to estimate the species Δt , that was calculated by
329 the decay of isotopes in the emissions to the ambient receptor site (Table S5). However, the studies
330 only calculated the Δt without estimating the species initial concentrations. Our study found that
331 approximately 76% of the publications that calculated the Δt used the species ratio method,
332 approximately 10% used both the ratio method and the sequential reaction model, while a few used
333 other methods (Table S5).

334

335 **3.1.2 Reducing the losses impacts in OVOC source analyses based on photochemical age**

336 Ambient OVOCs are an important fraction of VOCs, which primarily included aldehydes,
337 ketones, ethers, and alcohols (Mellouki et al., 2015) since OVOC photolysis is one of the main
338 sources of $\bullet\text{OH}$ radicals (Li et al., 2018b). The OVOCs can be directly emitted from biogenic and
339 anthropogenic sources (Huang et al., 2019; Huang et al., 2020; Tanimoto et al., 2014) and can also be
340 formed by oxidation with $\bullet\text{OH}$ radicals, O_3 , and NO_3 radicals (Legreid et al., 2008; Sahu et al., 2016;
341 Tanimoto et al., 2014). OVOCs were commonly apportioned by the photochemical age-based

342 parameterization method as shown in Eq. (8).

$$\begin{aligned}
 343 \quad [OVOC] &= ER_{OVOC} \times [tracer] \times \exp(-(k_{OVOC} - k_{tracer})[\bullet OH]\Delta t) + ER_{precursor} \times \\
 344 \quad [tracer] &\times \frac{k_{precursor}}{k_{OVOC} - k_{precursor}} \times \frac{\exp(-k_{precursor}[\bullet OH]\Delta t) - \exp(-k_{OVOC}[\bullet OH]\Delta t)}{\exp(-k_{tracer}[\bullet OH]\Delta t)} + ER_{biogenic} \times \\
 345 \quad (isoprene_{source}) &+ [background] \tag{8}
 \end{aligned}$$

346 where [OVOC], [tracer], and [background] are the concentrations of measured ambient OVOCs, the
 347 tracer (e.g., benzene, acetylene: C₂H₂, or carbon monoxide: CO, Table S7) from primary
 348 anthropogenic sources, and background OVOC concentration, respectively; k_{OVOC} , k_{tracer} , and $k_{precursor}$
 349 are the $\bullet OH$ rate constants of the OVOCs, tracer, and precursor, respectively, and k_{OVOC} and k_{tracer} are
 350 commonly obtained from the related publications (Atkinson and Arey, 2003); ER_{OVOC} and $ER_{precursor}$
 351 are the emission ratios of OVOCs and precursors relative to the tracer, respectively, $ER_{biogenic}$ is the
 352 emission ratio of OVOCs to the isoprene concentration emitted from biogenic sources (i.e.,
 353 $isoprene_{source}$), and ER_{OVOC} , $ER_{precursor}$, $ER_{biogenic}$, $k_{precursor}$, and [background] can be determined from a
 354 linear least-squares fit that minimizes the difference between the measured [OVOC] and those
 355 calculated from Eq. (8), ER values in the reviewed papers are listed in Table S8; $[\bullet OH]\Delta t$ represents
 356 the exposure of $\bullet OH$ radicals, which can be estimated by Eq. (2); and $isoprene_{source}$ can be estimated
 357 by Eqs. (6)-(7) and (1) based on the measured concentrations of ambient isoprene and its
 358 photochemical products (i.e., MVK and MACR). The chemical removal of isoprene in the
 359 atmosphere is so rapid that it is impossible to differentiate between primary and secondary OVOC
 360 sources based on the measured data. Therefore, $isoprene_{source}$ represents both primary and secondary
 361 biogenic sources (de Gouw et al., 2005).

