**Abstract.** In the context of climate change and increasing anthropogenic pressures in Africa, understanding the interactions between atmospheric chemistry, regional climate, and biogeochemical cycles is critical. This study investigates the potential role of biogenic nitric oxide emissions from African soils (BioNO), particularly in arid and semi-arid ecosystems, as ~~significant~~ major contributors to atmospheric nitrogen dioxide (NO<sub>2</sub>emissions-) concentrations and regional atmospheric chemistry. To this end, we rely on a modelling approach based on the RegCM5 regional climate model, including an updated atmospheric chemistry module and, amongst other, a specific parametrization for BioNO emissions. Throughout the paper, the ~~model performances~~ performances of the model are evaluated against various datasets, including in-situ observations from the IN-DAAF (International Network to study Depositions and Atmospheric chemistry in Africa) network and chemical reanalyses. Sensitivity studies demonstrate that integrating BioNO emissions into the model enhances the accuracy of simulated NO<sub>2</sub>, nitric acid (HNO<sub>3</sub>-and-), and ozone (O<sub>3</sub>) seasonal cycles and surface ~~concentration magnitudes, while reducing simulated biases against concentrations, and reduces simulated biases compared to~~ concentration magnitudes, while these concentrations and in-situ measurements. Similar biases are also observed ~~for chemical reanalyses, and a state-of-the-art in a chemical reanalysis model and in a state-of-the-art~~ chemistry transport model used for comparison. Beside-outlining In addition to highlighting the impact and added value of ~~BioNO flux representation for including BioNO fluxes in~~ BioNO fluxes in regional atmospheric chemistry models, our findings also ~~outline~~ highlight the suitability of the RegCM5 coupled system for ~~the study of studying~~ regional climate, chemistry and nitrogen cycle interactions over Africa.

## 1 Introduction

Tropical Africa is a ~~significant source of gas and particles~~ major source of gaseous and particulate emissions, affecting the regional and global atmospheric chemistry and climate. ~~Beside~~ In addition to large chemical sources linked to anthropogenic

activities (biomass burning, megacities), there ~~is also a significant amount of~~ are also substantial biogenic emissions which can ~~significantly interact with~~ strongly interact with the regional tropospheric composition ~~across various tropical locations in the tropics~~ (e.g., Aghedo et al., 2007). Nitrogen emissions originating from soil microbial processes are an important component of these emissions (Fudjoe et al., 2023). Indeed, soil microbial processes, such as nitrification and denitrification involve the production of reactive gaseous compounds released to the atmosphere (Delmas et al., 1995; Medinets et al., 2015; Schreiber et al., 2012). Soil NO (referred to as BioNO) emissions dominate the global net nitrogen oxide exchange between ecosystems and the atmosphere (Ludwig et al., 2001) ~~and have been estimated to approximate~~, and above-canopy emission estimates ranging from 4.7-26.7 TgN.yr<sup>-1</sup> ~~above canopy~~ (Davidson and Kinglerlee, 1997; Ganzeveld et al., 2002; Hudman et al., 2012; Jaeglé et al., 2005; Müller, 1992; Steinkamp and Lawrence, 2011; Vinken et al., 2014; Yan et al., 2005; Yienger and Levy, 1995). BioNO emissions play a crucial role in the formation of particles and key atmospheric gaseous compounds, such as O<sub>3</sub> and HNO<sub>3</sub> (Liu et al., 2020; Mosier, 2001; Vinken et al., 2014; Williams et al., 2009). ~~Soil microbial processes depend primarily on precipitation and soil moisture (Liu et al., 2009; Li et al., 2022). Over tropical Africa, which shows a marked rainfall seasonality, an accumulation of nitrogen in soils occurs during the dry season, leading to significant pulses of nitrogen emissions at the onset of the rainy season (Austin et al., 2004). Various~~ BioNO emissions are influenced by a variety of environmental and physical factors, including wind speed, floristic composition, nitrogen input (from organic and synthetic fertilization and atmospheric deposition), plant cover, soil temperature ~~and moisture~~, soil moisture content, soil pH, and ~~texture, influence~~ BioNO emissions (Delon et al., 2007; Williams et al., 1992) soil texture (Delon et al., 2007; Williams et al., 1992). Among these factors, soil moisture plays a dominant role in tropical regions, where seasonal rainfall patterns lead to marked fluctuations (particularly intense in Sahelian regions) in soil water content. This results in nitrogen accumulation during dry periods and important emission pulses following the onset of the rainy season (Austin et al., 2004; Meixner and Yang, 2006; Johansson et al., 1988; Yienger and Levy, 1995). Precipitation and soil moisture are recognized as key drivers of microbial processes that regulate NO fluxes (Liu et al., 2009; Li et al., 2022). While soil temperature and nitrogen content also influence NO fluxes, particularly in temperate zones, the pulse effect, which is driven by soil moisture, remains especially pronounced in tropical soils, where short but intense rainfall events can trigger sharp increases in NO emissions.

In tropical Africa, estimating BioNO emissions is ~~however~~ challenging due to a lack of observational data (e.g., Jaeglé et al., 2004; Van Der A et al., 2008). Nevertheless, global and regional modelling approaches, ~~which consider these influences to various degrees~~, have been proposed to quantify BioNO emissions (e.g., Hudman et al., 2012; Stohl et al., 1996; Stehfest and Bouwman, 2006; Yienger and Levy, 1995; Yan et al., 2005) and ~~ensuing chemical impacts~~ evaluate the potential impact on atmospheric chemistry. For instance, Williams et al. (2009) used an inventory of biogenic emissions derived from multi-annual simulations of the ORCHIDEE (Organising Carbon and Hydrology In Dynamic Ecosystems) vegetation model (Lathiere et al., 2006) to ~~examine study~~ the influence of ~~NO and BVOC emissions from soils and vegetation~~ BioNO and BVOC (Biogenic Volatile Organic Compound) emissions on Equatorial Africa's tropospheric composition. The global chemistry-transport model simulations revealed that NO emissions from soils in Africa ~~might contribute to 2-45 %~~ contribute between 2% and 45% of tropospheric ozone production. Delon et al. (2008) used a neural network-based parameterization coupled with a mesoscale model to investigate the impact of BioNO emissions on NO<sub>x</sub> and O<sub>3</sub> production in the lower ~~Equatorial Africa's troposphere on~~

~~a specific period troposphere over Equatorial Africa for a specific day~~ (6 August 2006) during the AMMA (African Monsoon Multidisciplinary Analysis) campaign in the Sahel. Their findings indicate an increase in tropospheric  $O_3$  and  $NO_x$  concentrations in the lowest few kilometres of the atmosphere ~~, in response to larger BioNO fluxes, compared to simulations using the prescribed inventory of Yienger and Levy (1995) when BioNO emissions are included.~~ Steinkamp et al. (2009) used the ECHAM5/MESSy atmospheric chemistry model (EMAC) to examine the influence of BioNO on lower tropospheric  $NO_x$ ,  $O_3$ , PAN,  $HNO_3$ , OH, and ~~CH4 lifetime the lifetime of CH4~~ ( $\tau_{CH4}$ ). Their results revealed that BioNO ~~significantly largely~~ contributes to  $NO_x$  levels ~~in numerous regions~~, especially in the tropics. Moreover, BioNO notably raises OH concentrations, thereby increasing the global troposphere's oxidizing capacity and resulting in ~~an a~~ 10% decrease in  $\tau_{CH4}$  ~~due to soil NO emissions.~~

