24

25 **Abstract:** Amines and aminiums play an important role in particle formation, liquid-  
26 phase reactions, and climate change, attracting considerable attention over the years.  
27 Here, we investigated the concentrations and compositions of aminiums in PM<sub>2.5</sub> in  
28 11 Chinese cities during the winter, focusing on the characteristics of aminiums  
29 during the polluted days and the key factors influencing aminium outbreak.  
30 Monomethylaminium was the dominant aminium species in most cities **except**  
31 Taiyuan and Guangzhou, followed by dimethylaminium. Diethylaminium dominated  
32 the total aminiums in Taiyuan and Guangzhou. Thus, the main amine sources in  
33 Taiyuan and Guangzhou were significantly different from those in other cities. The  
34 concentrations of the total aminiums (TA) in all cities increased significantly during  
35 the polluted days, with weak aminium outbreaks in Xi'an and Beijing. Additionally,  
36 the concentrations of TA in Xi'an and Beijing were insignificantly correlated with  
37 those of PM<sub>2.5</sub> and the major acidic aerosol components, while the opposite pattern  
38 was observed in 9 other cities. Thus, acid-base chemistry was significantly associated  
39 with the formation of aminiums in PM<sub>2.5</sub> in all cities **except** Xi'an and Beijing. Based  
40 on the sensitivity analysis of the aminiums/ammonium ratio to ammonium changes as  
41 well as excluding the effects of relative humidity and atmospheric oxidation, we  
42 proposed the possibility of the competitive uptake of ammonia versus amines on  
43 acidic aerosols or the displacement of aminiums by ammonia in Xi'an and Beijing  
44 (constraining aminium outbreaks). Overall, this study deepens the understanding of  
45 the spatiotemporal differences in aminium characteristic and formation in China.  
46 However, the uptake of amines on particles to form aminiums and the relevant

47 influencing factors require further mechanistic research.

52

### 53 **1. Introduction**

54 Low-molecular-weight amines are ubiquitous and important in the gaseous and  
55 particulate phases (Nielsen et al., 2012; Ge et al., 2011a; Berta et al., 2023). More  
56 than 150 amines have been identified in the atmosphere (Ge et al., 2011a). The most  
57 abundant and frequently reported amines in field observations are typically C1–C6  
58 alkylamines including dimethylamine, monomethylamine, trimethylamine,  
59 diethylamine, ethylamine, 1-propanamine, and 1-butanamine (Yang et al., 2023b; Liu  
60 et al., 2023). Amines can participate in various chemical and physical processes in the  
61 atmosphere, promoting the formation and growth of new particles and contributing to  
62 the production of secondary organic aerosols (Yao et al., 2018; Tong et al., 2020;  
63 Møller et al., 2020). Amines are thus considered to have a direct or indirect impact on  
64 air quality (Li et al., 2019; Tao et al., 2016; Shen et al., 2023). Air pollution (e.g.,  
65 haze) caused by high levels of atmospheric fine particles (PM<sub>2.5</sub>) has received  
66 considerable attention in China over the past decade due to rapid industrialization and  
67 urbanization (Liu et al., 2022b; Liu et al., 2022c). Evidently, controlling the emission  
68 strength of amine sources and understanding the transformation of atmospheric

69 amines can effectively reduce air pollution in cities.

70 The main sources of atmospheric amines during the air pollution period in cities  
71 in China are typically fossil fuel combustion and biomass burning rather than  
72 agricultural emissions (Feng et al., 2022; Liu et al., 2022c; Wang et al., 2022; Shen et  
73 al., 2017; Ho et al., 2016; Chang et al., 2022). Owing to the water solubility and  
74 alkalinity of amines, low-molecular-weight amines in PM<sub>2.5</sub> during the air pollution  
75 period are mainly present in the form of amine salts (i.e., aminiums) via the gas-to-  
76 particle partitioning of gaseous amines and subsequent acid-base chemistry (Zhang et  
77 al., 2021; Liu et al., 2022a; Ge et al., 2011a; Xie et al., 2018). It should be noted that  
78 organic amines (e.g., dimethylamine and trimethylamine) in nanoparticles (<200 nm)  
79 may also be largely present in the organic phase (Xie et al., 2018). In addition,  
80 oxidative degradation of higher-molecular-weight amines and displacement reactions  
81 are also potential formation pathways of aminiums in PM<sub>2.5</sub> (Tao et al., 2021; Qiu and  
82 Zhang, 2013; Tong et al., 2020). Although previous observational studies have  
83 investigated the compositions, concentrations, sources, and formation processes of  
84 low-molecular-weight aminiums in the particle phase in urban areas of Shanghai (Liu  
85 et al., 2023), Guangzhou (Shu et al., 2023), Qingdao (Liu et al., 2022c), Xuzhou  
86 (Yang et al., 2023b), China, there has been relatively little focus on the association  
87 between PM<sub>2.5</sub> and amine outbreaks. A recent study conducted in Wangdu County,  
88 Hebei Province, China has suggested that amines exhibited outbreak characteristics  
89 during the haze episode (Feng et al., 2022). Climate and air pollution conditions can  
90 vary greatly from city to city due to the vastness of China. However, it is poorly

91 understood how the characteristics and formation processes of low-molecular-weight  
92 aminiums in PM<sub>2.5</sub> vary between clean and polluted days in different cities in China,  
93 which may hinder the further assessment of the environmental impacts of amines with  
94 regional differences.

95 In winter in China, air pollution episodes are more frequent compared to other  
96 seasons. Thus, we present the measurements of aminiums in PM<sub>2.5</sub> collected from 11  
97 different Chinese cities during the winter (2017–2018). The aims of this study are (1)  
98 to investigate the spatial differences in the compositions and concentrations of  
99 aminiums in PM<sub>2.5</sub>, with a focus on the difference between them on clean days and  
100 polluted days, and (2) to understand the key factors controlling the formation of  
101 aminiums in PM<sub>2.5</sub> in different cities.