362 However, this method remains highly uncertain because of the source complexities of OVOCs
 363 (Mo et al., 2016; Schlundt et al., 2017). This method assumes that (1) anthropogenic emissions of
 364 OVOCs and their precursors are proportional to the selected primary tracer, (2) the removal process
 365 of OVOCs is dominated by reactions with $\bullet OH$ radicals, (3) biogenic sources of OVOCs are
 366 proportional to the emission of isoprene, and (4) the photochemical age for a sampled air mass can
 367 be determined (de Gouw et al., 2005).

368 This method estimates the source contributions of primary and secondary anthropogenic sources,
 369 biogenic emissions, and background to different OVOC species, and then further obtained the
 370 contributions of the four types of sources to the ambient OVOCs (de Gouw et al., 2005; Yuan et al.,

371 2012b; Zhu et al., 2021). This approach was difficult to finely apportion the contributions of primary
372 anthropogenic sources and to obtain the contributions of primary and secondary biogenic emissions.
373 Therefore, to obtain refined source apportioned results for OVOCs, many studies incorporated both
374 OVOC and PAMS species into the receptor model for source analyses (Guan et al., 2020; Yang et al.,
375 2019; Zhou et al., 2022).

376 This method defines the measured concentrations of OVOCs as the sum of the concentrations
377 after photochemical losses (i.e., losses caused by the formation of O₃ and SOAs via photochemical
378 reactions) of OVOCs directly emitted by anthropogenic sources (i.e., the first term in Eq. (8)), the
379 concentrations after photochemical losses of OVOCs formed by the conversion of precursors emitted
380 from anthropogenic sources (i.e., the second term in Eq. (8)), the concentration from biogenic
381 emissions (without considering losses because of small contributions of biogenic emissions) (i.e., the
382 third term in Eq. (8)), and the background concentration (i.e., the fourth term in Eq. (8)). Therefore,
383 although this approach considered the influences of photochemical losses in the calculation process,
384 the final results only reflected the contributions of four types of sources to the measured OVOCs and
385 could not characterize the impacts of photochemical losses. In addition, to compensate for the
386 photolytic losses in OVOCs in Eq. (8), which was not considered by de Gouw et al. (2005), Huang et
387 al. (2020) and Zhu et al. (2021) introduced a modification coefficient (*m*) before the *k*_{OVOC} to modify
388 it, assuming that the photolysis rate is proportional to the •OH reaction rate (de Gouw et al., 2005;
389 Wang et al., 2017). The *m* value depends on the relative rate of photolysis versus the •OH reaction
390 for an OVOC species. However, related studies remain limited at present.

391

392 **3.1.3 Methods for reducing loss effects in CMB source apportionments**

393 The chemical mass balance method uses known profiles measured at the source. Thus, any
394 reactions in transit will result in a change in that source's profile and difficulty in fitting the data at
395 the receptor site. Thus, corrections to the receptor site data are needed to make them comparable to
396 the measured source profiles. As early as the 1980s and 1990s, studies had been conducted to reduce
397 the impacts of different VOC species reactions on CMB estimation results, including minimization
398 of reaction effects by limiting source profiles to VOCs with similar reaction rates (Harley et al., 1992;
399 Lewis et al., 1993; Nelson and Quigley, 1983; Wadden et al., 1986) and VOC samples obtained

400 during winter (Aronian et al., 1989) or early in the morning (Scheff and Klevs, 1987). In 1983,
401 Nelson and Quigley (1983) estimated the reactions extent by the changes in the ratios of xylene to
402 ethylbenzene at the receptor and the release site and then obtained decay factors of other VOC
403 species. However, it was found that the concentrations adjusted by decay factors at the receptor site
404 had little impact on their estimated source contributions (Nelson and Quigley, 1983). Since the
405 emissions varied with time, especially during periods of intense photochemical reactions (Lin and
406 Milford, 1994), some studies tried to use decay factors to adjust the fractions of VOC species in the
407 source profiles at different times, making them more compatible with the data measured at the
408 receptor site (Lin and Milford, 1994; Na and Pyo Kim, 2007). However, this approach has not been
409 used other than in these two instances.