~~From a modelling point of view, there is a strong interest in integrating interactive BioNO emission in~~ Integrating interactive BioNO emissions into models of regional climate systems ~~: it can allow for instance to study the impact of present and future climate change and variability, including temperature fluctuations, and precipitation patterns, and soil moisture levels, on BioNO emissions. This understanding is crucial for predicting possible future emission trends, potential changes in the chemical environment, and developing effective mitigation strategies. Additionally, BioNO emission can BioNO emissions can also affect the formation of ozone and other secondary pollutants, which have has implications for air quality and as well as climate forcing and responses, which can be evaluated by means of coupled climate chemistry systems. Furthermore, These knock-on effects can be calculated using coupled climate chemistry systems. In addition to being able to include BioNO emissions and the consequent effects on secondary pollutants,~~ the regional climate modelling approach ~~allows the study of adopted in this paper can also be used to study~~ regional environmental disturbances such as land use and agricultural changes ~~in a flexible way. Finally, Since, Furthermore, since~~ climatic and land use gradients are particularly important in west and central Africa, the dynamical downscaling capabilities offered by the regional climate modelling approach are also ~~particularly interesting to capture the of particular interest for capturing~~ regional contrasts in emissions and processes at play.

One goal of the present study is to evaluate and extend such a system based on the International Centre for Theoretical Physics Regional Climate Model version 5 (ICTP RegCM5 ~~model (Giorgi et al., 2023), while estimating and analysing~~) (Giorgi et al., 2023). A second goal is to estimate and analyse the regional impact of BioNO emissions (from soils and vegetation) on key tropospheric species relevant to the atmospheric nitrogen cycle. The latter plays an important role in the chemistry of the atmosphere as well as the functioning of aquatic and terrestrial ecosystems and agrosystems (McNeill and Unkovich, 2007; Vitousek et al., 1997). This N cycle is ~~significantly markedly~~ disrupted by anthropogenic activities (agriculture, fossil fuel combustion, and biofuels) (Galloway et al., 2008). This issue is particularly concerning in tropical regions like Africa, where rapid population growth and seasonal cycles from natural and anthropogenic sources ~~contribute significantly strongly contribute~~ to changes in N emissions (Adon et al., 2010). We focus on  $NO_2$ ,  $HNO_3$ , and  $O_3$  because these species are tightly interconnected and are involved in different a range of environmental and health impacts.  $NO_2$ , a key reactive nitrogen species, contributes to the formation of  $HNO_3$  and  $O_3$ .  $HNO_3$  is formed when  $NO_2$  reacts with other substances in the atmosphere, and is an important contributor of rainfall acidity deposition and nitrogen supply to ecosystems.  $O_3$ , a powerful oxidant, is influenced by the presence of  $NO_2$  and ~~has significant implications~~ plays a crucial role in  $HNO_3$  formation. Understanding the

concentrations and fluxes of these species is essential for assessing nitrogen management and potential risks in Africa. ~~To a large extent, this work shares scientific goals with, and is carried out as part of the INSA (Integrated Nitrogen Study in Africa; ) and the INDAAF (International Network to study Depositions and Atmospheric chemistry in Africa; ) projects.~~

95 The study is structured as follows: Sections 2 and 3 will provide a description of the modelling context and developments, as well as measurement sites and relevant databases used in this study. Section 4 will focus on evaluating model performances in simulating key regional climatic features affecting emissions and tropospheric chemistry. Section 5 will discuss simulated BioNO in more detail. Model results and limitations concerning ~~their impact~~ the impact of BioNO on key atmospheric chemistry components will be discussed in Section 6.

100 **2 Model description**

**2.1 The Regional Climate-chemistry Model ~~RegCM5-CHEM~~RegCM5**

The present work is based on the latest version of the ICTP RegCM5, discussed in detail in Giorgi et al. (2023). Compared to previous versions, a ~~significant key~~ development has been the ~~integration of the MOLOCH~~ inclusion of the MModelo LOcale in H coordinate (MOLOCH) non-hydrostatic dynamical core (Davolio et al., 2020) ~~improving~~ . This has improved model efficiency, notably in ~~view of regards to~~ climate convection-permitting (CP) simulations (e.g., Ban et al., 2021; Coppola et al., 2020; Lucas-Picher et al., 2021; Pichelli et al., 2021; Prein et al., 2015).

This development is also important for atmospheric chemistry, which uses a large number of tracers, ~~by reducing as it reduces~~ the numerical cost of advection in the context of long-term simulations. As for previous model versions, several options are available for the model physics. In the present study we run successive tests (not discussed further here) to retain a model configuration based on the the RRTM (Rapid Radiative Transfer Model) for shortwave and longwave radiation, the University of Washington turbulence scheme (UW, Bretherton et al., 2004), the Nogherotto et al. (2016) bulk microphysics scheme and the Tiedtke convection scheme (Tiedtke, 1989). Continental surface processes are treated by the Community Land Model, version 4.5 (CLM4.5, Oleson et al., 2013) which also provides important coupling variables used ~~through in~~ the atmospheric chemistry interface, such as surface resistances, soil humidity and temperature. The meteorological boundary ~~condition fields~~ are provided at a six-hourly frequency conditions are provided every six hours, from the ERA5 reanalysis (Hersbach et al., 2020). The sea surface temperature data is ~~prescribed by the~~ provided by the Optimal Interpolated Weekly (OI\_WK every week) dataset.

Atmospheric chemistry processes used in this study are based on approaches initially developed in Solmon et al. (2006) and Solmon et al. (2021) for ~~aerosol~~aerosols, and Shalaby et al. (2012) and Ciarlo et al. (2021) for gas phases. The chemical reaction solver is ~~here~~-based on the CBM-Z photochemical mechanism module (Shalaby et al., 2012; Zaveri and Peters, 1999). It allows a comprehensive coverage of regionally ~~to globally significant species and~~and globally relevant species as well as the reactions involved in photo oxidant chemistry, while ~~keeping maintaining~~a good precision and numerical efficiency. CBM-Z notably includes key prognostic species such as O<sub>3</sub>, NO<sub>x</sub>, CO, VOCs. CBM-Z builds upon the widely used CBM-IV mechanism (Gery et al., 1989) and incorporates additional processes that enhance its applicability from urban air quality modeling to regional and global scales (Shalaby et al., 2012). It improves the representation of key chemical pathways by explicitly treating methane and ethane, refining parameterizations for higher alkanes, and incorporating a more detailed isoprene chemistry (Zaveri and Peters, 1999). Additionally, CBM-Z accounts for peroxy radical interactions and nighttime NO<sub>3</sub> chemistry, which are relevant in NO<sub>x</sub>-limited environments. However, as with most reduced chemical mechanisms, CBM-Z uses a lumped VOC representation, which may oversimplify NO<sub>x</sub>-VOC interactions, potentially affecting the formation of secondary species such as HNO<sub>3</sub> and O<sub>3</sub> (Carter, 2010). While these simplifications can introduce uncertainties, CBM-Z remains widely used due to its computational efficiency and its ability to capture key atmospheric trends (Shalaby et al., 2012; Zaveri and Peters, 1999; Gery et al., 1989; . The mechanism employs the Radical Balance Method (RBM), ensuring a stable and efficient numerical integration of chemical equations. Although more explicit mechanisms exist, their computational cost remains prohibitive for long-term regional climate simulations (Cao et al., 2021), making CBM-Z a suitable compromise between accuracy and efficiency for this study. It is also worth noting that biogenic and anthropogenic VOC emissions are potentially affected by potentially large uncertainties over Africa (Marais et al., 2014), and these uncertainties should be taken into account when considering the potential added value of a more complex chemical scheme.