102

## 103 **2. Materials and Methods**

### 104 **2.1. Site Description and Sample Collection**

105 A total of eleven urban sites were selected for aerosol sample collection,  
106 including Beijing (BJ; 116.41°E, 40.04°N), Taiyuan (TY; 112.58°E, 37.80°N), Xi'an  
107 (XA; 108.98°E, 34.25°N), Lanzhou (LZ; 103.73°E, 36.11°N), Haerbin (HEB, i.e.,  
108 Harbin; 126.64°E, 45.77°N), Wulumuqi (WLMQ, i.e., Urumqi; 87.75°E, 43.86°N),  
109 Chengdu (CD; 104.14°E, 30.68°N), Guiyang (GY; 106.73°E, 26.58°N), Guangzhou  
110 (GZ; 113.35°E, 23.18°N), Wuhan (WH; 114.36°E, 30.55°N), and Hangzhou (HZ;  
111 120.16°E, 30.30°N) sites (**Figure S1**). HZ and GZ are megacities situated in the  
112 Yangtze River Delta (YRD) and Pearl River Delta (PRD) regions respectively, both of

113 which have developed economies. WH is located in the central region of China. CD  
114 and GY are representative cities in southwest China. LZ, XA, TY, BJ, and HEB are  
115 cities in northern China. WLMQ, located in northwest China, is the largest inland city  
116 farthest from the ocean in the world. Obviously, the varying geographical locations  
117 and economic development levels of different cities lead to different air pollution and  
118 climate conditions between them.

119  $PM_{2.5}$  sampling in most cities was conducted on the rooftops of buildings (4–6  
120 floors in total) using a high-volume air sampler (Series 2031, Laoying, China) from  
121 December 1, 2017 to January 21, 2018 (winter). Specifically, the sampling periods in  
122 LZ, TY, HEB, BJ, XA, WLMQ, CD, WH, HZ, GZ, and GY were Dec. 2–30, 2017,  
123 Dec. 2–30, 2017, Dec. 18, 2017 – Jan. 15, 2018, Dec. 22, 2017 – Jan. 21, 2018, Dec.  
124 22, 2017 – Jan. 20, 2018, Mar. 3–28, 2018, Dec. 1 – 31, 2017, Dec. 6–29, 2017, Dec.  
125 4–31, 2017, Dec. 1–30, 2017, and Dec. 10, 2017 – Jan. 11, 2018, respectively (**Tables**  
126 **S1-S3**). At each site,  $PM_{2.5}$  was sampled once every one to two days for ~24 hours on  
127 prebaked quartz fiber filters (500 °C for 8 hours). Moreover, two random blank filters  
128 were collected. The total number of  $PM_{2.5}$  samples at each sampling site was shown in  
129 **Tables S1-S3**. All samples were stored at –30 °C. Meteorological data such as  
130 precipitation, wind speed, temperature, and relative humidity (RH), as well as  
131 concentrations of various pollutants were recorded during the sampling campaigns  
132 from the adjacent environmental monitoring stations. Sampling periods were  
133 classified as either clean or polluted days based on a daily average  $PM_{2.5}$  mass  
134 concentration of  $75 \mu\text{g m}^{-3}$  (Zhang and Cao, 2015) .

135

## 136 2.2. Chemical Analysis

137 The extraction of low-molecular-weight aminiums in the filter samples was  
138 carried out using the method described in our recent publication (Liu et al., 2023) and  
139 in a previous study (Liu et al., 2017). Briefly, the sample was filtered using a 0.22  $\mu\text{m}$   
140 Teflon syringe filter (CNW Technologies GmbH) after extraction with Milli-Q water  
141 ( $\sim 18.2 \text{ M}\Omega \text{ cm}$ ). The aminiums in the extracts that underwent pH regulation were  
142 derivatized using 0.1 mL of benzenesulfonyl chloride (BSC). The tube containing the  
143 derivatives was sealed and agitated for 30 minutes. To remove excess derivatization  
144 reagents, the extracts were agitated again for 30 minutes at  $80^\circ\text{C}$  after adding NaOH  
145 solution (0.5 mL of  $10 \text{ mol L}^{-1}$ ). Once the mixed solution had cooled down, it was  
146 acidified with a solution of HCl to adjust the pH to 5.5. A further extraction of  
147 derivatives was carried out by adding dichloromethane. It is important to mention that  
148 the organic phase was treated with  $\text{Na}_2\text{CO}_3$  solution and anhydrous  $\text{Na}_2\text{SO}_4$   
149 sequentially. A stream of nitrogen gas was used to concentrate the organic extracts.  
150 Finally, the sample was analyzed using GC-MS after adding dichloromethane and  
151 hexamethylbenzene. Dimethylaminium ( $\text{DMAH}^+$ ), monomethylaminium ( $\text{MMAH}^+$ ),  
152 diethylaminium ( $\text{DEAH}^+$ ), ethylaminium ( $\text{EAH}^+$ ), propylaminium ( $\text{PAH}^+$ ),  
153 butylaminium ( $\text{BAH}^+$ ), and pyrrolidinium ( $\text{PYRH}^+$ ) were quantified. Aminium  
154 recoveries varied between 73% for  $\text{DMAH}^+$  and 112% for  $\text{PAH}^+$ . The **detection limits**  
155 of the aminium measurements ranged from  $0.8 \text{ ng mL}^{-1}$  for  $\text{DEAH}^+$  to  $2.8 \text{ ng mL}^{-1}$  for  
156  $\text{MMAH}^+$ . Aminiums are undetectable in the blank. Detailed data quality controls were

157 described in our recent publication (Liu et al., 2023). It should be noted that we did  
158 not consider the impact of continuous aging of aminiums collected on the filter on the  
159 measurement results. This is mainly due to the following reasons. The PM<sub>2.5</sub> samples  
160 investigated in this study are all acidic (**Tables S1–S3**), promoting the protonation of  
161 amino groups. The protonated amino group is difficult to undergo oxidation by  
162 oxidants (e.g., hydroxyl radicals and ozone) (Nielsen et al., 2012).

163 Another filter cut was extracted with Milli-Q water to measure the  
164 concentrations of inorganic ions (e.g., NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, NH<sub>4</sub><sup>+</sup>, K<sup>+</sup>, Na<sup>+</sup>, Ca<sup>2+</sup>, and Mg<sup>2+</sup>) and  
165 organic acids (e.g., acetic acid, formic acid, succinic acid, oxalic acid, glutaric acid,  
166 and methanesulfonic acid) (Xu et al., 2022a; Xu et al., 2023; Liu et al., 2023; Lin et  
167 al., 2023). These inorganic ions were quantified via an ion chromatograph system  
168 (Dionex Aquion, Thermo Scientific, USA).

