10 **Abstract.** Multirotor drones (also known as small Uncrewed Aerial Systems [sUAS] or small Uncrewed Aerial Vehicles [sUAV]) are being increasingly used in atmospheric research to make measurements of the lower atmosphere, and their use is poised to increase in the future. New opportunities are now emerging for drone atmospheric sensing around smaller instrument footprints and lower sensor weights, such as ride-along applications and drone swarms, which necessitate characterizing the performance of unshielded sensors mounted to drones. In this work, we characterize the accuracy of thermodynamic
15 measurements, specifically temperature and water vapor mixing ratio, based on the sensor position onboard multirotor drones. To assess the influence of the drone mechanics on the measurements, ninety-eight drone flights with eight distinct thermodynamic sensor positions were performed next to an instrumented flux tower and a tethersonde carrying identical sensors, where the tower and tethersonde measurements are assumed as truth. The flights were at least nine minutes in length, and nine of the flights were conducted at night. At the best position, absolute daytime temperature errors were between -0.83K
20 and +0.61K at the 95% confidence interval, while nighttime temperature errors were smaller, ranging from -0.28 K and +0.48 K. Water vapor mixing ratio errors are within -0.22 g kg⁻¹ and +0.66 g kg⁻¹. We conclude that measurements in field campaigns are more accurate when sensors are placed away from the main body of the drone and are sufficiently aspirated, such as a position near, but not directly under, a spinning propeller.

1 Introduction

25 Small drones (hereafter referred to as drones; also known as small Uncrewed Aerial Systems [sUAS or UAS], small Uncrewed Aerial Vehicles [sUAV or UAV], or small Uncrewed Aircraft [sUA or UA]) have been used for atmospheric science research since 1956 (Vorontsov et al. 1958; Humphrey 1961). Until the 2010s, the drones utilized were exclusively fixed-wing drones (e.g., Schafer et al. 2001; Houston et al. 2011; Elston et al. 2014; Riganti and Houston 2017). Since then, multirotor drones have been introduced into atmospheric science research and have increased in popularity (e.g., Brady et al. 2016; Lee et al.
30 2017; Geerts et al. 2017, 2018; Vömel et al. 2018; van den Heever et al. 2021; Meier et al. 2022). The enhanced popularity of

multirotor drones is due in part to their ability to take off and land vertically, rapid maneuverability, hovering capability, low cost, and relative ease of piloting.

A wide body of research has investigated the accuracy of measurements made on fixed-wing drones (e.g., Spiess et al. 2007; Houston et al. 2016), on sensor housings for multirotor drones (Barbieri et al. 2019; Greene et al. 2019; Islam et al. 2019; de Boer et al 2024), and on purpose-built multirotor drones (Bell et al. 2020; Segales et al. 2020; Hervo et al. 2023). However, relatively less work has examined the accuracy of thermodynamic measurements made from commercial, off-the-shelf multirotor drones without additional housing. While many deployments of drones for atmospheric science research have used housings for their thermodynamic probes (e.g., Greene et al. 2019; Bell et al. 2020; Segales et al. 2020; Hervo et al. 2023; de Boer et al. 2024), others have relied on the shielding or aspiration provided by the drone and atmosphere (Bailey et al. 2020; Tikhomirov et al. 2021; van den Heever et al. 2021; Quesada-Moreno et al. 2024). Furthermore, some future applications of drones in atmospheric science may not be conducive to the additional weight and volume added by sensor shielding. These deployment opportunities are increasing, including “ride-along” deployments, where a sensor is added to an existing drone platform used for another purpose, such as package delivery, and in drone swarm operations which can use mini and micro
45 drones.

Little prior work has focused on the accuracy of thermodynamic measurements from drones that are without purpose-built ducts or housings. Several previous studies (Greene et al. 2018; Inoue et al. 2022) have examined sensor placements immediately below the spinning propellers, finding that placements close to the propeller tip tend to produce results with the
50 least amount of bias. Kimball et al. (2020a) examined the accuracy of unshielded thermodynamic sensors in various positions on a small (55 cm across) quadrotor drone platform, finding relatively small (<0.5 K) differences in the accuracy of temperature measurements between positions on the drone when compared to a shielded temperature sensor on a mesonet tower. Their analysis found a sensitivity in temperature measurements from exhaust vents on their platform, resulting in warm biases in sensors positioned within the exhaust path. Kimball et al., along with other previous work quantifying the characteristics of
55 drone-based thermodynamic measurements, primarily focus on absolute temperature measurements. While this is clearly an important measurement, drones have also been used to measure temporal changes in thermodynamics, characteristic of thunderstorm outflow boundaries and frontal boundaries (van den Heever et al. 2021). Quantifying the properties of thermodynamic gradient measurements is therefore necessary to enhance confidence in these drone-based measurements.

60 These previous studies have provided important steps toward understanding the errors induced by measuring thermodynamic variables onboard multirotor drones. However, the accuracy of thermodynamic measurements made from multiple sensor positions aboard a multirotor while in flight, during both day and night, has not yet been investigated. In the present study, we compare drone-based temperature and water vapor mixing ratio measurements from eight different sensor positions to measurements made on a tethered sonde and a flux tower located sufficiently far from the direct influence of the drone’s

65 propellers. These comparisons are conducted in a variety of meteorological and solar radiation conditions. Our goal is to
analyze the errors in the measurements of each of these fundamental atmospheric variables induced by the multirotor platform
itself. Further, by investigating these errors, we aim to provide field campaigns with a characterization of drone-based
temperature and water vapor mixing ratio measurements, both for absolute measurements and those conducted across time.
Finally, we include recommendations for sensor placement for future field campaigns that employ multirotor drones that are
70 incapable of carrying separate shielding.

2 Methodology

To assess the accuracy of thermodynamic measurements made from multirotor drones, a comprehensive experiment suite was
designed using a hexacopter drone (a multirotor with six rotors) The suite consisted of two parts. The first was conducted from
October 2018 to January 2019 adjacent to an instrumented tethered balloon (hereafter tethersonde) and the second from June
75 to July 2022 next to an instrumented flux tower. In total, 98 outdoor flights were conducted, 9 of which were flown at night,
producing approximately 15 hours of total sampling time, with 82 flights (12.5 hours) being tethersonde tests and 16 flights (3
hours) being flux tower tests.

2.1 Drone and Sensor Setup

The DJI Matrice 600 Pro (SZ DJI Technology Co., Ltd., Shenzhen, China) hexacopter was employed in these experiments.
80 The Matrice 600 Pro, pictured in Figures 1a and 1b, has been used in atmospheric science field campaigns and published
literature (e.g., Islam et al. 2019; van den Heever et al. 2021). The Matrice 600 Pro is powered by six batteries positioned at
the center of the drone platform, which is also the location of the avionics and flight computers. Six arms extend radially from
the center. Each arm contains an independently spinning motor and an attached 53 cm propeller. The drone dimensions are
1.668 m x 1.518 m x 0.727 m when in takeoff and landing configuration. After takeoff, the drone switches to cruise
85 configuration and its landing legs fold upwards to the sides, reducing the height of the drone (Figure 1a). The legs remain
retracted until the drone is configured for landing.

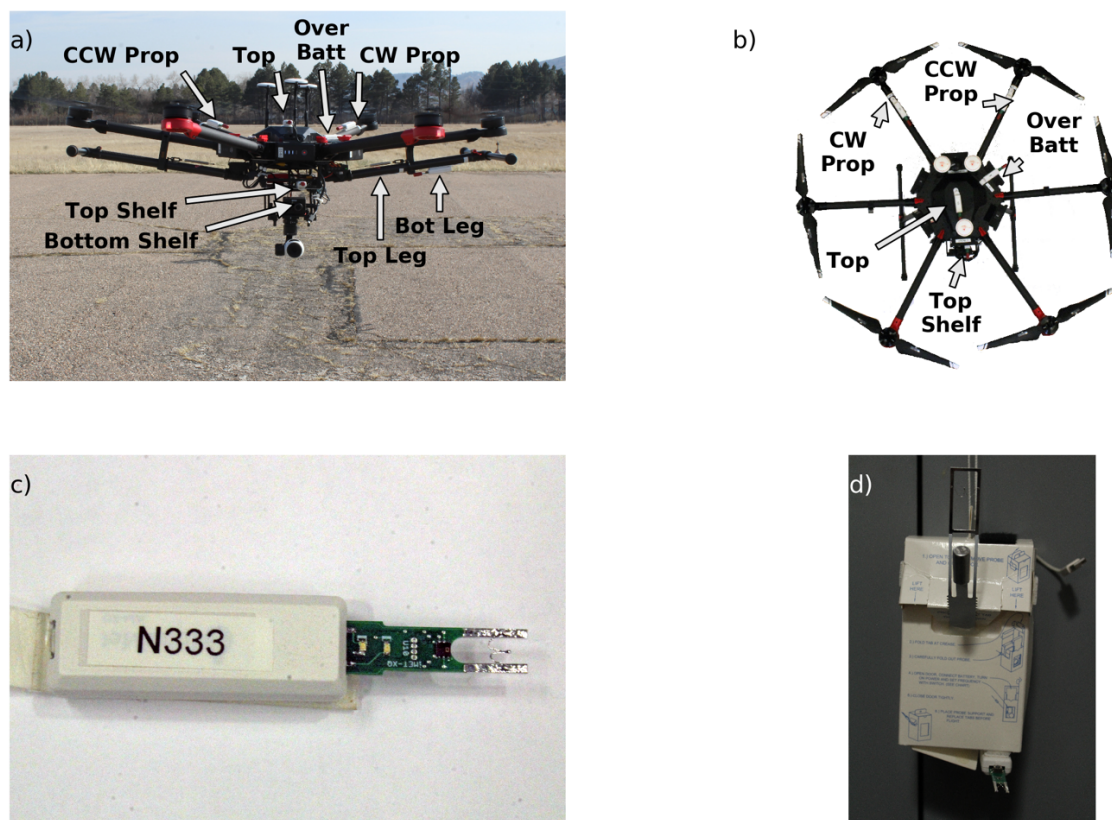

Figure 1: (a) Front-view picture of the DJI Matrice 600 Pro drone in-flight with the legs folded up. The 8 sensor positions are labeled. (b) Top-down photo of the drone with the legs down; the position of all visible sensors are labeled. (c) Photograph of an iMet XQ sensor. (d) Photograph of the iMet-1 radiosonde with an iMet XQ sensor attached to the bottom.