Aerosol gas partition is treated ~~here~~-using a thermodynamic equilibrium approach and the ISORROPIA-II scheme (Fountoukis and Nenes, 2007; Nenes et al., 1998), which is mostly relevant for fine ~~particles~~particle heterogeneous processes. Dry deposition processes and fluxes are parameterized according to Zhang et al. (2003), for 31 gas phase species in the model. Key ~~input for~~inputs for the Zhang deposition scheme include biophysical and physiological parameters, which are ~~prescribed~~provided to the model using pre-defined land use categories and mapping (Dickinson, 1986; Zhang et al., 2002). Some parameters, such as LAI (Leaf Area Index), roughness length, wind, surface temperature, etc. are provided through the CLM4.5 interface. In the present study, slight modifications have been made in the deposition scheme to account for African regional specificities:

- a. Default ground resistance (R<sub>g</sub>) values for ozone~~are~~are, based on Zhang et al. (2003)~~were used but for~~, are used. For the ocean domain, ~~we adjusted these values~~these values are adjusted by lowering them to obtain more realistic ~~values of dry deposition velocity~~dry deposition velocities (e.g., Charusombat et al., 2010; Wu et al., 2011; Zhang et al., 2002)~~and so surface concentrations over the Ocean, leading to more accurate surface concentration estimates over the ocean.~~
- b. The friction velocity (u\*) is a crucial parameter for calculating aerodynamic resistance (r<sub>a</sub>). According to Padro et al. (1991), the equation used to calculate r<sub>a</sub> requires that the Richardson number be maintained below 0.21 under stable

conditions. This is particularly important in tropical forested areas with weak mean winds, where both  $u^*$  and deposition velocity are often lower than those reported in the literature (e.g. Adon et al., 2013; Zhang et al., 2003). To ensure compliance with this criterion, we have set a lower threshold of 0.4 m/s for  $u^*$  in forests and 0.1 m/s in savannas, based on our statistical analysis.

The wet deposition flux is initially parameterized following the approach developed in the MOZART chemistry transport model (Emmons et al., 2010; Horowitz et al., 2003). 26 CBM-Z tracers are considered for wet removal through large-scale and convective precipitation processes. Compared to Shalaby et al. (2012) and Ciarlo et al. (2021), we ~~significantly upgrade~~ substantially improve the wet deposition parameterizations by developing a new interface which ~~uses directly directly uses~~ cloud to rainwater production and precipitation rate terms ~~diagnosed taken~~ from both the Nogherotto et al. (2016) stratiform and the Tiedtke (1989) convective rain rates.

Anthropogenic and biomass burning emissions are treated ~~through using~~ a preprocessing interface designed for the regional interpolation and chemical aggregation of different possible inventories. In this study, the monthly, 0.1 ~~deg-degree~~ resolution emission inventories from the Copernicus Atmosphere Monitoring Service (CAMS, version 6.2) is ~~considered used~~ for non-biomass burning emissions (Soulie et al., 2023). For biomass burning, we use daily emissions from GFED4 (Global Fire Emissions Data, version 4) ~~for with a 0.25 deg-as spatial resolution are considered-degree spatial resolution~~ (Randerson et al., 2018). For both inventories, the lumping of emitted VOC species to effective CBMZ species has been performed following a method similar to Huijnen et al. (2019). The biogenic VOC emissions are calculated ~~on-line-on-line~~ as part of CLM45 using the embedded MEGAN (Model of Emissions of Gases and Aerosols from Nature; Guenther et al., 2006) scheme. ~~Here-only~~ Only isoprene fluxes are passed to the atmospheric chemistry and transport interfaces (Strada et al., 2023).

Finally, an important development compared to Shalaby et al. (2012) and Ciarlo et al. (2021) concerns the chemical initial and lateral boundary conditions. ~~The We replace the~~ standard monthly climatology approach ~~has been replaced here~~ by a new interface using six-hourly CAMS chemical reanalysis (Inness et al., 2019; Wagner et al., 2021), consistent with the ERA5 dynamical forcing. For important chemical and aerosol species, this allows ~~to represent more explicitly us to more explicitly~~ represent the influence and variability of long range chemical transport events ~~possibly affecting the domain through that may affect the domain via~~ the boundaries.

## 2.2 The BioNO emission parameterization

Interactive BioNO emissions are ~~represented here included~~ following the empirical approach developed in Delon et al. (2007) (D2007), which is based on an Artificial Neural Network (ANN) supervised learning ~~considering algorithm applied to~~ several databases. In some regions, such as Africa, few in situ measurements of BioNO are available, leading to inaccurate estimates of ~~emissions affecting BioNO emissions, which in turn affects the estimation of species~~ concentrations in the lower troposphere (Jaeglé et al., 2005). The main advantage in using ~~this the~~ ANN algorithm is that it ~~can be connected on-line and's~~ linked to varying environmental parameters of specific regions of interest, and can be used for calculating accurate BioNO emissions whatever the type of soil and/or climate (Delon et al., 2007). For now, this ANN algorithm has been used only in Tropical

185 African climates (Delon et al., 2007, 2012, 2015). ~~The main advantage in using this ANN algorithm is that it's linked to varying environmental parameters of specific regions of interest, and can be used for calculating accurate BioNO emissions whatever the type of soil and/or climate~~ NO emissions are largely influenced by microbial activity, determined by the ~~soil physical properties~~ physical properties of the soil (porosity, soil texture, soil moisture etc.) ~~governing which also govern~~ substrate diffusion and oxygen supply (Skopp et al., 1990). D2007's parameterization includes seven explicative variables, including

190 wind speed, fertilisation rate, surface temperature, sand percentage, soil moisture, soil pH, and deep soil temperature (20-30 cm). Wind speed is used as an indicator of varying atmospheric conditions. Deep soil temperature relates to oxygen diffusion and nitrogen mineralization in the soil (Butterbach-Bahl et al., 2004). The sand percentage impacts water diffusion (Roelle et al., 2001). pH is a crucial factor due to its impact on chemical or biological mechanisms (Serca et al., 1994). ~~It~~ can also influence NO emissions through chemo-denitrification process (low pH) or biological activity (higher pH) (e.g., Ormeci et al.,

195 1999; Serca et al., 1994). Finally, the fertilisation rate is key ~~to reflect~~ for including the amount of externally introduced nitrogen (Sanhueza et al., 1990). The pH and fertilisation rates are ~~prescribed~~ determined using external databases ~~as inputs~~: soil pH data are obtained from IGBP-DIS (International Geosphere Biosphere Programme-Data and Information System; Igbp-Dis, 1998), and fertilisation rates, including N fertilizer and N manure, are sourced from Potter et al. (2010). The other variables are integrated ~~on-line~~ on-line within the model.