169

### 170 **2.3. Parameter calculation**

171 The thermodynamic model (ISORROPIA-II) was used for the prediction of the  
172 mass concentration of aerosol liquid water (ALW) and the pH value, which was  
173 detailed in our previous studies (Xu et al., 2022b; Xu et al., 2020; Xu et al., 2023).  
174 The ventilation coefficient (VC) can be used as an indicator to assess the state of  
175 atmospheric dilution of pollutant concentrations (Gani et al., 2019). It is calculated by  
176 multiplying the wind speed by the planetary boundary layer height (PBLH) (Yang et  
177 al., 2023a).

178

### 179 3. Results and discussion

#### 180 3.1. Compositions of aminiums in PM<sub>2.5</sub> in China during winter

181 **Figure 1** shows the average percentage distributions of various aminiums in  
182 PM<sub>2.5</sub> collected in different cities in China during winter, with a comparison between  
183 their mass fractions on clean and polluted days. MMAH<sup>+</sup> was the predominant species  
184 among the aminiums investigated in PM<sub>2.5</sub> in most cities in northern China, including  
185 LZ, XA, HEB, BJ, and WLMQ. MMAH<sup>+</sup> and DMAH<sup>+</sup> (as the second most abundant  
186 species) constituted over 63% of the total aminium concentrations in those northern  
187 cities. The relatively minor species, including DEAH<sup>+</sup>, EAH<sup>+</sup>, PAH<sup>+</sup>, BAH<sup>+</sup>, and  
188 PYRH<sup>+</sup>, contributed between 1% and 18% of the total aminium concentrations. The  
189 predominance of MMAH<sup>+</sup> was also found in cities in the YRD (HZ), central (WH),  
190 and southwestern (CD and GY) China, closely followed by DMAH<sup>+</sup>. Previous studies  
191 conducted in Xi'an (winter, China) (Ho et al., 2015), Beijing (winter, China) (Wang et  
192 al., 2022; Ho et al., 2016), Nanjing (winter, China) (Liu et al., 2023) Shanghai (winter,  
193 China) (Liu et al., 2023), Xiamen (winter, China) (Ho et al., 2016), Hong Kong  
194 (winter, China) (Ho et al., 2016), and Arabian Sea (autumn and winter) (Gibb et al.,  
195 1999), as well as at mountain (autumn, Nanling, China) (Liu et al., 2018) and  
196 background (winter, Pudong, China) (Liu et al., 2023) sites have suggested that the  
197 mass concentration fraction of MMAH<sup>+</sup> was highest in the measured aerosol amine  
198 salts. The Henry's constants of MMA ( $3.65 \times 10^1 \text{ mol kg}^{-1} \text{ atm}^{-1}$ ), DMA ( $3.14 \times 10^1$   
199  $\text{mol kg}^{-1} \text{ atm}^{-1}$ ), and EA ( $3.55 \times 10^1 \text{ mol kg}^{-1} \text{ atm}^{-1}$ ) are relatively lower than those of  
200 the other amines investigated (e.g.,  $1.32 \times 10^2 \text{ mol kg}^{-1} \text{ atm}^{-1}$  for DEA) (Ge et al.,

201 2011b), implying that the potential of MMA, DMA, and EA to be partitioned into  
 202 aqueous particles was weaker compared to DEA. Additionally, the gaseous forms of  
 203 these determined aminiums typically have strong alkalinity (Ge et al., 2011b). The  
 204 aerosol samples in this study were all acidic (Tables S1–S3). Thus, these results imply  
 205 that the increased emissions of MMA and DMA may partially explain the higher  
 206 abundance of MMAH<sup>+</sup> and DMAH<sup>+</sup> in PM<sub>2.5</sub> in these investigated cities during winter.  
 207

208  
 209 **Figure 1.** Average percentage distributions of various aminiums in PM<sub>2.5</sub> collected in  
 210 different cities in China during winter. The map was obtained from ©MeteoInfoMap  
 211 (version 3.3.0) (Chinese Academy of Meteorological Sciences, China).

212

213 In another northern city (i.e., TY), DEAH<sup>+</sup> was the most abundant aminium  
214 species (40% of the total aminium concentrations), followed by MMAH<sup>+</sup> (30%) and  
215 DMAH<sup>+</sup> (21%). The composition characteristic of aminiums in the city of GZ (PRD  
216 area) was similar to that observed in TY (**Figure 1**). Anthropogenic emissions,  
217 including vehicle exhaust and industrial production are considered to be the main  
218 contributors to aerosol DEAH<sup>+</sup> in urban areas (Chen et al., 2022b; Chen et al., 2019;  
219 Yang et al., 2023b; Chang et al., 2022). A recent study has suggested that ethanol  
220 gasoline vehicles can emit a large amount of ethyl-amines, leading to the outbreak of  
221 DEAH<sup>+</sup> during the haze episodes in Hebei Province (North China) (Feng et al., 2022).  
222 Thus, the relative emission strength of anthropogenic DEA in the investigated amines  
223 was probably higher in TY (an inland city with application of ethanol gasoline  
224 vehicles) than in other cities. In addition, previous studies have suggested that aerosol  
225 DEAH<sup>+</sup> can also be largely derived from marine emissions (Facchini et al., 2008;  
226 Dall'osto et al., 2019). Since GZ is a developed coastal city, local aerosol aminiums  
227 may be influenced by large gaseous DEA inputs from both local industrial production  
228 and marine sources.

229 The mass concentration fractions of aminiums on clean and polluted days were  
230 also compared (**Figure 1**). The dominant aminium species (i.e., MMAH<sup>+</sup>, DMAH<sup>+</sup>, or  
231 DEAH<sup>+</sup>) in PM<sub>2.5</sub> in all cities were not replaced by other aminiums from the clean  
232 days to the polluted days. This likely suggests that the main sources of atmospheric  
233 gas-phase amines in the cities did not change significantly on the polluted days. In

234 addition, the proportions of MMAH<sup>+</sup> and DMAH<sup>+</sup> tended to further increase from the  
235 clean days to the polluted days, while that of DEAH<sup>+</sup> with relatively low solubility  
236 showed a decreasing trend, especially in TY and GZ (where DEAH<sup>+</sup> was dominant).  
237 The concentrations of ALW in PM<sub>2.5</sub> were generally much higher on polluted days  
238 than on clean days, especially in the northern cities (Tables S1–S3). Clearly, liquid-  
239 phase processes likely played an important role in the formation of aminiums on  
240 polluted days.