90

The International Met Systems iMet XQ (Grand Rapids, MI, USA) sensor was used to make the thermodynamic measurements for this study. This particular sensor (Figure 1c) has been used previously to make thermodynamic measurements from multicopter drones (e.g., Hemingway et al. 2017; Themistocleous 2017; Dexheimer et al. 2018; Lee et al. 2019; Kimball 2020a; Kimball 2020b; van den Heever et al. 2021). The iMet XQ measures pressure, temperature, and relative humidity (RH) at 1 Hz. The specifications and sensor technologies of the temperature, RH, and pressure measurements are detailed in Table 1. The RH measurements were converted to water vapor mixing ratio using the temperature recorded at the RH sensor and the pressure measured by the iMet XQ for this study. Although analyzing the data using the original RH measurements does not qualitatively change the results (not shown), the conversion was performed to minimize potential impacts of temperature biases on the RH sensors. This is because RH depends not only on accurate temperature measurements but also on the assumption that the temperatures of the drone and the comparison sensor are the same—an assumption we investigate in this study. Nine of the 12 sensors employed in these tests saved the temperature of the RH sensor in addition to the other three variables, while

100

three of the older sensors did not report the RH sensor’s temperature and are therefore excluded from the analysis of RH. None of the sensors used in these experiments have a shield covering the temperature or RH sensor, although the temperature sensor’s reflective coating helps mitigate radiation error during daytime flights.

Table 1: Specifications of the iMet XQ sensor as reported by International Met Systems (International Met Systems 2018).

Variable	Technology	iMet Reported Accuracy	iMet Reported Resolution	iMet Reported Response Time
Temperature	Glass Bead Thermistor	± 0.3 K	0.01 K	2 s
Relative Humidity	Capacitive	$\pm 5\%$	0.7%	5 s with 1 m s^{-1} flow
Pressure	Digital Piezoelectric	± 1.5 hPa	0.02 hPa	<1 s

To examine the impacts of different sensor placements on thermodynamic measurements, eight different sensor sites onboard the drone were chosen for these experiments. The sensor sites are shown in Figures 1a and 1b. These eight sensor sites represent what we believe are the most common and/or logical locations for sensors onboard multirotor drones, and several are similar to those tested in previous studies (Greene et al. 2018; Kimball et al. 2020a). Two of the positions, *CWProp* and *CCWProp* (CW for a ClockWise-rotating propeller and CCW for a CounterClockWise-rotating propeller) are approximately 2 cm underneath the propellers and 5.5 cm inside the tip of the propeller when the propeller and arm are parallel. This distance is located away from the propeller tip by approximately 1/3 of the length of the propeller (8.8 cm on this platform), as recommended by Greene et al. (2018), and will be expected to get the most forced aspiration. The *Top* and *OverBatt* positions are situated on top of the drone and receive some aspiration from the drone airflow. *Top* is located at the highest point atop the avionics bay but below the three upward pointing GPS antennae, and the *OverBatt* position is located on top of a battery bay with the temperature sensor extended away from the central portion of the drone by approximately 2 cm. A similar placement to the *OverBatt* position was also used by Lee et al. (2019). One of the landing legs of the aircraft contain two positions, *TopLeg* and *BotLeg*, which are approximately 8 cm below one of the drone arms when in cruise configuration (Figure 1a). As *BotLeg* is directly below a propeller, it receives a high amount of forced aspiration from the propeller, while *TopLeg* receives relatively less forced aspiration as it is further from the propeller. The *TopShelf* and *BotShelf* positions are on platforms

125 mounted below the main electronics bay by approximately 7 and 15 cm, respectively, and receive relatively little drone-based aspiration.

2.2 Experiment Methodology: Tethersonde Tests

In the first part of this experiment, we flew the drone adjacent to a tethersonde during both day and night. All night flights were conducted after nautical twilight, and the measured insolation at the surface weather station was 0.0 W m^{-2} . The tethersonde was anchored in dead scrubland at the now-retired Christman Field Airport (hereafter Christman Field) in Fort
130 Collins, CO. The anchor point of the tethersonde was at least 50 m from roads, fences, and other objects that could inadvertently influence the observations. The tethersonde was initially raised to a height of at least 50 m above the surface during the day and 30 m at night using a rope, but it was then allowed to change its horizontal and vertical position through advection. The altitude for the tethersonde was chosen to be high enough to be above the surface layer but low enough to reduce the required drone battery power to climb and maneuver, thereby allowing longer sampling time on a single battery set.

135 After takeoff, the drone was flown directly upwards until the altitudes of both the tethersonde and the drone were within a few meters of each other. Despite this initial check, the tethersonde was on average 9.13 m higher than the drone for the 82 tethersonde flights (9.71 m during the day flights and 4.2 m for the night flights). This mean altitude bias does not substantially affect the thermodynamic errors measured. When comparing only the data when the drone was higher than the tethersonde,
140 the thermodynamic measurement errors are similar (not shown). While the tethersonde's horizontal position and altitude were allowed to vary in flight with the changing winds, the drone's position was fixed in space for each of the 82 flights using the drone's autopilot function.

The tethersonde instrumentation was mounted approximately 50 cm below the base of the balloon. This instrumentation
145 consisted of an International Met Systems iMet-1 radiosonde with an iMet XQ sensor of the same type as that onboard the drone (Figure 1d). Although both the iMet-1 radiosonde and iMet XQ record GPS and thermodynamic variables, the GPS from the iMet-1 radiosonde is used as the tethersonde's location value because the iMet XQ's GPS antenna was directed at the surface, causing degraded accuracy. On the other hand, the iMet XQ is used for the thermodynamic measurements to remove any error that may potentially be caused by differences in instrument technology between the iMet XQ and the iMet-1
150 radiosonde. The tethersonde was launched at the beginning of each flight day and allowed to remain airborne for the entire duration of the flights held on any one day. The tethersonde was, however, occasionally raised or lowered in order to avoid interference with crewed aircraft traffic or to change the attached iMet XQ sensor halfway through the flight day as part of the iMet XQ drone sensor rotations (see below). It should be noted that, similar to the sensors aboard the drone, the iMet XQ aboard the tethersonde was not shielded. While this means that the tethersonde may also have errors in the temperature
155 measurement arising from solar radiation, these should be similar to those on the drone. Further, the tests described in the next

section, which include shielded, aspirated sensors and nine night flights with the tethersonde, help to separate out this potential source of uncertainty.

Every flight had at least nine consecutive minutes of sampling time, not including the additional flight time necessary for
160 takeoff, transit, and landing. After each flight, the sensors attached to each of the positions on the drone were sequentially
rotated to a different position. The sensor rotation was performed to remove any potential bias caused by a specific sensor-
position combination. While the sensors aboard the drone were rotated after each flight, the sensor aboard the tethersonde was
only changed either between flight days or halfway through the flights on a given day. The sensor onboard the tethersonde
each day was drawn from the set of sensors used in the drone rotations and was rotated between the tethersonde and the drone
165 between flight days.

2.3 Experiment Methodology: Flux Tower Tests

The second part of the experiment was to conduct additional flights in June and July 2022 at the National Ecological
Observatory Network (NEON) North Sterling, CO site (Metzger et al. 2019; NEON 2024a,b,c,d,e). The tests at this site were
conducted at the same altitude (10 m AGL) and 5 meters downwind of the flux tower. At this location, the temperature
170 measurements were compared against both an unshielded, unaspirated iMet XQ sensor mounted to the flux tower (not shown),
and to the triple aspirated, one-minute-averaged air temperature (NEON 2024a) and humidity measurements (NEON 2024b)
taken at the *Top* of the flux tower. Because of the delay between these flights and the Tethersonde tests caused by impacts
from the COVID-19 pandemic, several of the iMet XQ sensors employed in the tethersonde tests were replaced by updated
iMet XQ2 sensors, which use the same temperature sensor as the iMet XQ. However, because the RH sensor changed between
175 the two versions of the instrument, only the RH results from the tethersonde study are examined here. Further, because the
XQ2 sensors were physically larger than the XQ sensors, only five of the eight positions tested in the tethersonde experiments
are used for the flux tower tests (*BotLeg*, *CWProp*, *OverBatt*, *TopLeg*, *TopShelf*). The NEON flux tower measurements are
quality controlled, maintained, and, for temperature, made up of three independent platinum temperature sensors forcefully
aspirated by a fan (NEON 2024a). However, these measurements are only available at a lower, one-minute resolution compared
180 with the 1 Hz resolution on the drone. Therefore, we use these measurements primarily to validate the tethersonde temperature
measurements, ensuring that the tethersonde flights yield robust results when compared to gold-standard, forcefully aspirated
temperature measurements. Like the tethersonde flights, the flux tower flights lasted at least nine minutes. However, unlike
the tethersonde flights, the sensors on the flux tower validation flights were not rotated between each flight but only daily.