200 ~~In output, NO emission fluxes are finally~~ The final NO fluxes are calculated at each model time step, ~~through the resulting~~ using the following equations:

$$\text{NOflux}_{\text{norm}} = w_{24} + w_{25} \tanh(S_1) + w_{26} \tanh(S_2) + w_{27} \tanh(S_3) \quad (1)$$

with

$$205 \quad S_1 = w_0 + \sum_{i=1}^7 w_i x_{j,\text{norm}}$$

$$S_2 = w_8 + \textcolor{red}{15} \sum_{\textcolor{red}{i}=8}^{\textcolor{red}{23}} \textcolor{blue}{15} \sum_{\textcolor{blue}{i}=9}^{\textcolor{blue}{15}} w_i x_{j,\text{norm}} \quad (2)$$

$$S_3 = w_{16} + \sum_{i=17}^{23} w_i x_{j,\text{norm}}$$

with  $j = 1 \rightarrow 7$

NOflux<sub>norm</sub> represents the normalised NO flux and the seven inputs mentioned above are represented by  $x_1$  to  $x_7$  (surface

210 ~~WFPS~~ Water-Filled Pore Space (WFPS), surface soil temperature, deep soil temperature, fertilisation rate, sand percentage, pH and wind speed respectively). Each input  $x_i$  is associated with a weight  $w_i$ , which represents the strength or influence of that input in determining the final NO flux.

The weights  $w_i$  in the ANN equations are determined using a supervised learning process. Initially, small random weights are assigned to prevent any input variable from dominating. The network is trained using a backpropagation algorithm, which

215 iteratively adjusts these weights to minimize the error between predicted and observed NO fluxes. In each iteration, the error is calculated, propagated backward, and the weights are updated accordingly. This process continues until the error is minimized, ensuring final weights accurately reflect the influence of each input variable on NO emissions.

The tanh (hyperbolic tangent) function is used as the activation function, introducing non-linearity essential for capturing complex interactions between environmental variables and NO emissions. It normalizes intermediate outputs to a range  
220 between -1 and 1, stabilizing learning and preventing extreme values.

The sub-equations (S1, S2, S3) structure the network into distinct layers, each capturing different aspects of the relationships between the environmental variables and NO emissions. While all sub-equations use the same input variables (x1 to x7), they apply different weights, allowing the network to explore multiple combinations and better capture non-linear dependencies. Each sub-equation acts as a filter, highlighting specific patterns or interactions, and their outputs are combined using the tanh  
225 function to produce the final normalized NO flux.

## 2.3 Model experiments

To test the ability of ~~RegCM5-CHEM to simulate~~ RegCM5 to simulate the African climate, BioNO emissions and to evaluate ~~its effect~~ the effect of BioNO emissions on atmospheric chemistry, we conducted two different simulations which are listed in Table 1. The simulations cover the period from January 2010 to February 2013, which includes a variety of climatic conditions  
230 and seasonal variations. The first two months are used as spin-up time for both experiments and are not considered in the analysis of the results.

1. BASE run: ~~BASE-run:-~~With biomass burning and anthropogenic emissions, without BioNO emissions.
2. BIONO run: With biomass burning, anthropogenic emissions and BioNO emissions.

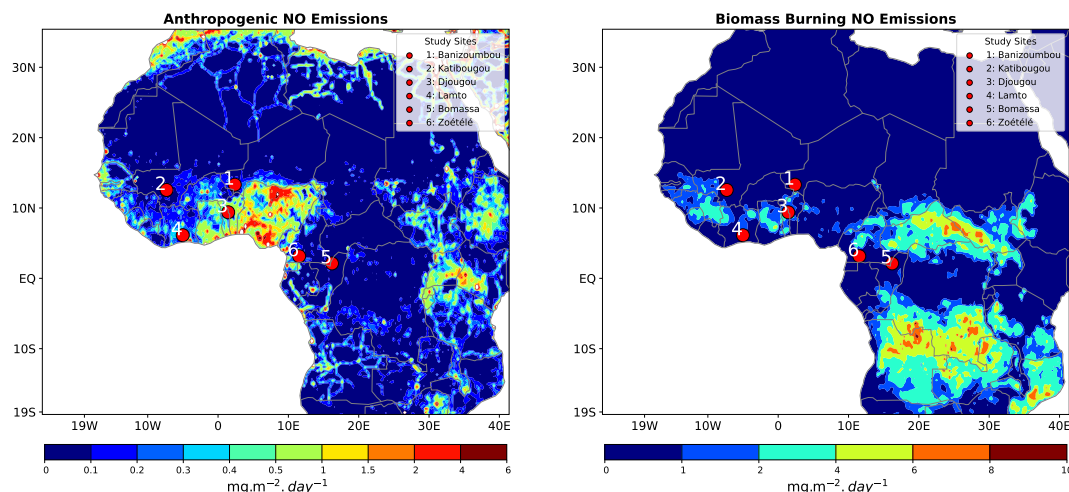

The model ~~is has a spatial resolution of~~ 30 km ~~\*x~~ 30 km ~~in longitude and latitude~~, with 35 vertical levels from the surface to  
235 3.6 hPa. The ~~corresponding~~ model time step is 210 s.

The model domain extends from 19.35°S to 35.48°N in latitude and from 24.98°W to 41.65°E in longitude, covering a large portion of the African continent. This domain was carefully selected to encompass key climatic and atmospheric processes relevant to the study, including the West African Monsoon, the Saharan Heat Low, and regions strongly influenced by biomass burning and anthropogenic emissions. While it does not cover the entire continent, the domain focuses on the most active  
240 regions for BioNO emissions and includes all of the INDAAF measurement sites used for model evaluation. Figure 1 shows the model domain and the locations of the INDAAF measurement sites.

## 3 Data and study sites

### 3.1 Study sites and ground-based observation of pollutants

**Figure 1.** Annual anthropogenic and biomass burning NO ~~emission-emissions~~ (averaged over ~~2010-2013~~2010–2013) and INDAAF measurement site locations, showing the full extent of the model domain used in the simulations. Measurement sites ~~localization-~~include Banizoumbou (Ba), Katibougou (Ka), Djougou (Dj), Lamto (Lam), Bomassa (Bom), and Zoétéle (Zoe).

265 ~~Monthly mean concentrations (used here as reference) are derived from the duplicates' means~~At each INDAAF site, two  
passive samplers are exposed simultaneously to ensure reproducibility, and the monthly concentrations are calculated as the  
average of these duplicate samples (Ossohou et al., 2023). Upon completion of the exposure period, all samplers, including  
field blanks, undergo laboratory analysis using ionic chromatography. ~~The LAERO bi-annualy~~LAERO has participated in the  
bi-annualy WMO-GAW (World Meteorological Organization - Global Atmosphere Watch) quality assurance program since  
270 1996, ~~evaluating which evaluates~~ the precision of ionic chromatography measurements for trace compounds~~twice-yearly~~. Re-  
sults, accessible under reference number 700106 at (QA/SAC - Americas, 2025), consistently demonstrate analytical precision  
of 5% or better for all ions. Additionally, the measurement accuracy of passive samplers, assessed through covariance with  
duplicates, was estimated at 9.8% for NO<sub>2</sub>, 20% for HNO<sub>3</sub>, and 10% for O<sub>3</sub> (Adon et al., 2010). Detection limits, determined  
using the exposure period and field blanks for the studied duration, are reported as 0.2 ± 0.1 ppb for NO<sub>2</sub>, 0.07 ± 0.03 ppb for  
275 HNO<sub>3</sub>, and 0.1 ± 0.1 ppb for O<sub>3</sub>.