241

### 242 3.2. Aminium concentrations and their linkage with PM<sub>2.5</sub> variations

243 **Figure 2** shows the average concentration distributions of various aminiums in  
244 PM<sub>2.5</sub> collected in different cities in China during winter, focusing on the difference  
245 between their concentrations on clean days and polluted days. The concentrations of  
246 total aminiums (TA) in TY ranged from 17.50 to 149.00 ng m<sup>-3</sup>, with an average of  
247  $56.90 \pm 41.81$  ng m<sup>-3</sup>. This average TA level was the highest among all the cities  
248 investigated. The average concentration of TA in WLMQ was found to be the lowest  
249 ( $4.16 \pm 1.24$  ng m<sup>-3</sup>), with a range of 2.10–6.50 ng m<sup>-3</sup>. As previously mentioned,  
250 WLMQ is a vast city with a lower population density and less developed industries  
251 compared to the more developed northern and coastal cities in China. Additionally,  
252 this region is surrounded by barren mountains and sandy land (Ma et al., 2024)  
253 (**Figure 2**). Apparently, the weak amine emission intensity appears to be responsible  
254 for the low levels of aminiums in the WLMQ.

255

256

257 **Figure 2.** Average concentration distributions of various aminiums in PM<sub>2.5</sub> collected

258 in different cities in the winter in China. The stacked bar chart from left to right

259 indicates the data for the full sampling period, the clean day, and the polluted day in

260 turn. The column chart in the bottom left corner shows the proportion of the increase

261 in TA concentration from the clean days to the polluted days. The map was obtained

262 from ©MeteoInfoMap (version 3.3.0) (Chinese Academy of Meteorological Sciences,

263 China).

264

265 **Table S4** provides an overview of the aminiums detected in atmospheric fine

266 particles detected in different seasons and regions. The ranges of average TA

267 concentrations in the northern cities (i.e., HEB, BJ, TY, XA, LZ, and WLMQ)

268 generally overlapped with those measured in the coastal (GZ and HZ), central (WH),

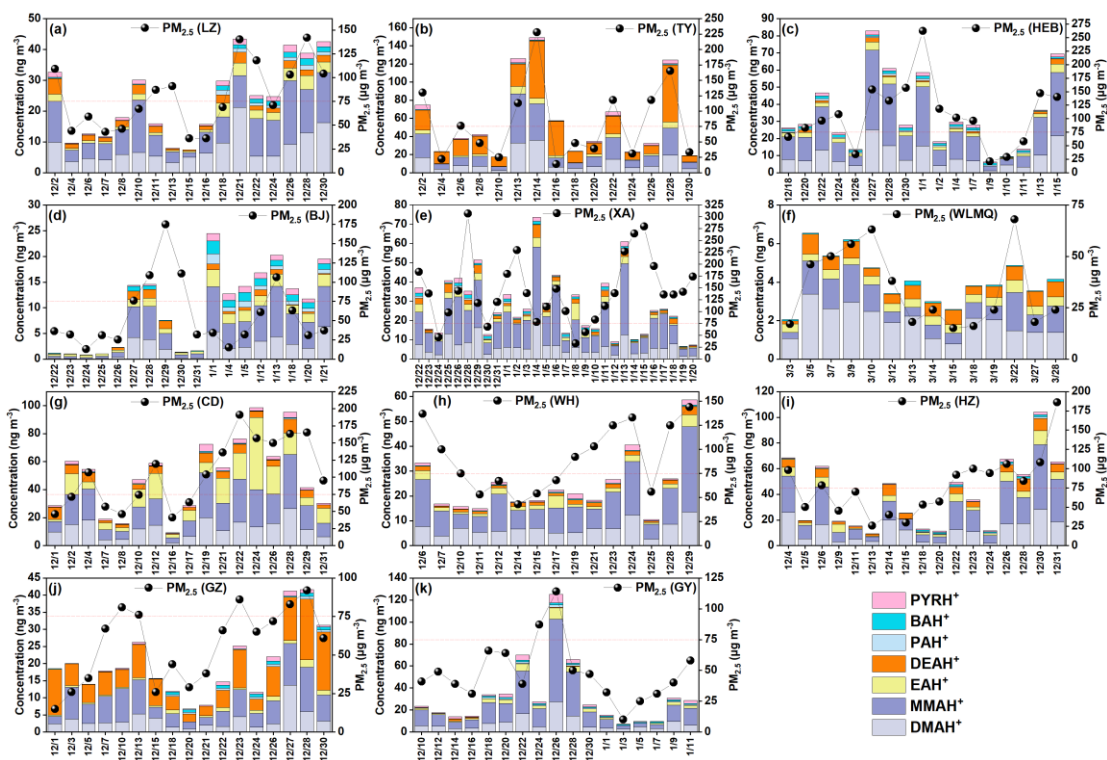

269 and southwestern (CD and GY) cities in this study (**Tables S1–S3**). Moreover, the

270 average TA concentrations investigated here (4.16 ng m<sup>-3</sup> – 56.90 ng m<sup>-3</sup>) were also

271 within the observation ranges reported in previous studies ( $1.49 \text{ ng m}^{-3} - 329.80 \text{ ng m}^{-3}$ ) (Table S4) (Ho et al., 2016; Liu et al., 2023; Shen et al., 2017; Huang et al., 2016; Choi et al., 2020; Liu et al., 2018; Shu et al., 2023). MMAH<sup>+</sup>, as the dominant aminium species in most of cities, showed the highest ( $18.33 \pm 12.82 \text{ ng m}^{-3}$ ) and lowest ( $1.07 \pm 0.55 \text{ ng m}^{-3}$ ) average concentrations in HEB and WLMQ, respectively. DEAH<sup>+</sup> was the most abundant aminium species in TY and GZ, with average concentrations of  $22.62 \pm 17.62 \text{ ng m}^{-3}$  and  $8.16 \pm 4.65 \text{ ng m}^{-3}$ , respectively (Tables S1 and S3). Two previous studies conducted in the GZ area in winter (2021 and 2015–2016) showed similar average DEAH<sup>+</sup> ( $\sim 7 \text{ ng m}^{-3}$ ) levels to this study (Liu et al., 2022b; Shu et al., 2023). However, DEAH<sup>+</sup> was not identified as the dominant aminium component in those two previous studies. Furthermore, lower aminium concentrations ( $< 8 \text{ ng m}^{-3}$ ) were generally found in most of the marine and polar regions (Dall’osto et al., 2019; Corral et al., 2022). In general, the concentration and composition of aminiums vary spatially, which may be attributed to spatial differences in amine sources, emission intensities, and the main factors affecting aminium formation.