2.4 Sampling Conditions

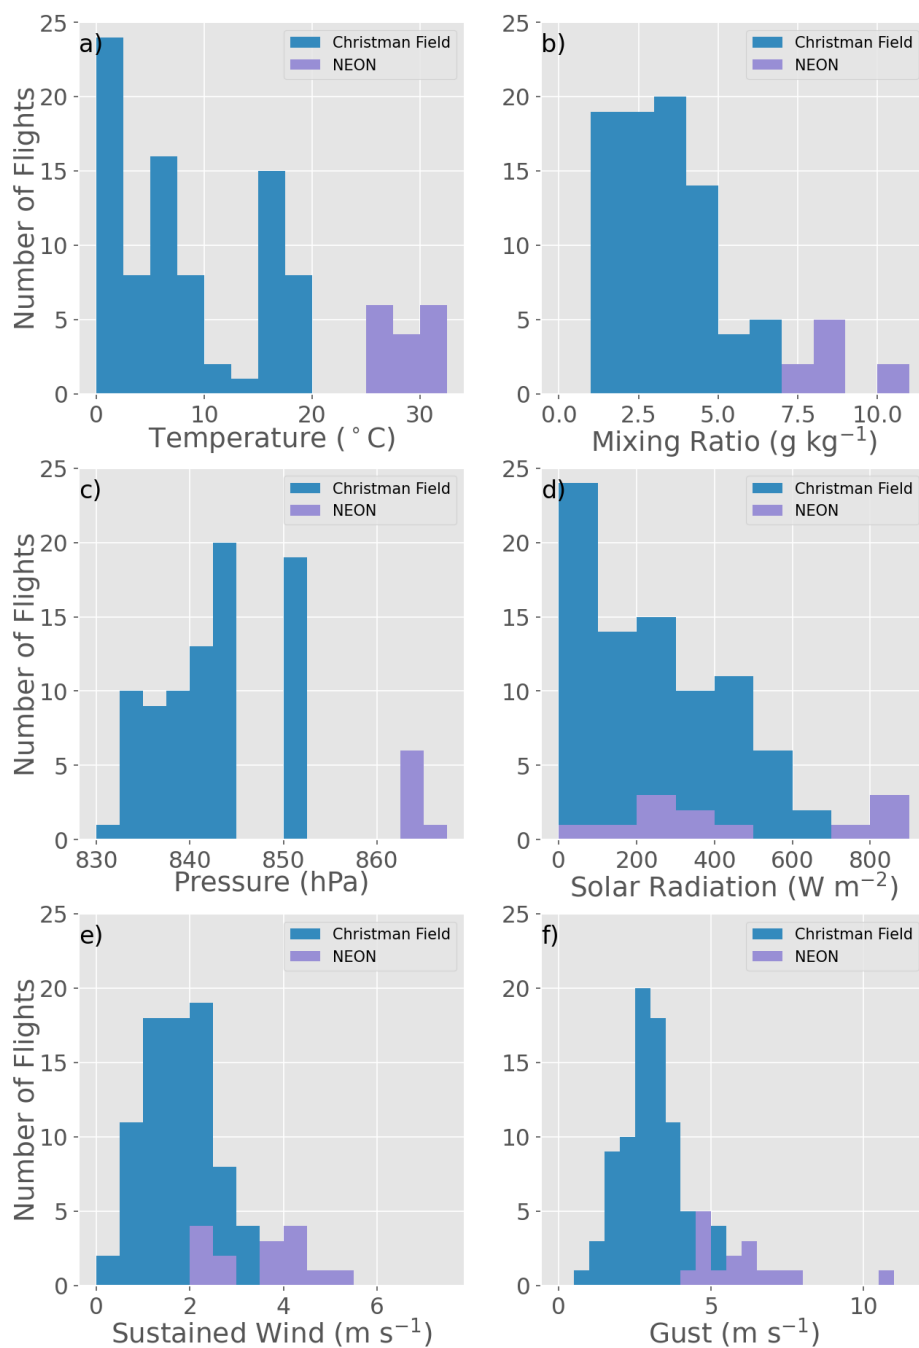

185 The 82 tethersonde and 16 flux tower flights were conducted in a variety of non-precipitating meteorological conditions
sampled by the co-located Christman Field weather station (tethersonde station) and the NEON flux tower instrumentation
(flux tower). The range of observed pressure (Figure 2c) is limited to between 830 and 855 hPa at the Christman Field site and

860 and 870 hPa at the NEON site due to the differences in the site's elevations (1573 m above mean sea level at Christman Field; 1365 m above mean sea level at the NEON site). Like the pressure, the water vapor mixing ratio conditions observed (Figure 2b) are also bounded by the dry climate in Colorado. The experiments were performed primarily in low wind conditions, particularly with the tethered flights at Christman Field, as is evident from the distribution of sustained wind (Figure 2e) and gusts (Figure 2f). Low wind conditions were necessary to limit the motion of the tethered drone, and thus limit its altitude variability with respect to the drone. The wide range of temperature, water vapor mixing ratio, and solar radiation (Figure 2d) conditions tested in this study significantly extend all of the previous studies described in Section 1.

Average Weather during Flights

195

Figure 2: Histograms of conditions, averaged over the duration of each flight, observed by the weather stations during all flights from Christman Field (blue) and the NEON Flux Tower (purple; NEON 2024a,b,c,d,e). Shown are surface (a) temperature, (b) mixing ratio, (c) pressure, (d) solar radiation, (e) sustained wind speed, and (f) wind gust.

2.5 Data Quality Control

200 Several steps were taken to quality control both the tethersonde and drone thermodynamic data. Only those measurements for which the drone's measured altitude is within 30 m (50 m) in the vertical (horizontal) of the tethersonde's measured altitude were used in order to enhance the likelihood that the tethersonde and drone measured air with similar thermodynamic properties. The 30 m vertical threshold was chosen because the nominal accuracy of the GPS aboard the iMet-1 radiosonde is ± 15 m. The 50 m horizontal threshold was selected as a compromise between the two instruments being as far apart as possible while measuring as close to the same air as possible, as the length scale of boundary layer eddies is proportional to the height above the surface (Arya 2001). Because these two are proportional, rather than equal, this may result in these two instruments potentially measuring different eddies, and therefore actual differences in temperature. It is assumed, however, that any difference due to potentially measuring different eddies is small and mitigated by the large number of samples. As the flux tower is a non-moving platform and lower in altitude than the tethersonde, the flux tower results use a quality control threshold of 3 m in the vertical and 10 m in the horizontal. The results of this study are not sensitive to the specific distance thresholds (not shown). In addition to removing data points where the drone and tethersonde were too far apart, data points were also removed if any sensor recorded invalid data. No averaging was performed on the data except as described in Section 3d.

For both temperature and mixing ratio, we examined the differences at each time between the measurements taken aboard the drone and the measurements taken aboard the tethersonde or flux tower. We define this difference as the error. The error is comprised of three potential sources: instrument error, drone-induced error, and radiative error. The instrument error is defined as any error caused by fluctuations in the instrument itself other than the calibration biases that have already been corrected. The drone-induced error is any error directly associated with the drone that would not exist if the instrument was mounted to the tethersonde or flux tower. Possible sources of drone-induced error include heat dissipated by the drone motors, avionics, and batteries, and airflow perturbations (i.e., rotorwash) induced by the rapidly spinning rotors which mix the air. The radiative error component is defined as any error resulting from the effects of solar radiation, including heating of the sensor itself by the sun, heating of the surface of the drone below the sensor, or any other error that does not exist at night.