### 3.2 Climatic and chemical evaluation datasets

For further model evaluation, we use a variety of sources, including data from meteorological stations and satellites, as well  
as reanalysis products. Table 3 summarises information about ~~all~~the variables used from each database. Precipitation data

are obtained from the Tropical Rainfall Measuring Mission 3B42-version 7 (TRMM; Huffman et al., 2007). Temperature data are sourced from the Climatic Research Unit version TS4.03 (CRU; Harris et al., 2020). For circulation dynamics, we use data derived from the ~~European Environment Agency~~ ECMWF (European Centre for Medium-Range Weather Forecasts) Reanalysis version 5 (ERA5; Hersbach et al., 2020). CRU data is exclusively based on in situ observations, while TRMM data originates from satellite observations. As mentioned above, ERA5 reanalysis data is derived from a combination of in situ measurements and satellite observations assimilated in a Numerical Weather Prediction model simulation. By using ~~different~~ multiple sources of observational data (in situ and satellite) as well as reanalysis estimates, ~~for we are able to quantify and account for uncertainties in parameter estimates~~ (precipitation (Pr), wind field (U,V, and W), and 2 m surface temperature (T); ~~we account for associated uncertainties, particularly in West Africa~~). This is particularly relevant for Africa due to the limited availability of in situ measurements and the complexity of the regional climate.

**Table 3.** Summary of validation data for physical parameters.

	TRMM	CRU	ERA5
Variables	Pr	T	T, U, V et W
Spatial resolution	0,25°	0,5°	0.25°
Spatial coverage	Ocean/Land	Land	Ocean/Land
Period	1997-2020 (6H)	1901-2018 (mensual)	1940-present (6H)

For the chemical evaluation, ~~the model outputs were~~ model outputs are compared with the INDAAF in-situ measurement database. To complement this local evaluation we also compare ~~the model model outputs~~ to CAMS chemical reanalysis (~~Inness et al., 2019; Wagner et al., 2021~~), and ~~data~~ (~~Inness et al., 2019; Wagner et al., 2021~~), to outputs from the ~~state-of-the-art~~ state-of-the-art chemistry transport model GEOS-Chem (~~Goddard Earth Observing System Chemistry;~~), and (~~Goddard Earth Observing System~~), and to ground-level NO<sub>2</sub> concentrations derived from OMI and TROPOMI satellite NO<sub>2</sub> observations (Cooper et al., 2022). GEOS-Chem is a global 3D Chemical Transport Model (CTM) driven by assimilated meteorological observations from NASA’s Goddard Earth Observing System (GEOS). It ~~addresses atmospheric composition issues across models~~ the atmospheric chemical composition at both local to global scales.

CAMS (Copernicus Atmosphere Monitoring Service) provides chemical reanalysis data by assimilating diverse observational sources, including satellite and in-situ measurements, which improves the accuracy of the simulated chemical ~~fields~~ species. The ground-level NO<sub>2</sub> concentrations ~~were~~ are derived from OMI and TROPOMI satellite observations (Cooper et al., 2022). Initially determined using OMI, these NO<sub>2</sub> column densities ~~were~~ are downscaled using TROPOMI, then converted to surface concentrations with the GEOS-Chem model, ~~constrained by~~ and constrained using ground monitoring data (Cooper et al., 2020, 2022). Both CAMS and GEOS-Chem are subject to ~~their own~~ model uncertainties, however ~~with an added observational~~

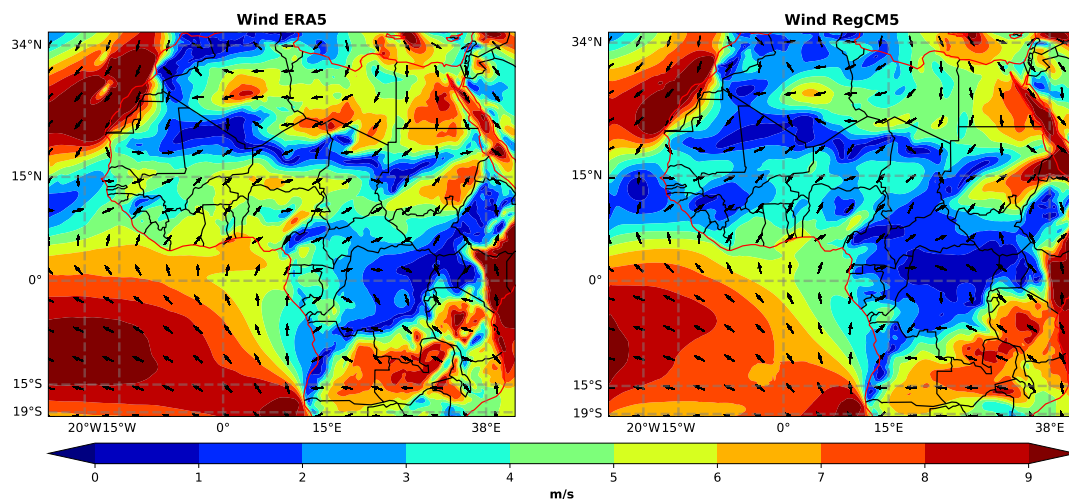

~~constraint in the case of CAMS reanalysis. CAMS includes an additional observational constraint which reduces uncertainty compared to the GEOS-Chem model. The calculation of the TROPOMI-derived NO<sub>2</sub> data also carries uncertainties introduces~~  
305 ~~uncertainty~~, particularly in the conversion from column ~~densities to surface concentrations, which may introduce discrepancies density to surface concentration~~. These include potential errors in satellite retrievals ~~data~~ and air mass factor calculations.

#### 4 Regional Climate validation

The ~~simulation of African climate by the model~~ ability of the RegCM5 model to accurately simulate the African climate is evaluated in terms of seasonal and daily ~~mean for the means over the period of 3 simulated~~ years. An exhaustive analysis of  
310 climate simulations is out of the scope of this paper. We report here model performance in terms of temperature, precipitation and monsoon circulation, which are key features of the African climate ~~, strongly impacting and strongly impact~~ atmospheric chemistry.

Figure 2 compares the ERA5 reanalysis to simulated mean wind at 850 hPa i.e. in the monsoon layer. ~~Overall the model~~ RegCM5 manages to reproduce the main features of the monsoon circulation with a mean characteristic southwesterly flow  
315 ~~up to about of up to~~ 17°N, and Harmattan-like circulation over northern Africa. However ~~RegCM5~~, the model tends to underestimate the intensity of the mean monsoon flow from the Gulf of Guinea to the Sahel. The monsoon front and the Saharan Heat Low (SHL) are also reasonably captured by the RegCM5 model, although the SHL amplitude is ~~somehow~~ underestimated (Figure 2). This could explain or contribute to the weaker Monsoon flux and the ~~sahelian precipitation underestimation discussed further underestimation of sahelian precipitation discussed later~~ (Figure 3-c) ~~following~~, which is consistent with  
320 the connections described in Peyrillé et al. (2007), Lavaysse et al. (2009), Chauvin et al. (2010), Lavaysse et al. (2010) and Evan et al. (2015). Outside of the monsoon domain, the ~~central equatorial Africa wind minimum minimum central equatorial African wind~~ is consistently captured, ~~compared to the ERA5 data~~.