287 The average concentrations of TA in all the investigated cities exhibited a similar variation pattern from clean to polluted days, which was characterized by higher levels on polluted days (Figure 2). Specifically, the average aminium concentration showed an increase of up to 206% in HEB during the polluted period. TA concentrations in LZ, TY, CD, HZ, and GZ also increased greatly by 91% (in GZ) –190% (in TY). It seems that PM<sub>2.5</sub> pollution can be accompanied by an outbreak of

293 aminiums. In contrast, a relatively small percentage increase in TA concentration  
294 during the polluted days was found in WH (57%), XA (50%), and BJ (25%). To  
295 further explore the linkage between changes in PM<sub>2.5</sub> and fluctuations in aminiums,  
296 the temporal variations in the mass concentrations of aminiums and PM<sub>2.5</sub> were  
297 compared across various cities (**Figure 3**). The concentrations of total and major  
298 aminiums in LZ, TY, HEB, WLMQ, CD, WH, HZ, GZ, and GY showed a temporal  
299 variation highly similar to that of PM<sub>2.5</sub>, as indicated by a significant correlation  
300 between TA and PM<sub>2.5</sub> in these cities ( $r = 0.61\text{--}0.85$ ,  $P < 0.05$ ). However, high levels  
301 of PM<sub>2.5</sub> can correspond to low levels of aminiums in XA (e.g., Dec. 29 and Jan. 2,  
302 14, 15, and 16) and BJ (e.g., Dec. 28, 30). The correlations between TA and PM<sub>2.5</sub> in  
303 these two cities were also insignificant ( $P > 0.05$ ). These results suggest that the  
304 formation of aminiums in XA and BJ during the polluted period may be constrained  
305 by some special factors, which will be **discussed** in the following discussion.

306

307 **Figure 3.** Temporal variations in the mass concentrations of aminiums and PM<sub>2.5</sub>  
 308 observed at the (a) LZ, (b) TY, (c) HEB, (d) BJ, (e) XA, (f) WLMQ, (g) CD, (h) WH,  
 309 (i) HZ, (j) GZ, and (k) GY sites.

310

### 311 3.3. Formation of aminiums and potential ammonia suppression in aminium 312 outbreaks

313 It is well documented that aminiums in PM<sub>2.5</sub> can be formed mainly via the  
 314 uptake of their gaseous form (i.e., amines) by aqueous particles, followed by acid-  
 315 base neutralization reactions (Ge et al., 2011b; Xie et al., 2018; Sauerwein and Chan,  
 316 2017; Qiu and Zhang, 2013; Liu et al., 2023). Clearly, the formation of particle-phase  
 317 aminiums was closely associated with the origins of the corresponding gas-phase  
 318 amines (as precursors of aminiums). We found that TA and major aminiums (e.g.,  
 319 MMAH<sup>+</sup>, DMAH<sup>+</sup>, and DEAH<sup>+</sup>) showed a significant positive correlation ( $P < 0.05$ )

320 with either SO<sub>2</sub>, NO<sub>2</sub>, or K<sup>+</sup> (as indicators of fuel combustion and biomass burning  
321 (Tian et al., 2020; Liu et al., 2023; Kunwar and Kawamura, 2014)) in LZ, TY, HEB,  
322 BJ, WLMQ, CD, WH, HZ, GZ, and GY (**Figure 4** and **Figure S2**). Thus, although  
323 lacking sufficient indicators (e.g., biogenic source traces) to trace the source of  
324 amines, our results can at least indicate that fossil fuel combustion or biomass burning  
325 may be important contributors to atmospheric amines in most of the investigated cities  
326 during the winter. This consideration was also supported by previous studies about the  
327 potential source analysis of aerosol aminiums in Guangzhou, Xuzhou, and Wulumuqi  
328 during the winter (Yang et al., 2023b; Shu et al., 2023; Ma et al., 2024). In contrast,  
329 the concentrations of TA in XA were weakly correlated ( $P > 0.05$ ) with those of K<sup>+</sup>,  
330 SO<sub>2</sub>, and NO<sub>2</sub>. Several studies conducted in XA have suggested that aerosol nitrogen-  
331 containing organic compounds **can be largely derived from** fossil fuel combustion and  
332 biomass burning (Zhang et al., 2023a; Zhang et al., 2023b; He et al., 2023; Yang et al.,  
333 2024). Moreover, the traditional method of identifying amine sources through  
334 correlation analysis (Berta et al., 2023; Liu et al., 2022b; Liu et al., 2022a; Huang et  
335 al., 2022; Corral et al., 2022) can also have significant uncertainties, as implied by the  
336 following two cases. First, the uptake of amines by aerosol particles might be  
337 constrained by low ALW concentration, weak particle acidity, or high ammonia levels  
338 (Liu et al., 2022b; Chen et al., 2022a; Ge et al., 2011b; Sauerwein and Chan, 2017;  
339 Chan and Chan, 2013; Wang et al., 2010). Second, amines might be largely  
340 decomposed by atmospheric oxidants (e.g., hydroxyl radical and ozone) (Nielsen et  
341 al., 2012; Qiu and Zhang, 2013). Thus, the abovementioned weak correlations

342 between aminiums and indicators in XA cannot definitely indicate that the  
 343 contributions of fossil fuel combustion and biomass burning to amines in XA were  
 344 insignificant. Presumably, the prerequisite for amine source apportionment using the  
 345 correlation between aminiums and indicators is that the gas-phase amines can be  
 346 largely converted into aminiums in PM<sub>2.5</sub> through secondary processes without the  
 347 influence of constrained factors. To further explore this issue, the following discussion  
 348 focuses on the main factors affecting the formation of aminiums in particles.