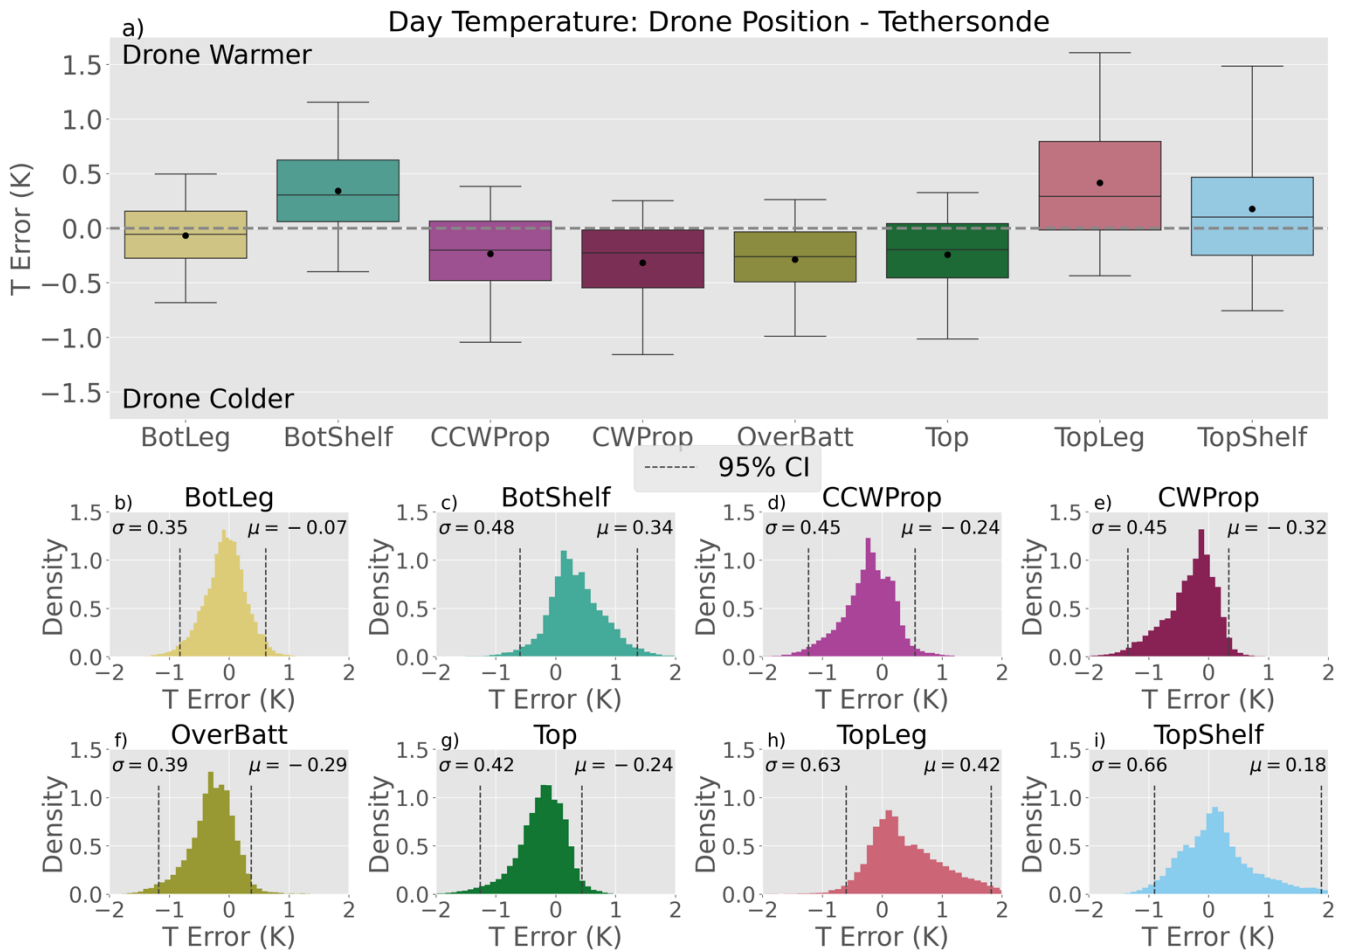

3 Results

3.1 Daytime Temperature

225 We separate our discussions of temperature into daytime and nighttime, and we begin by examining the daytime results. The temperature error, defined as the temperature measured by the tethersonde or flux tower subtracted from the temperature measured by the drone at each time, was calculated separately for each sensor position (i.e., $T_{drone, sensor\ location} - T_{tethersonde}$ or $T_{drone, sensor\ location} - T_{flux\ tower}$; where T is the temperature in K). The temperature error for each sensor location on the drone is shown in Figure 3 for the 73 daytime tethersonde flights (a total of approximately 40,000 individual temperature

230 observations for each sensor position). The mean errors between the drone and tethersonde are less than ± 0.42 K for all eight
 235 siting locations tested, although the spread between the 2.5th and 97.5th percentiles reaches 2.79 K, with the largest spread
 being $-0.91 \text{ K} \leq T \leq +1.88 \text{ K}$ for *TopShelf* (Figure 3). The *BotLeg* position, which is approximately 8 cm below the propeller
 and is shielded from the direct downward air forced from the propeller by the leg it is mounted on, has the smallest magnitude
 mean error (-0.07 K). This is in contrast to *TopLeg*, which has the largest magnitude mean error ($+0.42$ K) despite being located
 only ~ 10 cm horizontally from the *BotLeg* position.

240 **Figure 3:** (a) Box plots of the drone sensor temperature minus the tethersonde sensor temperature, i.e. the “errors” (positive values indicate that the drone is warmer than the tethersonde), for all daytime flights. The box outlines denote the 25th, 50th, and 75th percentiles, whiskers extend to the 5th and 95th percentiles, and the dots indicate the distribution means. (b-i) Density histograms of the daytime flight temperature errors for each individual drone sensor as labeled on each panel. The 2.5th and 97.5th percentiles are marked with dashed vertical black lines to indicate the 95% confidence interval. The error standard deviation (σ) and mean error (μ) are labeled at the top of each panel.

One can categorize the eight sensors shown in Figure 3a into two main groups: those sensors that have a cold mean bias and lower error standard deviations (*BotLeg*, *CCWProp*, *CWProp*, *OverBatt*, *Top*), and those positions that have a warm mean bias and higher error standard deviations (*BotShelf*, *TopLeg*, *TopShelf*). These differences can also be seen in Figure 3b-i, which show histograms of the errors for each of the eight sensor positions. The three sensor positions with the warm mean bias and higher errors (Figure 3c, h, and i) can be characterized as non-normal distributions that are skewed towards warmer temperatures relative to the tethersonde data. Most of the remaining positions (Figure 3d-g) are similarly non-normal, but have smaller error standard deviations and negative tails, indicating a large cold bias relative to the tethersonde.

To validate the tethersonde measurements, we examine the change in temperature errors in several of the positions between the tethersonde experiments and the flux tower experiments (Table 2), since the flux tower instrumentation is aspirated, quality controlled, and frequently calibrated (NEON 2024a). In each position except for *TopLeg*, the mean bias of the drone sensor compared to the control sensor is warmer in the flux tower experiments than the tethersonde experiments. However, the change in bias is within the accuracy range ($\pm 0.3\text{K}$ for one sensor; a maximum of $\pm 0.6\text{K}$ for a sensor pair) specified by the iMet XQ and XQ2 documentation (Table 1). Further, the standard deviations between each pair of experiments are quite similar, each being within 0.15K of its pair. This indicates that the error between the drone measurements and the shielded, aspirated flux tower are largely comparable to the error between the drone measurements and the unshielded, un-aspirated (other than natural aspiration from wind) tethersonde. Given the similarities between the experiments, we will focus on the larger dataset of tethersonde observations for the remainder of the manuscript.

Table 2: Comparisons between the Tethersonde daytime tests and NEON Flux Tower Tests for temperature. T represents the difference between drone temperature measured per position from the control sensor. $\sigma(T)$ represents the standard deviation of this value.

Position	Mean T, NEON	$\sigma(T)$, NEON	Mean T, Tethersonde	$\sigma(T)$, Tethersonde
<i>BotLeg</i>	0.11 K	0.47 K	-0.07 K	0.35 K
<i>CWProp</i>	0.16 K	0.45 K	-0.32 K	0.45 K
<i>OverBatt</i>	0.29 K	0.54 K	-0.29 K	0.39 K

<i>TopLeg</i>	0.30 K	0.59 K	0.42 K	0.63 K
<i>TopShelf</i>	0.52 K	0.59 K	0.18 K	0.66 K

We now assess the three components of error (instrument, drone, and radiation) to understand the causes of the mean temperature errors. The substantial sampling time during daytime (11 hours; ~200,000 data points total), and the fact that random instrument errors are typically symmetric around zero after being corrected for any mean bias, suggests that the random instrument errors are largely mitigated and thus play a trivial role in the mean thermodynamic errors. Therefore, the mean observation errors are primarily caused by drone-induced errors, radiative errors, or both.

To better characterize the radiative error present during the daytime flights, the flights are stratified by the average solar radiation that is observed at the surface weather station (Figure 4). Each of the solar radiation bins shown in Figure 4 contains observations obtained from between eight and ten flights. With increasing insolation, the median bias generally becomes colder for those sensors receiving a larger amount of aspiration (*BotLeg*, *CCWProp*, *CWProp*, *OverBatt*, *Top*). For those sensors receiving less aspiration (*BotShelf*, *TopLeg*, *TopShelf*), the mean bias typically becomes warmer with more insolation (*BotShelf*, *TopLeg*) and/or the error bars become substantially larger (*TopLeg*, *TopShelf*). The reason for these opposite trends appears to be twofold: (1) the reflective coating onboard the iMet sensors is likely inadequate to reflect all of the incoming solar energy; and (2) since the tether sonde does not receive forced aspiration unlike the drone which is aspirated by the propellers, the temperature measured on the tether sonde might be biased warm relative to the true environmental temperature, thus leading to a perceived cold bias on the drone for the five positions receiving more aspiration. This hypothesis is supported by the flux tower experiments, in which all unshielded positions on the drone that were tested were warmer than the shielded, aspirated flux tower sensor. Figure 4 further shows that the spread of the error generally increases with increasing solar radiation for all sensor positions. This suggests that simply placing sensors underneath propellers may not be sufficient to counteract the solar radiative error. Rather, Figure 4 suggests that efforts to properly shield sensors could be worthwhile. However, such shields can block ambient airflow, including airflow produced by the drone, thereby reducing sensor aspiration and inducing a lag to the sensor measurements. Such effects should therefore be taken into consideration when designing sensor shields. The impacts of radiative error on the mean thermodynamic errors and how we can separate this source of error from drone-induced error are further examined in Section 3b.