RegCM5 ~~mostly~~ captures the patterns and spatial gradients of the 2 m surface temperature from hot Sahara regions to colder tropical forests, ~~but with however, there is~~ a cold bias over the northern Sahel/Southern Sahara (~~range ranging from~~ -5 to -1  
325 °C) during the monsoon season (JJA: ~~June-July-August~~) (Figure 3-f). Attributing surface temperature bias to ~~specific causes is uneasy due to temperature a specific cause is difficult due to~~ surface-atmosphere interactions and feedbacks (Sylla et al., 2012; Tadross et al., 2006). For the Sahelian and Sahara regions ~~RegCM~~, RegCM5 shows a negative bias which is likely linked to a bias in the surface radiative budget, ~~depending which in turn depends~~ on simulated surface ~~SW and LW net radiation Shortwave (SW) and Longwave (LW) net radiation~~ (related to surface radiative parameters, ~~It may also be a result of~~ possible  
330 excessive high level cloudiness (e.g., Sylla et al., 2012; Zittis et al., 2016) or/and aerosol ~~for instance estimations~~ (e.g., Lavaysse et al., 2011; Wang et al., 2015). In the ~~heat low SHL~~ region, this cold bias is ~~likely consistent with consistent with a~~ weaker monsoon flux and ~~sahelian precipitation. In lower precipitation in the Sahel. In contrast, in~~ the equatorial region the temperature bias could be linked, ~~on the contrary~~, to excessive cooling induced by overestimated precipitations ~~values~~. Sylla et al. (2012) showed that cold bias in surface temperature is generally consistent with positive rainfall bias. Locally ~~the surface temperature overestimation~~, the overestimation of surface temperature over coastal central Africa has also been ~~noticed observed~~ by

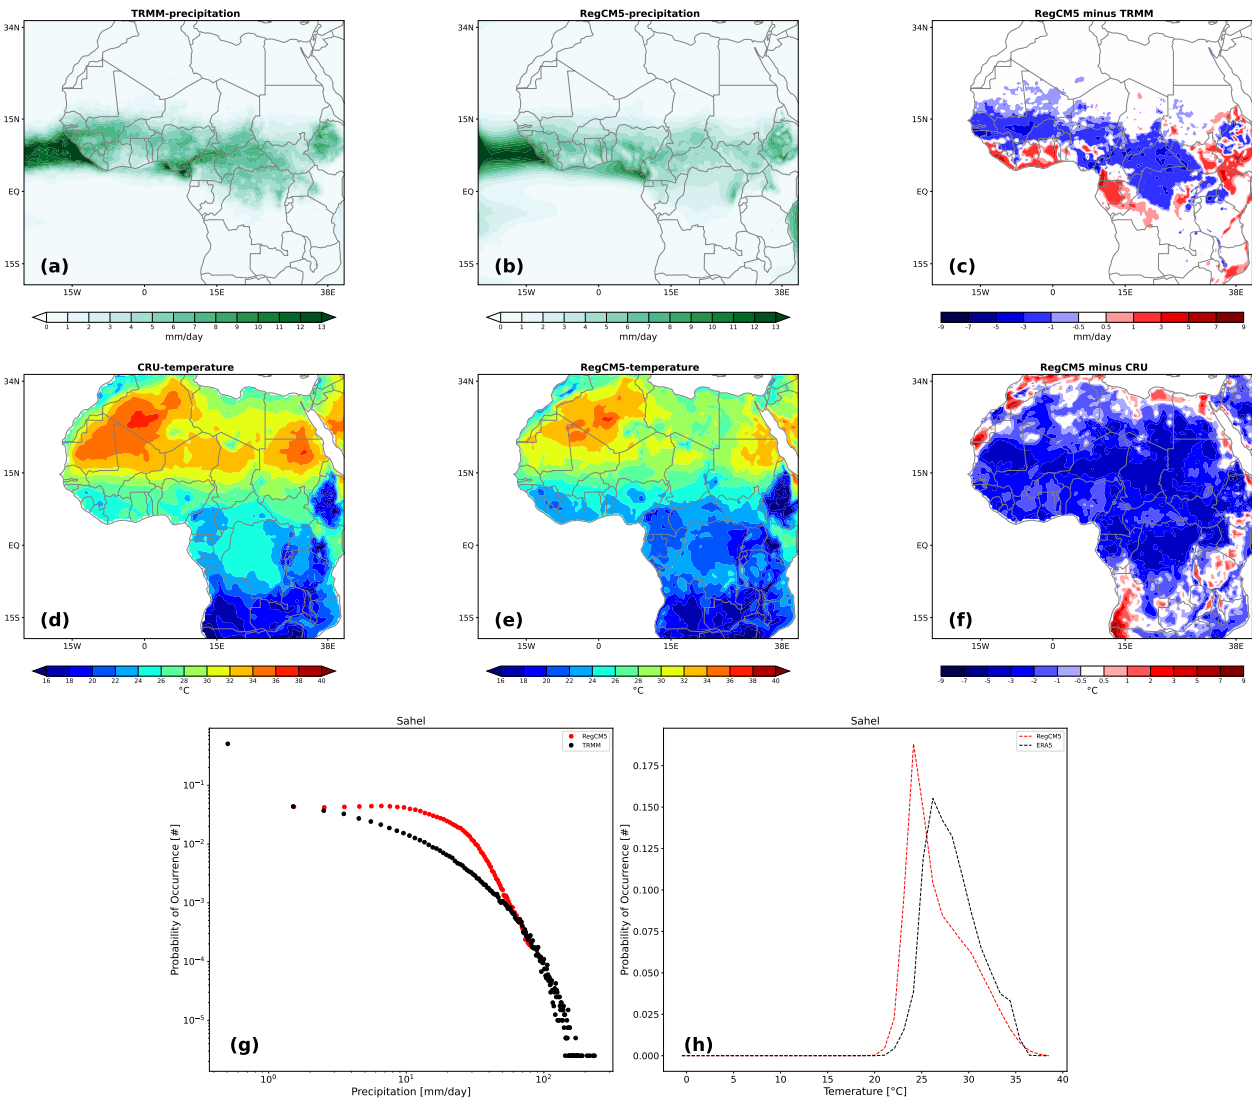

**Figure 2.** JJA (June-July-August) Monsoon wind speed at 875 hpa for ERA5 reanalysis and ~~RegCM~~ RegCM5 simulation.

Mbienda et al. (2023). This bias in Central Africa might stem from ~~an~~-inadequate modelling of the low-level cloud cover that is typical of this area (Philippon et al., 2019). For precipitation, simulated values vary from 0 to more than 13 mm/~~day~~.day<sup>-1</sup> over the study domain~~region~~, with a ~~consistent spatial/seasonal~~ spatial and seasonnl patterns of precipitation consistent with TRMM observations (Figure 3a-b)~~pattern of precipitation compared to TRMM observation. In general. In summary~~, the most predominant biases in our simulation are an underestimation ~~in-of~~ precipitation values in the Sahel and Central Africa, and an overestimation closer to equatorial regions (~~about~~ from -5 to -0.5 in Sahel/Central Africa and ~~from~~ 1 to 5 mm/day in the Cameroon Highlands). ~~We also observe~~ The RegCM5 model successfully reproduces the rain belt over the Sahelian region, associated with the InterTropical Convergence Zone (ITCZ), stretching from the mountains of Darfur in East Africa to the Guinea Highlands and downstream into the Atlantic. In some subregions, ~~observation~~ observational data sets do not fully agree.