349

351 **Figure 4.** Diagrams presenting correlations between the concentrations of TA and  
 352 other parameters at (a–c) different sites. The colors of the different solid circles  
 353 indicate different correlation coefficients *r*. The size of the solid circle indicates the  
 354 significance of the correlation between the two corresponding parameters: the larger  
 355 circle indicates that the correlation is more significant, while the symbol “×” indicates  
 356 that the *P*-value is greater than 0.05.

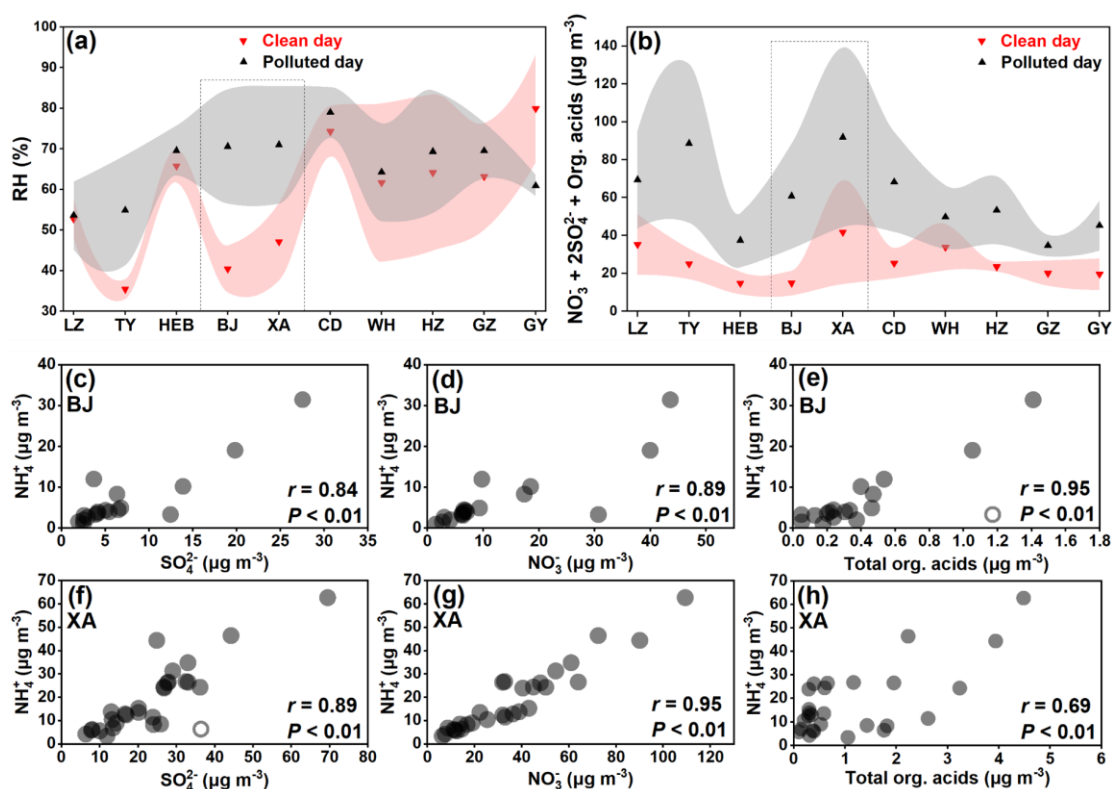

357

358 The concentrations of TA in LZ, TY, HEB, WLMQ, CD, WH, HZ, GZ, and GY  
 359 showed significant positive correlations ( $P < 0.01$ ) with those of the acidic  
 360 components (e.g., NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, organic acids, and acidity (expressed as [(NO<sub>3</sub><sup>-</sup> +  
 361 2SO<sub>4</sub><sup>2-</sup>) – NH<sub>4</sub><sup>+</sup>] (Feng et al., 2022)), whereas an insignificant correlation ( $P > 0.05$ )

362 was found between them in BJ and XA (**Figure 4** and **Figure S3**). Thus, acid-base  
363 chemistry was tightly associated with the formation of aminiums in PM<sub>2.5</sub> at all sites  
364 excepting BJ and XA. A recent laboratory study has suggested that amines can be  
365 neutralized by H<sub>3</sub>O<sup>+</sup> to form aminiums within picoseconds under conditions of high  
366 concentrations of particle sulfuric acid (Zhang et al., 2021). In addition, it has also  
367 been found that organic acids (e.g., formic acid) are able to participate in the  
368 nucleation of methanesulfonic acid–methylamine through an acid-base reaction  
369 (Zhang et al., 2022). The particles are acidic (especially on polluted days) at all study  
370 sites, with an average pH value ranging from 2.4 to 5.7 (**Tables S1–S3**). Amines can  
371 also partition into the particles by direct dissolution under high RH conditions (Ge et  
372 al., 2011b). Significantly increased RH values (i.e., high ALW) (**Figure 5a**) and acidic  
373 components (**Figure 5b**) on polluted days were also observed in XA and BJ.  
374 Nevertheless, the insignificant correlation between aminiums and acidic components  
375 and ALW concentrations in XA and BJ, together with a relatively small proportional  
376 increase in aminiums (**Figure 2**) from clean to polluted days at these two sites suggest  
377 that besides acidity and RH, there were other key factors affecting aminium formation  
378 in XA and BJ. As we know, the oxidative degradation of amines is one of the main  
379 pathways for the removal of atmospheric amines (Qiu and Zhang, 2013; Murphy et  
380 al., 2007). Furthermore, for atmospheric oxidants (e.g., hydroxyl radical) reacting  
381 with low-molecular-weight alkylamines, a negative temperature dependence of the  
382 rate coefficients has been reported (Nielsen et al., 2012). However, the winter air  
383 temperature in northern China was relatively low (< 0 °C in XA and BJ) (**Tables S1–**

384 S3); moreover, there was no significant change in the atmospheric oxidation  
 385 (indicated by  $O_x$  levels ( $O_x = O_3 + NO_2$ )) of polluted and clean days in XA (higher  $O_x$   
 386 level during clean days) and BJ. In particular, the protonated amino group has been  
 387 suggested to be difficult to undergo oxidation by hydroxyl radicals and ozone  
 388 (Nielsen et al., 2012). Accordingly, atmospheric oxidation and temperature may not  
 389 be the main factors affecting changes in aminium concentrations during clean and  
 390 polluted days. Furthermore, the insignificant correlation between aminiums and acidic  
 391 components in XA and BJ suggests that other factors affecting aminium formation  
 392 must be considered.