Figure 4: As in Figure 3a, except that for each sensor position, the tetheronde data is stratified by solar radiation, E ($W m^{-2}$), observed by the surface weather station.

295 The temperature results demonstrate for the worst-case scenario for any single temperature measurement made during the daytime that the accuracy at a 95% confidence interval (hereafter CI) has a range of $-1.34 K \leq T \leq +1.88 K$ when not removing the mean biases (Figure 3b-i). The sensor position with the narrowest CI is *BotLeg*, which had a 95% CI of $-0.75 K \leq T \leq +0.65 K$. While we examined absolute temperature measurements in this section, Section 3d contains an analysis of the errors when measurements of temperature gradients are sought instead of measurements of absolute temperature values.

300

3.2 Nighttime Temperature

Nighttime flights were conducted with the tetheronde to understand the effects of radiative error and to separate the radiative error from the drone-induced error. Figure 5 shows the analyses of temperature using only the 9 nighttime flights (approximately 1.5 total flight hours). The errors in measured temperature are notably smaller at night than during the day.

305 The largest mean bias in temperature decreases from 0.42 K during the day to 0.24 K at night, and the largest 95% CI range decreases from 2.75 K to 1.5 K. This indicates that radiative errors, either due to the heating of the sensor itself or as a result of heating the drone body, are substantial contributors to the total errors observed in the daytime flights.

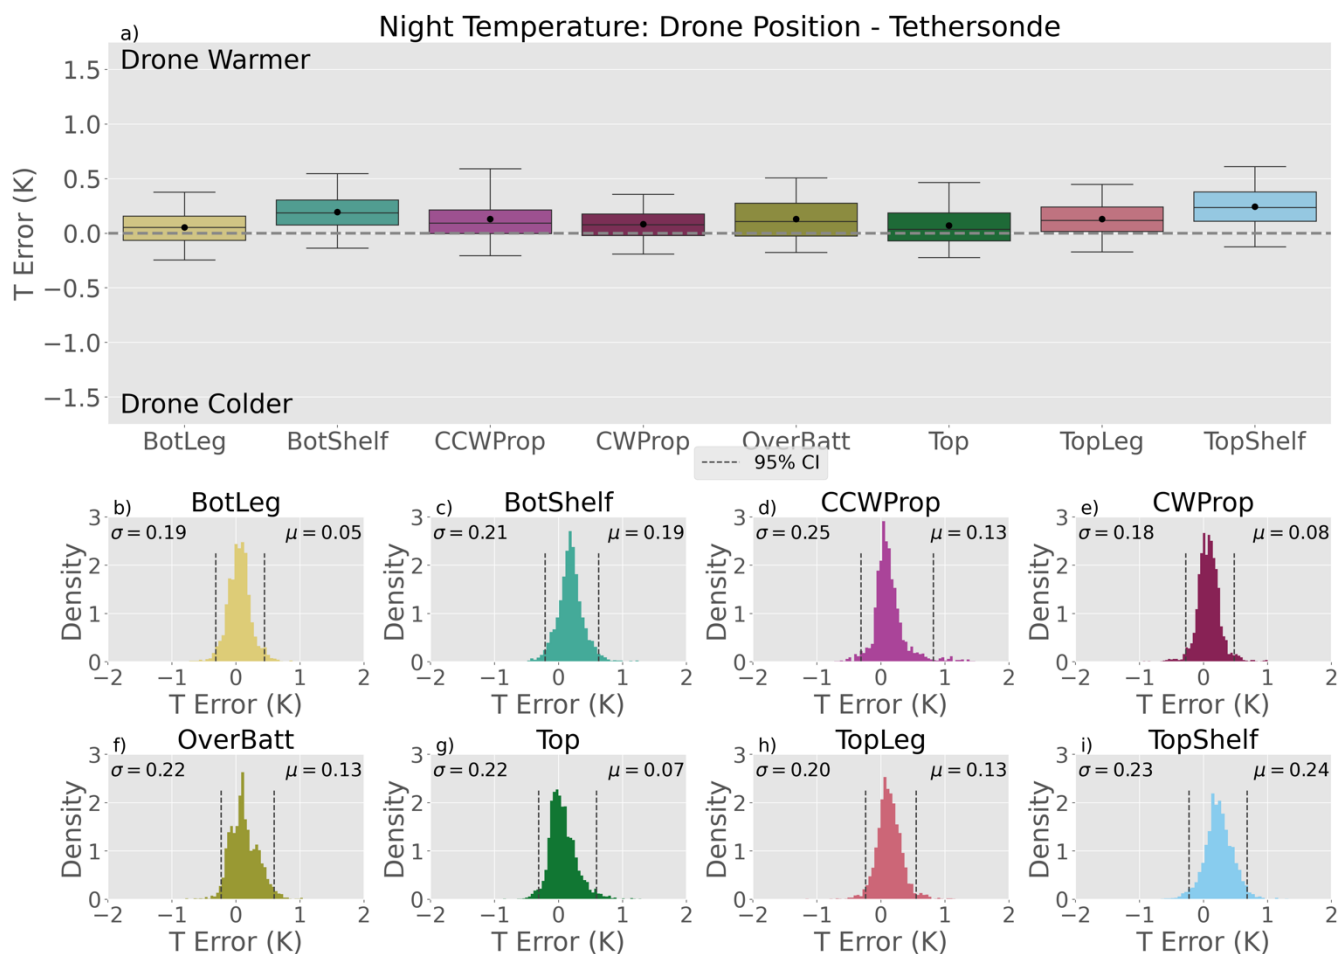

Figure 5: As in Figure 3, but for temperature errors during the nighttime flights only.

310

Recall that for the daytime flights, the various drone sensor positions either have a warm or cold mean bias depending on the amount of aspiration they receive. In contrast, at night, all eight tested positions have a warm bias (Figure 5), and the magnitude of the warm bias ranges from +0.05 K to +0.24 K. This could be due to a combination of two factors: the mean altitude bias between the drone and tethersonde (4.2 m) and the heat generated by the drone. However, a 4.2 m mean altitude bias is unlikely to result in a warm bias on the order of 0.1 K. Even if a dry-adiabatic lapse rate is assumed in the near-surface boundary layer (an unrealistically strong lapse rate at night), a 4.2 m altitude difference only translates to a mean bias of +0.04 K. We therefore speculate that the primary cause of the temperature bias is that the drone, unlike the tethersonde, is a significant source of heating. The batteries' onboard temperature sensors indicate that each battery can increase its temperature by up to 25 K while in flight. The *TopShelf* position has the greatest mean bias, which is likely due to its position directly below the main electronics and battery bay. The *BotLeg* has the smallest mean bias, similar to the daytime temperature results. The small bias for the

320

BotLeg position is once again likely because this sensor position is farthest from the main electronics bay and motors. Even the two positions that are located directly below the propellers (*CWProp* and *CCWProp*), which should receive the most aspiration among the sensor positions, have warm biases at night. The warm biases for the under-propeller positions are likely due to the heat generated by the motors in flight or by the propellers circulating air warmed over the main body of the drone to these positions. Overall, the nighttime flight results demonstrate that even if sensors are properly shielded from radiation error during the day, drone-induced errors are present and must be accounted for during daytime and nighttime flights.

When comparing the nighttime distributions of error (Figure 5b-i) to those of the daytime position errors (Figure 3b-i), the nighttime distributions are narrower (Figure 5b-i). For the nighttime flights, the 95% CI of all the sensor siting locations is at worst $-0.31 \text{ K} \leq T \leq +0.82 \text{ K}$ when not adjusting for the mean bias. Although these data are not normally distributed, the smaller tails and narrower distributions characteristic of the nighttime flights suggest that shielding the temperature sensor aboard the drone could improve data quality and reduce error for the daytime measurements for all the sensor siting locations tested. Further, these data suggest that forced aspiration can reduce the bias induced by the drone's heating, as demonstrated by the relatively colder mean errors of the three positions with the most aspiration (*CWProp*, *CCWProp*, and *BotLeg*).

3.3 Water Vapor Mixing Ratio

The water vapor mixing ratio measurements (abbreviated here as q_v) from all 82 tethersonde flights are analyzed together (Figure 6). All sensor positions except *CWProp* have mixing ratio mean bias magnitudes of at most 0.1 g kg^{-1} , with six positions having a mean bias against the tethersonde of less than 0.05 g kg^{-1} (Figure 6). Furthermore, the non-propeller positions (i.e., all but *CWProp* and *CCWProp*) have unimodal distributions with 95% CIs of less than $\pm 0.3 \text{ g kg}^{-1}$ (Figure 6b-i). This is in contrast to the sensor siting locations under the propellers (*CWProp* and *CCWProp*), which have a total 95% CI of $-0.22 \text{ g kg}^{-1} \leq q_v \leq +0.66 \text{ g kg}^{-1}$ (Figure 6d,e).