410 There are two methods to obtain the decay factors: one method was to considering an urban
411 airshed as a continuous stirred tank reactor and relating the decay factor for a given species to its
412 first-order reaction rate constant (Friedlander, 1981). The other method was to conduct estimation
413 based on the reaction rate constants of specific VOC species and “aging coefficients” (Junninen et al.,
414 2006; Lin and Milford, 1994). The details and limitations of the two methods are provided in Text S1.
415 However, this method of adjusting source profiles cannot truly address the issue of reactive losses
416 affecting the CMB apportioned results. Since the receptor measured data and adjusted source profiles
417 input to CMB were both data after reactive losses. With the progress of VOC source analyses studies
418 in recent years, this method has not been widely applied and further developed in CMB source
419 analyses. This change might be because CMB itself required input from VOC source profiles, but
420 there were relatively few locally measured VOC source profiles due to high costs and difficult to
421 obtain access to the source facilities (Yang et al., 2022b).

422 Alternatively, with the monitoring of highly time resolved VOCs data in recent years, it became
423 infeasible to use CMB to conduct source analyses, because CMB requires analysis of one sample
424 (one hour) at a time resulting in needing thousands of separate analyses (Yang et al., 2022b).
425 Additionally, the weights in the analyses are generally based only on the measurement uncertainties
426 of the measurement samples from specific sources at a few specific times. Thus, CMB does not
427 account for variability in the source profiles that is included in the uncertainty values used to weight
428 the data in PMF (Yang et al., 2022b). To reduce the impact of reactive losses, the initial concentration

429 data estimated by photochemical age-based parameterization method has been used as input into
430 CMB for source analyses (Shao et al., 2011). Additionally, the methods for reducing the impacts of
431 reactive losses in PMF and CMB primarily focused on the PAMS species, and few considerations for
432 OVOCs.

433

434 **3.2 Effects of reactive losses on source analyses**

435 According to the review of relevant publications, it has been found that most of the current
436 studies analyzed the impacts of VOC photochemical losses on the source contributions by comparing
437 the PMF apportioned results based on the measured and initial concentrations estimated by a
438 photochemical age-based parameterization method (Gao et al., 2018; Kong et al., 2023; Li et al.,
439 2023; Liu et al., 2023c; Zou et al., 2023). For example, Wang et al. (2013) found that the
440 contributions of biogenic and industrial emissions were underestimated by 30% and 10%,
441 respectively, due to photochemical losses. Liu et al. (2023a) suggested that biogenic emissions and
442 polymer production-related industrial sources in Tianjin were underestimated by 73% and 50%,
443 respectively. Wu et al. (2023a) also reported that the underestimation of the contribution of biogenic
444 emissions was substantially higher than other sources. In 2023, Liu et al. (2023a) systematically
445 investigated the impacts of photochemical losses of VOCs on the PMF apportioned factor profiles
446 and contributions by comparing the estimated results based on the initial and measured
447 concentrations, and found that the photochemical losses reduced the concentrations of these highly
448 reactive species in the apportioned factor profiles based on the measured data. Meanwhile, Gu et al.
449 (2023) also obtained similar results. However, due to the uncertainty of initial concentration
450 estimation, the reliability of these results needs further validation and evaluation. Thus, further
451 research is required.

452

453 **3.3 Estimation methods of VOC reactive losses**

454 There were two main methods for estimating the reactive losses of VOCs in the atmosphere.
455 The first was to estimate the initial concentrations of VOCs utilizing the photochemical age-based
456 parameterization method (Liu et al., 2023a; Wu et al., 2023b), and the differences between the initial
457 and the measured concentrations were considered to the photochemical losses of VOCs (Table S9)
458 (as shown in Eq. (9)) (Wang et al., 2023; Wu et al., 2023b). Due to the uncertainty in the initial

459 concentration estimation (as shown in section 3.1.1.2), there were also uncertainties in the estimated
 460 photochemical losses.

$$461 \quad [VOC]_{C,t} = [VOC]_t \times (\exp(k_{VOC}[\bullet OH]\Delta t) - 1) \quad (9)$$

462 where $[VOC]_{C,t}$ represents the photochemical loss of VOC at time t , k_{VOC} represents the reaction rate
 463 constants with $\bullet OH$ radicals of VOC, and $[\bullet OH]\Delta t$ represents the exposure of $\bullet OH$ radicals.