For instance, in comparison to GPCP data, which is consistent with gauge-based precipitation datasets in Africa (Sylla et al., 2013b), TRMM data shows weaker ~~precipitations~~ precipitation values over East Africa~~and~~, the Guinea Highlands, and ~~over~~ the Cameroon Highlands (Nikulin\* et al., 2011; Nikulin et al., 2012). This variability amongst observations should be kept in mind ~~while when~~ evaluating the model~~results. As outlined in many studies, the model's results. Model~~ precipitation is extremely sensitive to the choice of parameter combinations used in the physics configurations, such as convection, land surface scheme, boundary layer, etc. The number of parameter combinations is large and model optimization is a complex and often time-consuming ~~issue (e.g., KhayatianYazdi et al., 2021). With the present set up, the main task (e.g., KhayatianYazdi et al., 2021).~~

Using the parameterization evaluated above, the precipitation and temperature biases remain reasonable, especially considering the range of bias shown by ~~state-of-the-art~~ state-of-the-art CMIP6 (Coupled Model Intercomparison Project phase 6) Global Climate Models and CORDEX (COrdinated Regional Downscaling EXperiments) RCMs for ~~the~~ African climate simulations (e.g., Buccignani et al., 2018; Zittis et al., 2016).

**Figure 3.** Summer (JJA) means Precipitation and Surface Temperature Biases (TRMM and CRU vs. RegCM5), and Frequency of Daily Temperature and Precipitation Events (ERA5, TRMM, and RegCM5). Units: Precipitation in mm/day, Temperature in °C.

For the west African region, Figure 4 shows a time-latitude Hovmoeller diagram of precipitation ~~zonally-averaged-averaged~~ within zones between 10°W and 10°E for the RegCM5 model and TRMM observational data. ~~Both in model and observations,~~

the ~~The~~ three characteristic phases of the African monsoon (Hourdin et al., 2010; Koné et al., 2022; Sultan et al., 2003) ~~are highlighted~~ can be observed in both the simulated results and the observational data. For TRMM, the onset of the rainy season occurs in mid-April and extends until mid-June, as evidenced by the core of the rainfall band along the Guinea coast between approximately 4° and 7°N, while the simulations show a delayed onset from mid-May to June with lower intensity rainfall. In TRMM observations, the monsoon phase itself is characterised by a shift of the rainfall maximum band, between July and September, reaching 15°N. For this phase, the simulations show a consistent northward precipitation shift, but the maximum does not penetrate as far north as in the ~~observation, in relation with the Sahelian precipitation underestimation observations,~~ consistent with the underestimation of Sahelian precipitation values pointed out earlier. The monsoon withdrawal is observed with precipitation gradually shifting towards the coast. The late season ~~precipitation~~-rainfall is more intense in our simulations compared to TRMM. ~~Again these~~ ~~These~~ characteristic seasonal patterns are ~~rather satisfactorily~~ ~~adequately~~ captured by the ~~model in reference to state-of-the-art~~ RegCM5 model compared to state-of-the-art climate models. ~~Beyond seasonal means, simulated~~ Simulated daily temperature and precipitation intensity ~~variability~~ are also analysed using Probability Density Functions (PDFs) (Giorgi et al., 2023) and compared to ERA5 and TRMM respectively. ~~These are presented here, for June-July-August of the study period, for the model and the observations in~~ In this paper, we include results for a 3 month period (JJA) over the Sahel region (Figures 3-g and 3-h ~~on the Sahel region, which has a particular meteorological regime for precipitation and where the relevant~~), as this region has a distinctive precipitation regime and presents the most important impact of BioNO ~~occuremissions~~: Sahel (10°W-10°E; 10°N-16°N).

For the daily temperature PDFs (Figure 3-h), the ~~model simulation captures~~ ~~simulated results are comparable to~~ the observed distribution, although ~~over the region~~, RegCM5 peaks are slightly shifted compared to the ERA5 data. ~~Overall we observe that simulated values between 20 and 30 °C appear with~~ In the simulated results we observe a high frequency ~~of occurrence (more than (>18 %) while we have of temperatures between 10 and 30°C, and less than 15 % for temperatures above of days with temperatures exceeding 30°C. However~~ Over the region presented here, ERA5 presents the higher frequency of occurrence ~~for high temperatures data has a higher frequency (2-16 %) of hot days (25-35 °C) over the region with 2-16 %, against (%) compared to simulated results (1-13 %for simulated values)~~. This can ~~also~~ be linked to the underestimation of temperature values shown by RegCM5 compared to ~~the observation observations~~ (Figure 3-f).

The corresponding precipitation PDFs are intercompared in Figure 3-g. ~~Overall~~, RegCM5 is close to TRMM in low (less than 10 mm/day) and high (more than 100 mm/day) precipitation intensities. ~~Over the domain, RegCM5 is characterised by, but~~ has higher frequencies of ~~mid-precipitation~~ ~~mid-precipitation~~ intensities (between 10 and 60 mm/day) than TRMM. For high precipitation intensities (more than 70 mm/day), simulated ~~precipitation intensity frequencies remain lower than the observed ones, consistently~~ frequencies remain slightly lower than TRMM values, which is consistent with the mean precipitation bias shown in Figure 4 (cold bias for ~~sahel~~ ~~the Sahel~~ region).

~~The simulation quality is considered at this stage good enough for supporting~~ After the evaluations discussed above, we consider that the performance of the simulation model is sufficiently good to support further analysis focusing on atmospheric chemistry.

**Figure 4.** JJA Hovmoller diagram of monthly precipitation ( $\text{mm}\cdot\text{day}^{-1}$ ) averaged between longitudes  $10^{\circ}\text{W}$  and  $10^{\circ}\text{E}$  of the study period.

## 5 BioNO fluxes

Since soil moisture is an important driver of microbial activity and BioNO emissions (Skopp et al., 1990), we ~~evaluated~~evaluate simulated soil moisture ~~compared-by~~comparing it to the Famine Early Warning Systems Network Land Data Assimilation System FLDAS (McNally et al., 2017, 2018) (Figure 5). As shown in the figure, JJA soil moisture is ~~larger~~greatest in subregions dominated by dense vegetation (~~Forests-forest~~regions:  $-7^{\circ}\text{N}$ - $4^{\circ}\text{N}$ ) and in regions where precipitation events are more intense. Despite the overall slight underestimation of simulated soil moisture compared to FLDAS observed data, especially in Saharan regions, ~~RegCM~~RegCM5 captures the spatial distribution of soil moisture both in DJF (December-January-February) and JJA. FLDAS integrates various observational datasets and uses advanced modelling techniques to provide soil moisture data, but its accuracy in arid regions like the Sahara ~~can be challenging~~is uncertain due to sparse in-situ data and the extreme dryness of the environment. Soil moisture data in such regions are often derived from remote sensing sources like microwave satellites, which can struggle with accuracy in arid zones where ground measurements are extremely rare (Rao et al., 2022). The ~~BioNO emission-spatial-distribution~~spatial distribution of BioNO emissions reflects the influence of the different explicative variables considered in the D2007 ANN. ~~Overall, in~~In both seasons, weak BioNO emissions in Saharan regions (above  $16^{\circ}\text{N}$ ), are associated with low N content, no N input, low soil moisture and ~~a high sand percentages~~sandy soils. A high ~~sand percentage~~percentage of sand in the soil leads to increased evaporation and drainage rates (Delon et al., 2008), which prevents the soil from retaining enough water to support the microbial processes responsible for NO emissions. Between  $8$  and  $16^{\circ}\text{N}$  (Sahel), ~~higher-BioNO-emission-spots-result-in~~locations with high BioNO emission result from a combination of large soil moisture, latitudinal distribution of soil pH(~~less-high~~), ~~and-significant~~, and important nitrogen input (shown in Potter et al., 2010).