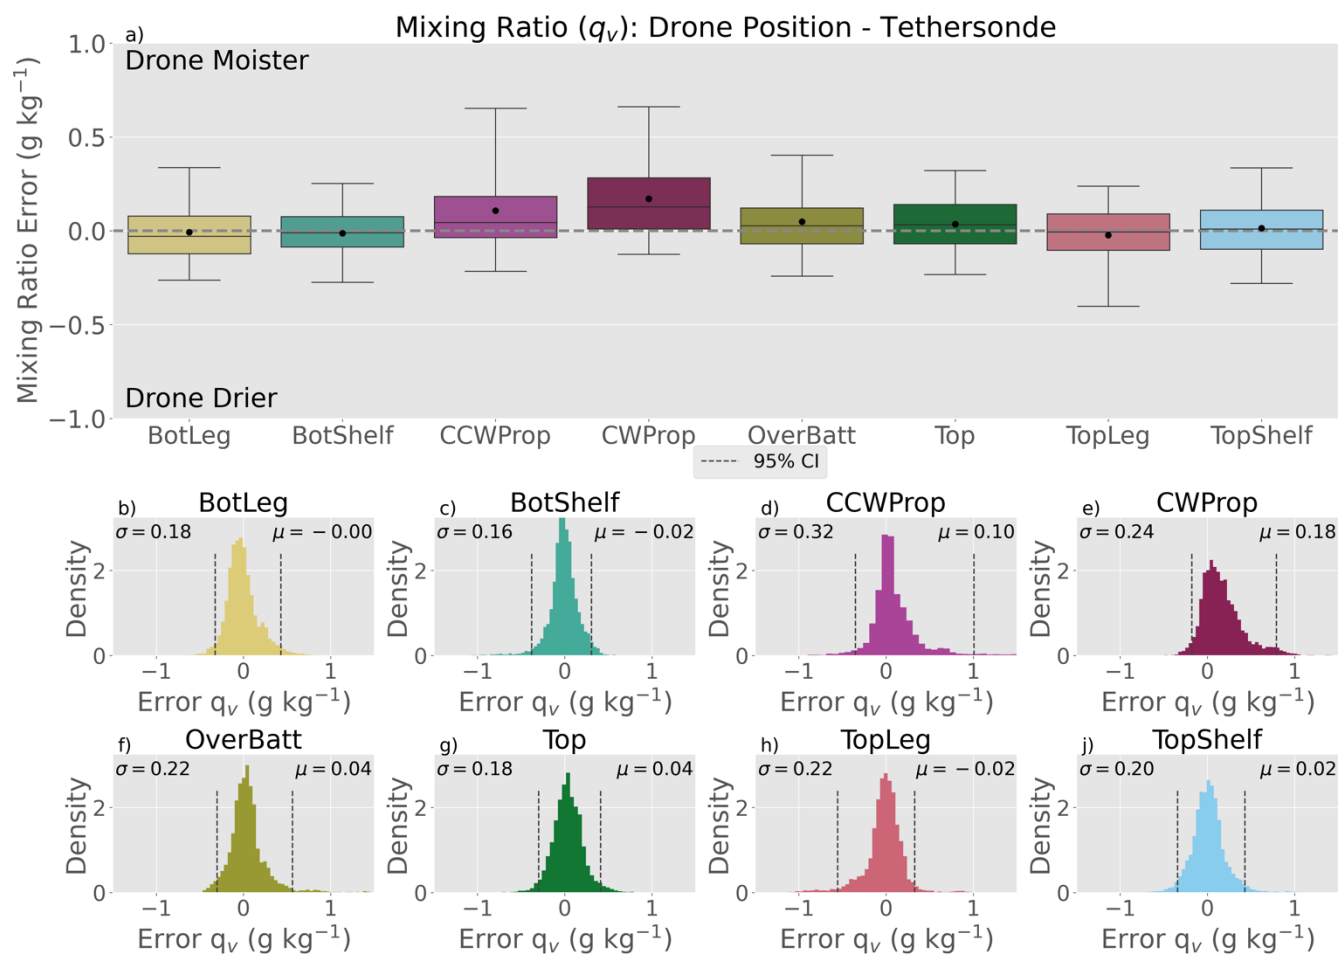

Figure 6: As in Figure 3, but for water vapor mixing ratio errors for all flights.

- 345 The wide 95% CIs of the *CCWProp* and *CWProp* positions compared with the other positions merit investigation. In each of these cases (Figure 6d-f), the wider CIs are caused by relatively longer tails on the positive side of the distribution (where the drone is moister than the tethersonde). As the drone does not carry any water onboard and does not produce water in flight, the unequal water vapor mixing ratio distributions must be a result of error induced either by the drone or by solar radiation.
- 350 The 82 tethersonde flights are stratified by solar radiation (Figure 7), as in Section 3a for temperature, to determine the contribution of solar radiation to the water vapor mixing ratio error. This figure shows that, for most positions, the errors (spread and mean bias) in water vapor mixing ratio increase with increasing solar radiation. The signal is stronger in the standard deviation than in the mean bias because some positions' mean bias decreases. The increase in standard deviation with increasing solar radiation suggests that there is a component of radiative error to the total water vapor mixing ratio error. This
- 355 is despite the fact that the RH sensor measures the temperature that the RH is based on. We speculate that the radiative error

may result from the RH measurement having a different response time than the temperature measurement on the RH sensor module. If these two parts of the sensor reported their temperature and RH with different response times, the measured RH may lag the temperature measurement, leading to errors when the temperature is rapidly changing, such as in direct sunlight (see the lag analysis in Appendix 1). However, it is impossible to conclusively determine the exact cause of the radiative error with the data collected. Future work should explore this issue further.

Tethersonde Flights Stratified by Solar Radiation (E; W m⁻²)

Figure 7: As in Figure 4, but for water vapor mixing ratio errors.

3.4 Temperature and Water Vapor Mixing Ratio Gradients

Several field campaigns that have utilized multirotor drones, such as C3LOUD-Ex (van den Heever et al. 2021) and LAFE (Wulfmeyer et al. 2018), have been interested in measuring temporal or spatial gradients in the thermodynamic variables rather than singular or absolute measurements of these variables. In this section, we examine the accuracy of the drone measurements when considering temperature or water vapor mixing ratio gradients in time where the relative magnitudes in a variable, as opposed to the absolute magnitudes, are important to the scientific investigation of interest.

Before examining temperature or water vapor mixing ratio gradients, we first apply a moving average to these data, as is commonly done with temperature and water vapor mixing ratio measurements. We apply a 20-second moving average to the temperature and water vapor mixing ratio data. This interval is chosen because it is longer than the e-folding times of error autocorrelation for all sensor positions in daytime temperature and water vapor mixing ratio (see Appendix 1 and Figure A1

for further discussion of this interval). While some of the positions in nighttime temperature have longer e-folding intervals, 20-seconds is still used across the experiments for the purpose of consistency and as most of the data during these two example campaigns were taken during daytime. We specify that only 75% of the data points contained in the moving average window must be valid data points after our quality control to provide a balance between capturing sufficient data points and data accuracy. This requirement means that for a single 20 s period, there must be 15 valid data points for a moving average to be calculated. If there are fewer than 15 valid data points, the moving average is not calculated, and the 20 s period is flagged as invalid. The filtered data are notated with an overbar for the remainder of this discussion (e.g. \bar{T} , \bar{q}_v).

To characterize the measurement error expected when sampling some temporal gradient, such as $\frac{\Delta \bar{T}}{\Delta t}$, where t is time, an appropriate time interval (Δt) must first be chosen. We consider time intervals of 9 min (the total time of each flight) or less for this analysis. Increasingly large Δt s reduce the number of usable data points. To provide a compromise between a sufficiently long Δt such that it is larger than the moving average time, and a sufficiently short Δt to allow as large a sample size as possible, a time interval of 60 seconds is chosen. Testing reveals that the main findings are not qualitatively sensitive to the exact Δt used (not shown). The filtered temperature (\bar{T}) is subtracted from the filtered temperature 60 seconds later (i.e. $\bar{T}_{t+60s} - \bar{T}_t$, notated here as $\Delta_{60s}\bar{T}$) (Figure 8). It is evident from this figure that for the daytime temporal temperature gradients, the errors at each sensor siting location are smaller than the errors in the absolute temperature measurements (Figure 3), with a worst-case $\Delta_{60s}\bar{T}$ error of (-1.08 K, +1.12 K) at a 95% CI (Figure 9). Unlike the absolute measurements of temperature, the biases in $\Delta_{60s}\bar{T}$ are all near zero.