464 The second method applies to other VOC species without isoprene in which the losses could be
 465 estimated utilizing isoprene conversion (Wiedinmyer et al., 2001). In this study, it was defined as the
 466 isoprene loss reference method (Table S9). Its principle is to first use the photochemical-age
 467 parameter method based on the sequential reaction model as shown in Eqs. (1) and (6)-(7), to
 468 estimate the photochemical loss of isoprene (i.e., $\Delta isoprene$), and then the photochemical losses of
 469 other VOC species can be estimated by proportion relationship ($\frac{k_{VOC}}{k_{isoprene}} \times \frac{[VOC]_t}{[isoprene]_t}$) between Δ
 470 *isoprene* and other species losses (Wiedinmyer et al., 2001; Xie et al., 2008) (as shown in Eq. (10)).
 471 This method assumes that the relative source strengths of VOCs are constant in an immediate area
 472 surrounding the site, that atmospheric transport and dispersion are non-limiting factors compared
 473 with chemistry (Xie et al., 2008), and the photochemical losses of other VOC species can be
 474 calculated by Eq. (10).

$$475 \quad [VOC]_{C,t} = \Delta isoprene \times \frac{k_{VOC}}{k_{isoprene}} \times \frac{[VOC]_t}{[isoprene]_t} \quad (10)$$

476 where $k_{isoprene}$ represents the reaction rate constants with $\bullet OH$ radicals of isoprene, and $[isoprene]_t$
 477 represents the measured concentration of isoprene at time t .

478 Because isoprene mainly originates from natural sources (Fu et al., 2008; Kuhn et al., 2004; Lu
 479 et al., 2019), while many other VOC species are primarily emitted from anthropogenic sources (Li et
 480 al., 2021; Seinfeld and Pandis, 1986; Wei et al., 2011). Therefore, the assumption of this method
 481 itself has an obvious issue, which resulted in high uncertainties in the estimations. This defect
 482 substantially limits its application, only 2 publications have utilized this method to quantify chemical
 483 losses of VOCs in this study (Wiedinmyer et al., 2001; Xie et al., 2008), and most studies still used
 484 the first method (Table S9).