393

394

395 **Figure 5.** The values of (a) RH and the concentrations of (b) major acidic  
 396 components (expressed as  $NO_3^- + 2SO_4^{2-} + \text{total organic acids}$ ) on clean and polluted  
 397 days in different cities. The triangle and the shaded area represent the mean value and

398 the associated standard deviation, respectively. The correlations of  $\text{NH}_4^+$  with the  
399 concentrations of  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , and total organic acids at (c–e) BJ and (f–h) XA. Open  
400 circles represent outliers.

401

402 Furthermore, we found that the concentrations of  $\text{NH}_4^+$  were strongly ( $P < 0.01$ )  
403 correlated with those of acidic components in XA and BJ (**Figures 5c–h**). This  
404 indicates that the acidity of the particles was sufficient for the uptake of ammonia to  
405 form ammonium at these two study sites. Typically, the concentration of ammonia in  
406 the atmosphere is 1 to 3 orders of magnitude higher than that of low-molecular-weight  
407 alkylamines (Zheng et al., 2015; You et al., 2014; Yao et al., 2016; Wang et al., 2010).  
408 The uptake coefficient of alkylamines on acidic particles is lower than that of  
409 ammonia (Wang et al., 2010); moreover, Wang et al. (2010) proposed that fresh  
410  $\text{H}_2\text{SO}_4$  particles can be overwhelmingly neutralized by ammonia when both amines  
411 and ammonia are present in the air. In particular, although the strong acidic condition  
412 was conducive to the formation of aminiums, amines and ammonia may compete for  
413 uptake into acidic aerosol particles (Chen et al., 2022a). Thus, the constraint of  
414 ammonia on amine uptake at much higher ammonia levels than amine levels may be a  
415 possible explanation for the insignificant acid-dependent aminium formation in XA  
416 and BJ (**Figures 4a,b**).

417 To further explore the role of ammonia (or ammonium) in aminium formation,  
418 the average ratios of TA to  $\text{NH}_4^+$  on clean and polluted days in different cities were  
419 examined (**Figure 6a** and **Table S1–S3**). The average ratios of TA to  $\text{NH}_4^+$  were found

420 to be lower in XA and BJ, especially on the polluted days, which was similar to the  
421 characteristics of the TA/(NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>) ratios (**Figure S4**). The sensitivity analysis of  
422 the TA/NH<sub>4</sub><sup>+</sup> ratio (the lowest in XA and BJ) to NH<sub>4</sub><sup>+</sup> changes (**Figures 6b,c** and  
423 **Figure S5**) suggests that when TA/NH<sub>4</sub><sup>+</sup> > 2, the NH<sub>4</sub><sup>+</sup> concentrations in XA and BJ  
424 remained at a relatively low level (less than 6 μg m<sup>-3</sup> and 15 μg m<sup>-3</sup> in BJ and XA,  
425 respectively) with the increase of TA/NH<sub>4</sub><sup>+</sup> ratio, indicating that the formation of  
426 aminiums was not limited by ammonia at low amine and ammonium levels (in this  
427 case, TA was significantly ( $P < 0.01$ ) correlated with NH<sub>4</sub><sup>+</sup>). When TA/NH<sub>4</sub><sup>+</sup> < 2, the  
428 formation of aminiums may be constrained by higher amine and ammonium levels,  
429 which can also be supported by the insignificant ( $P > 0.05$ ) correlation between TA  
430 and NH<sub>4</sub><sup>+</sup> in this case. In contrast, the distributions of the ratios of TA to NH<sub>4</sub><sup>+</sup> in other  
431 cities were mainly in regions greater than 2 (**Figure S5**). The TA concentrations were  
432 thus significantly positively correlated with ammonium in these cities (excepting BJ  
433 and XA) (**Figure 4**). A recent study on the uptake of marine aerosol DMA by acidic  
434 aerosols has found that the concentrations of particle DMAH<sup>+</sup> generally decreased  
435 with increasing atmospheric ammonia concentrations (Chen et al., 2022a); moreover,  
436 these researchers proposed the possibility that aminiums can be displaced by  
437 ammonia in a high ammonia environment. Accordingly, high atmospheric ammonia  
438 levels can indeed constrain the conversion of amines to aminiums, even if the aerosol  
439 is acidic. In addition, due to the lower VC values (**Tables S1–S3**) on polluted days  
440 compared to clean days, the atmospheric amines were less able to diffuse on polluted  
441 days. This may result in an accumulation of aminiums on polluted days via acid-base

442 chemistry. However, a large decrease in average  $TA/NH_4^+$  and  $TA/(NH_3 + NH_4^+)$  ratios  
 443 from clean to polluted days occurred in XA ( $t$ -Test,  $P < 0.05$ ) (Figure 6a, Figure S4,  
 444 and Table S1–S3), followed by BJ. These results indicate that the uptake of amines on  
 445 acidic particles relative to that of ammonia was significantly reduced from clean to  
 446 polluted days in XA and BJ. Presumably, the aminiums/ammonium ratio was likely an  
 447 important indicator to reveal the competitive uptake of ammonia against amines on  
 448 acidic aerosols, or the displacement of aminiums by ammonia in a high ammonia  
 449 environment. Thus, this study provides a special field case that emphasizes the  
 450 potential suppression of ammonia on aminium outbreaks during the polluted days.

451

452

453 **Figure 6.** The (a) average ratio of TA to  $NH_4^+$  on clean and polluted days in different  
 454 cities. The triangle and the shaded area represent the mean value and the associated  
 455 standard deviation, respectively. Scatterplots of the mass concentration of  $NH_4^+$  with  
 456 the ratio of TA to  $NH_4^+$  at the (b) BJ and (c) XA sites.