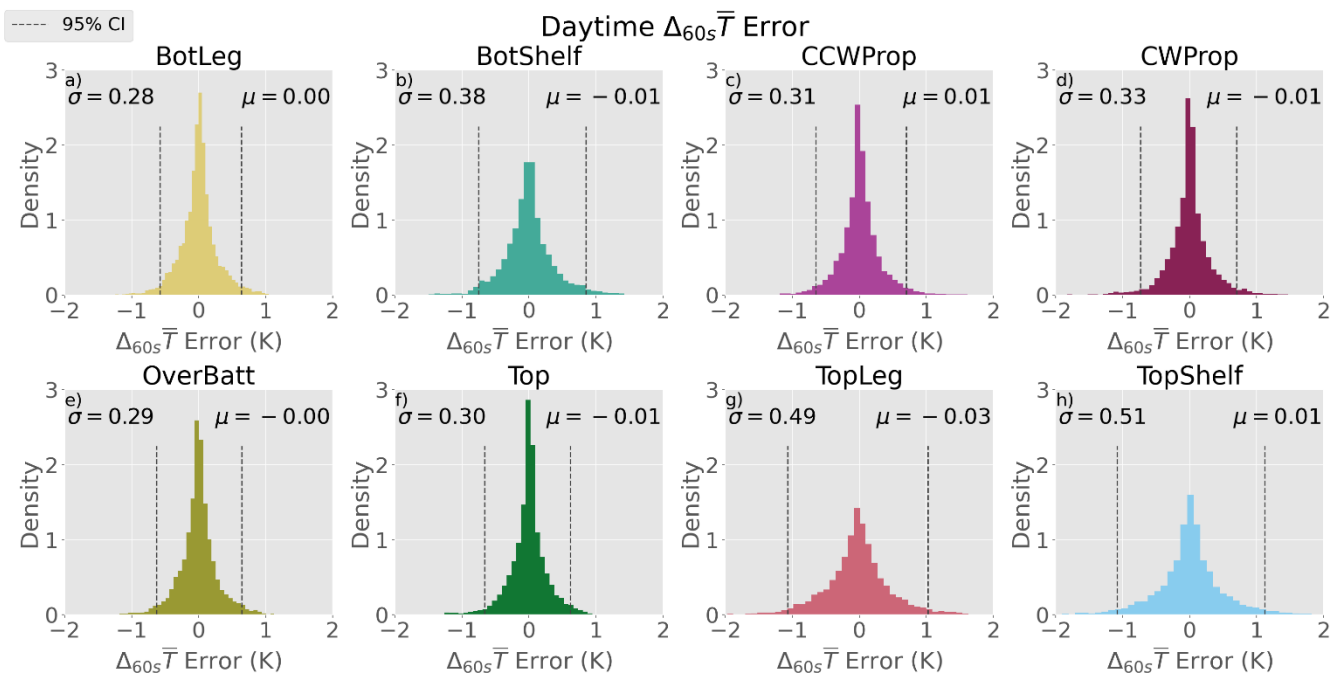

Figure 8: As in Figure 3b-i, but showing the quantity $\Delta_{60s}\bar{T}$, as defined in the text, for all daytime flights.

395 As shown in Sections 3a and 3b, the daytime and nighttime temperature accuracies differ due to the impacts of solar radiation. With that in mind, an analysis of 60sT error is conducted for the nighttime flights. The 95% confidence error for temperature gradients at night (Figure 9) are approximately the same as each independent nighttime temperature measurement (Figure 5). This result suggests that when measuring temperature gradients during the day, the accuracy may differ if there are variations in the incoming solar radiation, such as might ensue from changing cloud properties as the error in the measurement may change with changing cloud cover.

400

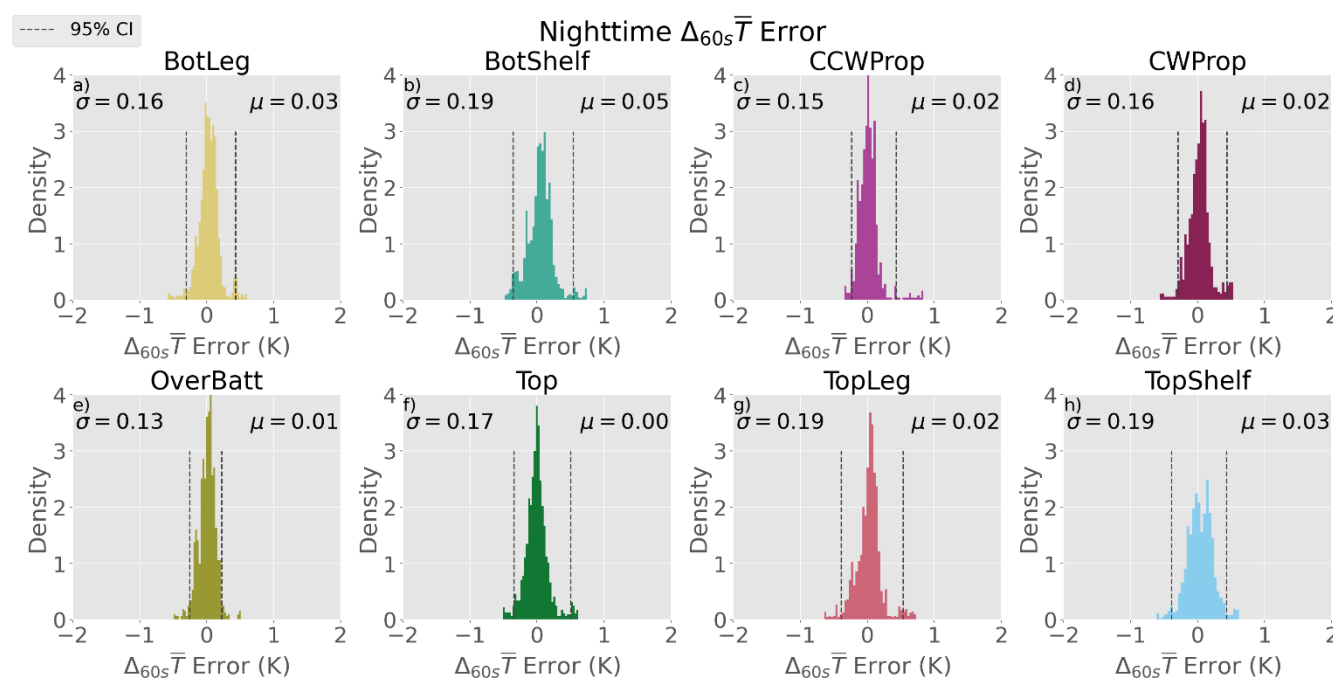

Figure 9: As in Figure 8, but for $\Delta_{60s}\bar{T}$ during the nighttime flights only.

We performed a similar analysis for the NEON flux tower days to validate the temperature difference results from the tethered drone. For this, we conducted an experiment measuring the mean absolute difference between the drone $\Delta_{60s}T$ and the NEON site $\Delta_{60s}T$ (i.e., $\sum |\Delta_{60s}T_{Drone} - \Delta_{60s}T_{NEON}|$). The values for each of the sensors were between 0.33 and 0.36K, within the combined accuracy range of the two instruments ($\pm 0.3K$ for the iMet XQ2s on the drone, an average of $\pm 0.08K$ for the NEON site), demonstrating that the measurements of temperature gradients are valid.

410 We also examine the error in measurements of temporal water vapor mixing ratio gradients (keeping the symbology identical to that for temperature). Figure 10 shows the error distributions for all eight sensor siting locations for $\Delta_{60s}\bar{q}_v$. In all eight

415 sensor siting locations, the maximum water vapor mixing ratio gradient error is $\pm 0.50 \text{ g kg}^{-1}$ at the 95% confidence level, lower than many of the absolute value water vapor mixing ratio errors. Furthermore, the mean water vapor mixing ratio gradient error is approximately zero for all sensor positions. For field campaigns interested in gradients, unshielded sensors onboard drones can provide added value at accuracy ranges smaller than for absolute measurements. The implications of our results for field campaign measurements are now explored in the next section.

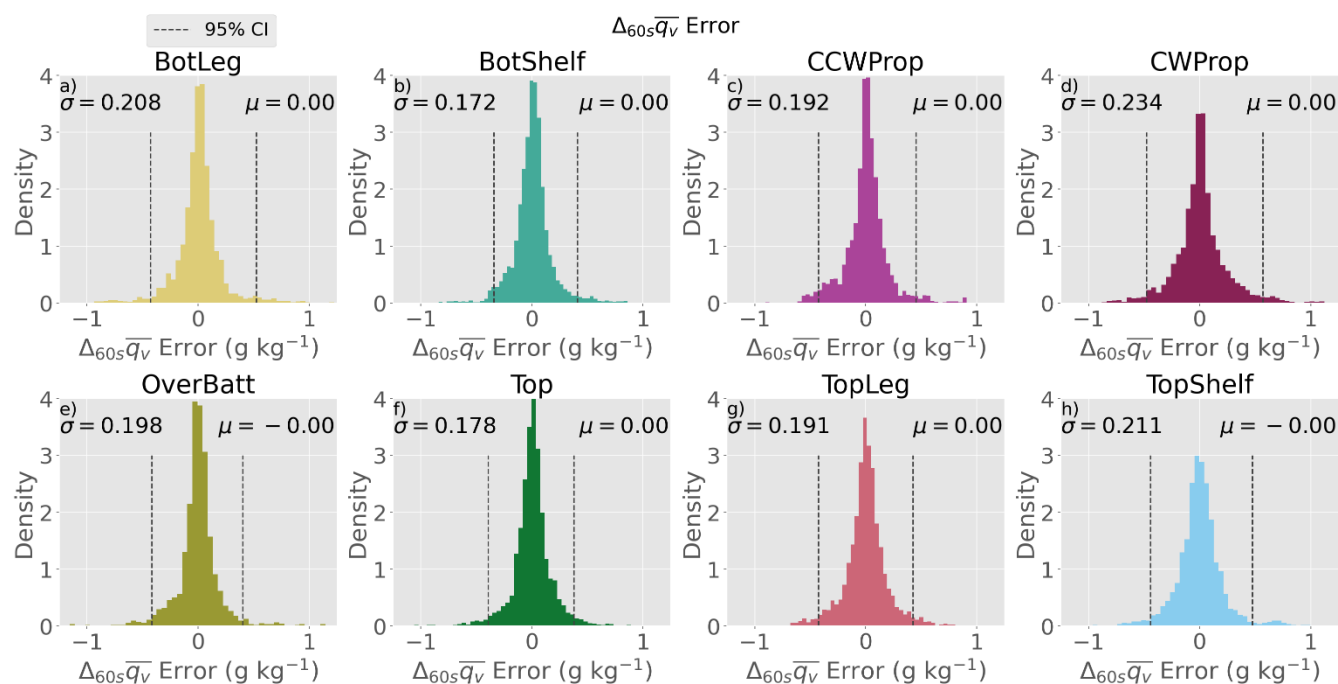

Figure 10: As in Figure 8, but for $\Delta_{60s}\bar{q}_v$, where q_v is water vapor mixing ratio.