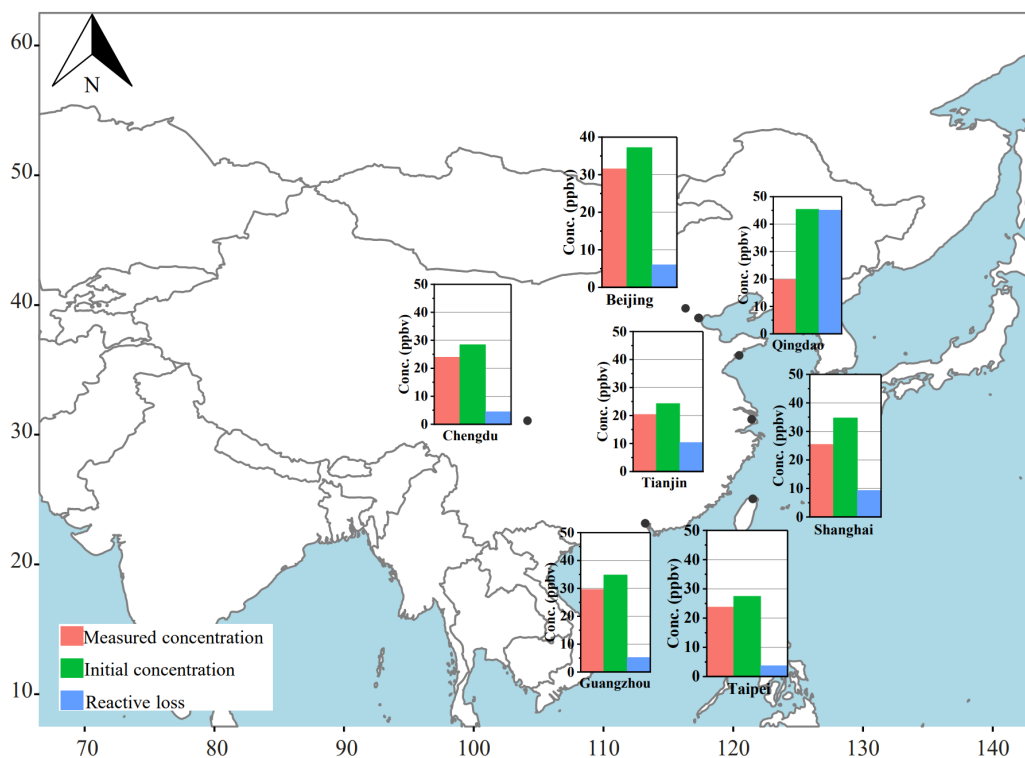

485

486 3.4 Spatiotemporal variation of VOC reactive losses

487 According to the papers reviewed in this study, we found that studies on the VOC

488 photochemical losses were mainly conducted in Chinese cities. The VOC losses in different cities are
 489 provided in Figs. 2-3 and S1 and Table S10. Due to relatively limited number of studies, the
 490 representativeness of the analyses of the spatiotemporal distributions of photochemical losses of
 491 VOCs might also be limited. In addition, this study converted the unit of ppbC in some papers (Chen
 492 et al., 2023) to ppbv for better comparative analyses.

493
 494 **Figure 2.** The measured, initial, and reactive loss concentrations of ambient VOCs in Beijing (Gao et al., 2018; Ma et al., 2022; Zhan et al., 2021), Tianjin (Liu et al., 2023a; Wang et al., 2023), Shanghai
 495 (Wang et al., 2013), Chengdu (Kong et al., 2023), Guangzhou (Wang et al., 2023), Qingdao (Gu et al.,
 496 2023), and Taipei (Chen et al., 2023). The data in Beijing was the average from three published
 497 papers data. The horizontal axis represents longitude (°E), and the vertical axis represents latitude
 498 (°N). The base map is from Natural Earth.
 499

500

501 The photochemical loss of VOCs in Qingdao was the highest (45.1 ppbv), followed by Tianjin
 502 (2.9-17.8 ppbv), Shanghai (9.00-9.60 ppbv), Taipei (0.76-8.29 ppbv), Beijing (3.40-7.72 ppbv),
 503 Chengdu (2.30-6.60 ppbv), and Guangzhou (5.20 ppbv). The chemical loss rate (i.e., chemical
 504 loss/initial concentration) in Qingdao (69.1%) was the highest, and the lowest was in Taipei (2.97%-

505 27.3%). Compared to other VOC groups, alkenes had the highest loss (Figs. 3 and S1), accounting
 506 for 55.4%-93.3% of the total losses, followed by aromatic hydrocarbons (3.81%-38.7%), and alkanes
 507 (2.33%-22.7%) (Table S11). There were substantial differences in VOC species with high losses in
 508 different cities (Fig. 3). The losses of ethene, propene, and isoprene in most cities were relatively
 509 higher than those of other species (Fig. 3), likely closely related to their high reactivities (Table S4).
 510 The reactive losses of 1-butene and trans-2-butene in Qingdao were 10.96 and 9.96 ppbv,
 511 substantially higher than other species, while the loss of 1-hexene (9.50 ppbv) in Tianjin was
 512 remarkably higher compared to other species. However, the losses of isoprene in Beijing, Chengdu,
 513 and Taipei were the highest (Fig. 3).