457

#### 458 4. Conclusions and atmospheric implications

459 The concentrations, compositions, and temporal and spatial variations of  
 460 aminiums in  $PM_{2.5}$  in 11 different Chinese cities during the winter were systematically  
 461 investigated to reveal the key factors affecting the aminium outbreak during the

462 polluted days. Specifically, MMAH<sup>+</sup> was the dominant species among the aminiums  
463 investigated in PM<sub>2.5</sub> in most cities, including LZ, XA, HEB, BJ, WLMQ, HZ, WH,  
464 CD, and GY, followed by DMAH<sup>+</sup>. In contrast, DEAH<sup>+</sup> was found to be the most  
465 abundant aminium species in TY and GZ, followed by MMAH<sup>+</sup> and DMAH<sup>+</sup>. This  
466 result can be attributed to the fact that the main sources of amines in TY and GZ were  
467 significantly different from those in other cities. However, due to the lack of amine  
468 emission inventories and sufficient tracers in these investigated cities, this study did  
469 not provide a detailed analysis of the specific sources of amines in these investigated  
470 cities.

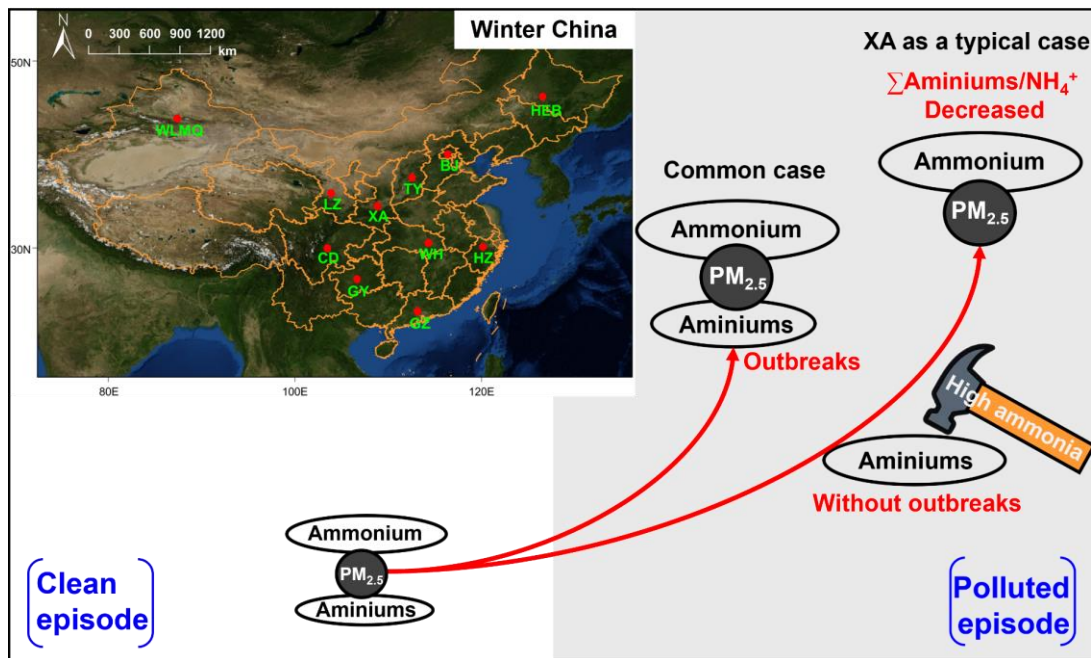

471 We found that the concentrations of TA and major aminiums in all cities showed  
472 a similar pattern of variation from the clean days to the polluted days, which was  
473 characterized by higher levels on the polluted days. However, the lowest percentage  
474 increase in TA concentration during the polluted days was found in XA (50%) and BJ  
475 (25%). Moreover, the concentrations of TA in XA and BJ were insignificantly ( $P >$   
476 0.05) correlated with those of PM<sub>2.5</sub> and the main acidic components in PM<sub>2.5</sub>.  
477 However, the significant correlations of TA with PM<sub>2.5</sub> and the main acidic  
478 components were observed in other cities. Thus, acid-base chemistry was strongly  
479 associated with the formation of aminiums in PM<sub>2.5</sub> in all cities with the exception of  
480 XA and BJ. The concentrations of NH<sub>4</sub><sup>+</sup> were significantly ( $P < 0.01$ ) correlated with  
481 those of the acidic components in XA and BJ, indicating that the acidity of the  
482 particles was sufficient for the uptake of ammonia to form ammonium at these two  
483 sites. Further, based on the sensitivity analysis of the TA/NH<sub>4</sub><sup>+</sup> ratio (the lowest in XA

484 and BJ) to  $\text{NH}_4^+$  changes as well as excluding the effects of ALW and atmospheric  
485 oxidation, we proposed a possibility about the competitive uptake of ammonia against  
486 amines on acidic aerosols in the ambient atmosphere in XA and BJ. This  
487 consideration may explain the insignificant acid-dependent aminium formation in XA  
488 and BJ. The main finding of this study has been illustrated in a diagram (**Figure 7**).

489 In general, this study has preliminarily explored the characteristics of aminiums,  
490 ammonium, and  $\text{PM}_{2.5}$  from the clean days to the polluted days according to the  
491 observational data from 11 different Chinese cities, highlighting the possibility of the  
492 competitive uptake of ammonia versus amines on acidic aerosols, or the displacement  
493 of aminiums by ammonia under a high ammonia condition. **Although a recent study**  
494 **has also demonstrated the possibility of individual aminium being displaced by**  
495 **ammonia in an environment of high ammonia level** (Chen et al., 2022a), **the uptake of**  
496 **amines on particles to form aminiums and the impact mechanisms of relevant**  
497 **influencing factors are still not fully understood.** This is because acidity,  
498 environmental ammonia and amine content, temperature, and liquid-phase reactions  
499 all affect the uptake of amines, although acid-base neutralization of amines seems to  
500 be the most important pathway for amine uptake. Furthermore, if the uptake of amines  
501 is significantly constrained by the aforementioned factors, the traditional source  
502 apportionment methods using correlation analysis between particle aminiums and  
503 tracers will have significant uncertainty due to the weakened partitioning of the  
504 amines into the particle phase (i.e., causing insignificant correlations between  
505 aminiums and indicators). Further laboratory validation experiments are required to

506 substantiate this inference. In addition, it is essential to conduct prolonged  
 507 observational research in settings with elevated ammonia levels and depleted amine  
 508 concentrations in the near future.  
 509

510