4 Implications of our Results for Recent Field Campaigns

420 The results presented here characterize the accuracy of thermodynamic measurements made from unshielded sensors in eight different sensor siting locations on one multirotor drone platform. To understand the implications of these findings for the use of drone platforms in field campaigns, two campaigns that used unshielded sensors to measure thermodynamics from multirotor drones are now discussed. The C3LOUD-Ex field campaign (van den Heever et al. 2021) was conducted in July of 2016 and May-June of 2017 and employed a suite of instruments to measure storm updrafts and surface outflows using targeted observations. C3LOUD-Ex utilized six multirotor drones to measure storm-produced cold pools, areas of evaporatively-cooled dense air in contact with the ground and identified via temperature gradients near their edges. The results for temperature and water vapor mixing ratio gradients outlined in this study (Section 3d) are therefore particularly relevant for C3LOUD-Ex. The drones used in this campaign were identical to the drone used in the present study, and the C3LOUD-Ex drone sensors were placed in the *TopShelf* position. Continental cold pools produced by deep convection, the focus of C3LOUD-Ex, typically

430 have near-surface temperature differences ranging from -2 to -20 K relative to the environment (Engerer et al. 2008). The results presented here indicate that 60sT errors onboard the drone are at worst $-1.08 \text{ K} \leq \Delta_{60sT} \leq +1.12 \text{ K}$ at the 95% confidence level. We therefore conclude that most unshielded drone temperature measurements described here are sufficient to successfully measure most mid-latitude continental cold pools produced by deep convection.

435 The Land-Atmosphere Feedback Experiment (LAFE; Wulfmeyer et al. 2018) was a field campaign completed in August 2017 in central Oklahoma. LAFE used a suite of instruments to observe land-atmosphere feedbacks over different soil types and soil moisture conditions. During LAFE, two multirotor drones with thermodynamic instruments were operated, including at least one drone that had an in situ thermodynamic sensor near the *OverBatt* position tested in this work (Wulfmeyer et al. 2018; Lee et al. 2019). The drones were used to measure vertical and horizontal profiles of temperature and humidity over different
440 soil types and soil moisture to identify the spatial structures that may exist in these variables. Lee et al. (2019) reported that during the transects, the temperature varied by $\pm 0.5 \text{ K}$ and the dewpoint temperature by approximately $\pm 1 \text{ K}$. Our study indicates that the magnitudes of the variance in temperature and humidity measured by the drones in the LAFE campaign are likely to be real atmospheric features at the 95% CI.

5 Conclusions

445 Multirotor drones have enabled new types of observational strategies and sampling in atmospheric science field campaigns. This work provides new insights into understanding the measurements made onboard multirotor drones. We have examined temperature and water vapor mixing ratio measurements made from drones and have characterized the biases and errors induced by placing unshielded, un aspirated sensors in different positions on multirotor drones. Eight sensor positions, representing the most common locations utilized in field campaigns to date, were tested by flying a multirotor drone for 98
450 flights (15.5 total flight hours), including 9 flights at night. The multirotor drone was flown in close proximity to a tether sonde carrying the same sensors and located at a similar altitude, as well as next to an instrumented flux tower. Temperature and water vapor mixing ratio measurements at each sensor siting location were compared with those from the tether sonde. Flux tower measurements were used to validate the temperature results from the tether sonde. The errors were defined as the difference between the drone sensor measurements and the tether sonde measurements.

455

The results from the observational experiments indicate that when sampling temperature during the day using a sensor unshielded from incoming solar radiation, measurement errors at a 95% confidence level range from $-0.83 \text{ K} \leq T \leq +0.61 \text{ K}$ for the sampling position with the lowest spread, to $-0.91 \text{ K} \leq T \leq +1.88 \text{ K}$ for the position with the greatest spread. When making measurements at night without the impacts of incoming solar radiation, the location with the greatest spread is reduced
460 to $-0.31 \text{ K} \leq T \leq +0.82 \text{ K}$. However, at night, there is never the less a warm mean bias in temperature due to the heat generated by the batteries and avionics onboard the drone. If temporal gradients in temperature rather than absolute temperature

measurements are of interest, the expected 95% confidence interval (CI) for daytime temperature gradient errors range from $-0.57 \text{ K} \leq T \leq +0.63 \text{ K}$ to $-1.08 \text{ K} \leq T \leq +1.12 \text{ K}$, depending on sensor location.

465 Our analysis of water vapor mixing ratio indicates that solar radiative error impacts the water vapor measurements made onboard the drone because the reported accuracies vary when stratified by solar radiation. The largest error in water vapor mixing ratio was found to be $\pm 0.30 \text{ g kg}^{-1}$, except for the sensor position below the two propellers and the position directly over a battery, where the largest 95% CI was $-0.22 \text{ g kg}^{-1} \leq q_v \leq +0.66 \text{ g kg}^{-1}$. The error when sampling a temporal water vapor mixing ratio gradient had a 95% CI of approximately $\pm 0.50 \text{ g kg}^{-1}$, regardless of sensor position.

470

Our results place a narrower CI on thermodynamic measurements made from drones than those presented by Barbieri et al. (2019). This is most likely because we focused on the results from single drone platform rather than an ensemble of different drones. In field campaigns where multiple drones of different types are to be deployed, understanding the platform-specific differences in drone-induced errors would be critical. The results presented here suggest that the error bounds for drone thermodynamic measurements can be greatly reduced by placing the sensor in certain positions and conducting error characterization flights for each drone platform used. Further, we found that measurements of temperature and water vapor gradients have smaller errors than absolute measurements of those quantities.

475

The results demonstrated here also elucidate some of the best practices when sampling temperature and water vapor with multirotor drones. In general, the smallest error spread and mean bias in temperature and water vapor mixing ratio were found for the siting location furthest away from the main body, including the batteries and avionics. For the specific drone used in the present study, the *BotLeg* position best meets these criteria, although this position can be challenging to mount sensors on. Future developments in drone sensor engineering should also focus on ways to extend the sensors away from the main body of the drone without substantially increasing the weight or changing the aerodynamic characteristics and balance. For drone platforms where a probe or extension is not possible, measurement errors are likely to be higher due to the heat generated by the drone itself. Even aspiration and shielding may not be sufficient to remove the errors induced by drone heating, as suggested by the nighttime results presented here. Many test flights should also be completed to better understand the errors and biases when introducing an aspirated shield. For field projects that have already completed their sampling phase with unshielded sensors onboard, the error values and biases that have been characterized in this work should be accounted for when analyzing the data collected.

485

490

Future work should examine the impacts of small, lightweight sensor aspiration and shielding on the measurements on a variety of drone platforms and seek to understand whether the potential benefit of such aspiration and/or shields outweighs the weight and cost. Our analysis of the nighttime flights conducted to eliminate the impacts of solar radiative error suggest that sensor shielding may not entirely eliminate errors in temperature measurements, because heat from the drone batteries and avionics

495

can still bias the measurements. The biases in shielded sensors should therefore be investigated before shielding is employed in future campaigns. Additionally, errors associated with measurements onboard a smaller drone platform may not be identical to the errors on our larger platform because different drone platforms produce varying amounts of heating and propellor wash. Finally, this research provides characterizations of measurement errors based on sensor siting locations that are useful both to already-completed field campaigns and to future “ride-along” deployments where sensor positioning may not be selectable by researchers. We suggest that in future campaigns employing drones for thermodynamic measurements, thermodynamic sensors should be sited as far away from the main body of the drone (and hence the batteries and avionics) as possible and should be shielded from the impacts of insolation.

Appendix A

To determine the appropriate length of the moving average such that noise is removed but the signal is preserved, we calculate the autocorrelation of the error for each position. Here, we use the e-folding time (i.e., the time at which the error autocorrelation is lower than $1/e$) as a metric to determine the length of the moving average. The e-folding time of the error autocorrelation is greater than 1 s for all positions for daytime temperature, nighttime temperature, and water vapor mixing ratio (Figure A1). In general, the positions receiving the most forced aspiration from the drone (i.e., *CWProp* and *CCWProp*) have the smallest error autocorrelation for a given lag time, indicating a relatively higher level of noise in the measurements. In all cases during the daytime, the e-folding time is at most 20s, while at night, the positions with the least aspiration (i.e., *BotShelf* and *TopShelf*) have longer e-folding times.

Figure A1: Autocorrelation by sensor position from the tethersonde experiments of a) daytime temperature error, b) nighttime temperature error, and c) water vapor mixing ratio. The grey dashed line shows the e-folding line (i.e., $\frac{1}{e}$)

Data Availability

The National Ecological Observatory Network flux tower data are available under DOIs 10.48443/YEX7-7Z81, 10.48443/K9VK-5K27, 10.48443/pde7-k607, 10.48443/rt4v-kz04, and 10.48443/9qpc-5v70. Drone data and tethersonde data will be uploaded upon acceptance.

520 Author contribution

SF, LG, and SV conceptualized the idea. SF, LG, and JB designed the experiments, and SF, LG, JB, PM, JP, SH, and CN carried them out. SF, JB, LG, CN, and SV analysed the results. SF, LG, and SV obtained the funding. SV provided project administration. SF drafted the manuscript with edits from all coauthors.