514

515 **Figure 3.** The photochemical losses and percentages of the main VOCs in Beijing (a: cited from
 516 publication (Gao et al., 2018) and b: cited from publication (Zhan et al., 2021)), Qingdao (Gu et al.,
 517 2023), Taipei (Chen et al., 2023), Tianjin (Liu et al., 2023a), and Chengdu (Kong et al., 2023).

518

519 In addition, the VOC reactive losses in spring and summer were substantially higher than those
520 in autumn and winter. Atmospheric oxidation and meteorological factors can have impacts on the
521 VOC losses. The trend of the reactive losses of VOCs was often consistent with the changes in the
522 concentrations of O_x (O_3+NO_2) in the atmosphere (Wang et al., 2013). In addition, studies also found
523 that both solar radiation and temperature can have a substantial impact on the chemical reactions of
524 VOCs (Yadav et al., 2016). However, compared to the solar radiation, temperature directly affects
525 the reaction rates of VOC species (Atkinson and Arey, 2003). Liu et al. (2023a) suggested that the
526 reactive losses of ambient VOCs were highly correlated with temperature; when the temperature was
527 above 25 °C, the losses of VOCs increased most substantially.

528

529 **3.5 Source analyses of VOC reactive losses in the atmosphere**

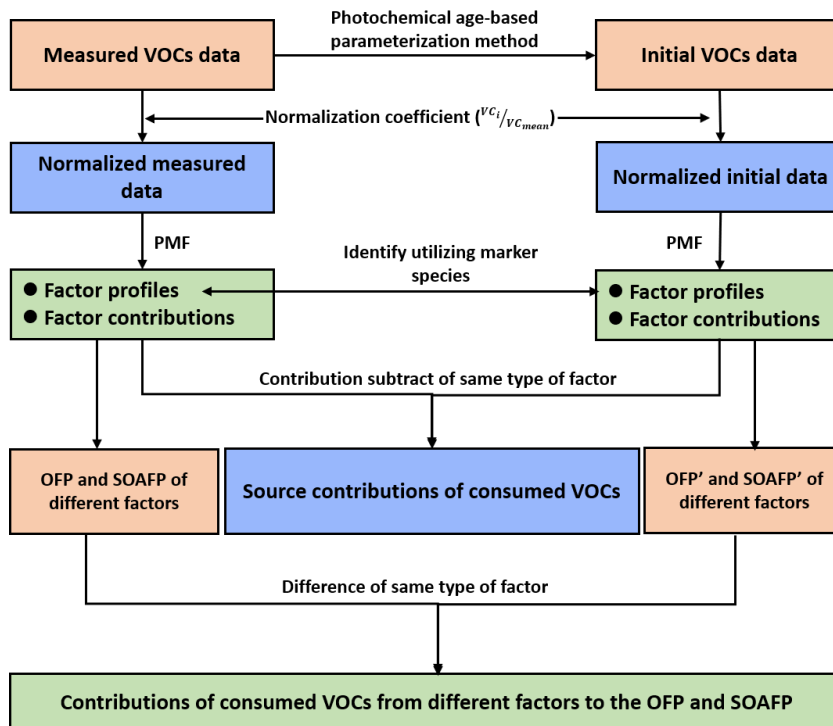

530 At present, source apportionments utilizing the measured and initial VOC concentrations do not
531 consider the complementary issues of O_3 and SOA formation (Gu et al., 2023; Wang et al., 2022b).
532 The chemical losses of VOCs by reaction (i.e., reactive VOCs forming SOA and O_3) were real
533 contributors to these pollutants (Ma et al., 2022; Wang et al., 2013). Thus, it is important to apportion
534 the reactive losses of VOCs to provide the input needed to identify the responsible source types and
535 thereby allow effective control of O_3 and secondary aerosol pollution. In 2023, Gu et al. (2023)
536 developed a source analyses method for consumed VOCs (i.e., the reactive losses of VOCs) in the
537 atmosphere and conducted an applied study. This method was that the measured and initial data were
538 first used to conduct source analyses by PMF, and then the difference in the contributions of the
539 same factors from the paired analyses were considered to be the source contribution of consumed
540 VOCs in the atmosphere. The ozone formation potential (OFP) and SOA formation potential
541 (SOAFP) of the consumed VOCs from the different sources were estimated. To reduce the impacts of
542 atmospheric dispersion on the apportioned results, dispersion-normalized PMF (DN-PMF) was
543 applied for source analyses in this method, and its principle is provided by Dai et al. (2020) and Gu
544 et al. (2022). The method flowchart is shown in Fig. 4. Similar studies were reported by Wang et al.
545 (2022b) and Wang et al. (2023). However, the current method for apportioning the sources of
546 consumed VOCs in the atmosphere is still imperfect. The shortcomings included: the uncertainty in
547 estimating the initial concentrations of VOCs (see section 3.1.1.2); the issue of factor identification,
548 even if identified as the same type of factor, there were substantial differences in their factor profiles

549 (Liu et al., 2023a); and the current studies focused on the PAMS species, and apportionments of
 550 OVOC losses have not yet been conducted. There were numerous technical issues, for example, there
 551 is still a lack of rational methods for estimating the OVOC initial concentrations.

552 The source analyses of the consumed VOCs conducted by Gu et al. (2023) in Qingdao found
 553 that biogenic emissions (56.3%), vehicle emissions (17.2%), and gasoline evaporation (9.37%) were
 554 the main sources of the consumed VOCs. However, the apportioned results from Wang et al. (2023)
 555 in Tianjin and Guangzhou suggested that biogenic emissions (43% and 35%, respectively), solvent
 556 usage (14% and 18%, respectively), and industrial sources (14% and 22%, respectively) were the
 557 major contributors of the consumed VOCs. Therefore, biogenic emissions may be an important
 558 source of reactive losses of VOCs. However, due to the limited research currently available, the
 559 representativeness of the results is still insufficient at present.

560

561

562

Figure 4. The method flowchart of source analyses for consumed VOCs in the atmosphere.

563

564 **4 Conclusions**

565 This study systematically reviewed the major methods of reducing the impacts of reactive loss
566 and the existing critical issues in the current VOC source analyses research. The purpose was to
567 clarify the future research directions needed to improve the accuracy of VOC source apportionments,
568 and provided a potential supporting role in completely solving the issue of VOC chemical conversion.
569 PMF is currently the most useful tool in treating highly time-resolved data compared to other
570 receptor models. Estimating the initial concentrations of ambient VOCs based on photochemical age
571 is the primary approach to reduce reactive loss effects in PMF. However, due to the shortcomings
572 existing in the photochemical-age estimation method, such as only considering the photochemical
573 reactions with •OH radicals during the day and not considering the reactions with O₃ (especially for
574 alkene species) and NO₃ radicals, difficulty in dynamically adjusting the required •OH-radical
575 reaction rate constants with temperature changes, high uncertainty in the estimation of
576 photochemical age, and difficulty in quantifying the initial concentrations of OVOCs, etc., resulting
577 in substantial uncertainty in the PMF apportioned results based on the initial concentration data.
578 Furthermore, both the measured and initial VOCs data do not match the ambient O₃ or SOAs
579 measured synchronously, the VOCs consumed by reactions are real contributors to these pollutants.
580 Source analyses of the consumed VOCs can effectively guide the prevention and control of O₃ and
581 SOAs pollution in the atmosphere. Therefore, in addition to the research into more accurate
582 quantitative approaches for ambient VOC reactive losses, the source analyses of consumed VOCs
583 and the accurate quantification of their separate contributions to O₃ and SOAs should also be
584 important directions for future research.