410 The seasonal variability of Sahelian emission hot spots is mostly driven by soil humidity ~~as illustrated on~~, as illustrated in Figure 5. There is also a ~~significant~~ substantial canopy inhibition factor in the region of large LAI which ~~for example reduces forest emission~~, for example, reduces forest emissions to the atmosphere. As outlined in Delon et al. (2008), the Artificial Neural Network (ANN) algorithm used in this study tends to be more suitable for the Sahel region compared to forested region because it is primarily trained on data from semi-arid regions and temperate zones, ~~making it more uncertain in forested regions~~

415 ~~where the environmental conditions and soil characteristics differ significantly~~. In forested areas, factors such as dense canopy cover (affecting soil temperature and moisture), higher organic matter content (affecting nitrogen cycling dynamics), and different microbial communities influence soil processes and NO emissions (Davidson et al., 2000; Pilegaard, 2013) differently compared to semi-arid and temperate zones. This discrepancy highlights the need for further region-specific training data to improve the model's accuracy in diverse ecosystems.

420 The limited flux measurements for BioNO emissions in Africa make a systematic evaluation of the model challenging. In this study, simulated BioNO emissions range from 0.02 to 7 mg.m<sup>-2</sup>.day<sup>-1</sup>, ~~i.e. corresponding to seasonally averaged flux values ranging~~ from 0.1 to 37.52 ngN.m<sup>-2</sup>.s<sup>-1</sup> ~~as seasonal averaged flux over the domain~~. This is within the range ~~given by found by both~~ Delon et al. (2008) (from 0.43 to 6.52 mg.m<sup>-2</sup>.day<sup>-1</sup>) and Davidson and Kingerlee (1997) (from 0.5 to 28 ngN m<sup>-2</sup>.s<sup>-1</sup>). The simulated BioNO ~~are also rather consistent with the measured fluxes values are also consistent with~~

425 measured values from the flight B227 observed data of the British Aerospace 146 (BAe-146) under the Facility for Airborne Atmospheric Measurements (FAAM) program: 0.8 to 35 ngN m<sup>-2</sup>.s<sup>-1</sup>, but remain greater than ~~the Ganzeveld et al. (2002) estimation estimations from Ganzeveld et al. (2002) for the Sahel region: 2.32 to 11.6 ng N.m<sup>-2</sup>.s<sup>-1</sup>, for the Sahel region~~. Our simulated BioNO are in ~~better~~ good agreement with NO fluxes from soil emissions measured during the DACCIWA field campaign West Africa) in June and July 2016, which ranged from 0 to 48.39 ngN m<sup>-2</sup>.s<sup>-1</sup> (Pacifico et al., 2019). Feig

430 et al. (2008) also obtained NO flux fields ~~from in the range of~~ 4.7 to 27.01 ngN m<sup>-2</sup> s<sup>-1</sup>, but for South ~~Africa. The summary of all these estimates can be found~~ Africa. A summary of these estimates is presented in table 4 ~~and additional~~. Additional measurements of BioNO emissions from wet African savannas can be found in table 7 of Delon et al. (2012).

~~As for the~~ Over the whole simulation domain, the total amount of nitrogen emitted ~~from BioNO on the whole domain, simulated values range from~~ due to BioNO emissions range between 0.01 ~~to and~~ 4.4 TgN.month<sup>-1</sup>. If we downscale for the Sahel

435 region (~~10°W-10°E, 10°N-20°N, and 10°W-10°E, 10°N-20°N, corresponding to an~~ area of 2.3 10<sup>6</sup> km<sup>2</sup>) as done in Stewart et al. (2008), the simulated emissions ~~amount ranged range~~ from 0.0006 to 0.23 TgN. month<sup>-1</sup>. This value is consistent with ~~Stewart et al. (2008) both~~ Stewart et al. (2008)'s estimates of 0.03 to 0.3 TgN for 2 months (July and August) and Yan et al. (2005)'s estimates of 1.373 TgN.yr<sup>-1</sup> for ~~the entire all of~~ Africa. Delon et al. (2010) ~~also showed~~ calculated an annual estimate of 0.35 TgN. yr<sup>-1</sup> over the Sahel region. ~~Vinken et al. (2014) showed on the same domain (Sahel) an annual total of~~ Over

440 the same region (the Sahel), Vinken et al. (2014) estimated total annual BioNO emissions to be 0.52 TgN. yr<sup>-1</sup> ~~with~~, using a top-down soil NO<sub>x</sub> emission inventory for 2005 based on retrieved tropospheric NO<sub>2</sub> column from the Ozone Monitoring Instrument (OMI).

Our total ~~estimated amount is~~ estimate is also consistent with Williams et al. (2009) ~~estimated BioNO in~~, who estimated BioNO emissions for the same Sahel region (0.575 TgN. yr<sup>-1</sup>) ~~which is~~ based on biogenic emission inventories provided by Granier

**Figure 5.** Simulated BioNO emissions (in mg.m<sup>-2</sup>.day<sup>-1</sup>) and Soil Moisture Comparison for DJF and JJA Seasons: Analysis Using FLDAS Noah Land Surface Model L4 for 10-40 cm Soil Depth (in %).

et al. (2000) and Lathiere et al. (2006). It's worth noting that our estimated emission fluxes, particularly in the Sahel region, are higher than those reported by Simpson and Darras (2021) which were calculated using the EMEP MSC-W model (Meteorological Synthesising Centre – West of the European Monitoring and Evaluation Programme), part of the Copernicus Atmosphere Monitoring Service (CAMS) project. Their estimates ranged from 0 to 3.5 mg m<sup>-2</sup> day<sup>-1</sup> over the study period and region. The In our study, the ANN algorithm incorporates ,here-additional surface controlling parameters, which may explain the higher-emission-fluxes-obtained-in-our-study why our model higher emission estimates.

**Table 4.** Summary of some BioNO emissions estimates from litterature

Regionc/Biomes	Range of fluxes (ngN.m <sup>-2</sup> .s <sup>-1</sup> )	Period	Citation
Sahel	2.32 - 35.29	August 2006	Delon et al. (2008)
Sahel	2.32 - 11.6	-	Ganzeveld et al. (2002)

**6 ~~RegCM~~RegCM5 simulations and the impact of BioNO emissions**

**6.1 Regional and local nitrogen**

**6.1.1 NO<sub>2</sub> concentration**

455 We first analyse the simulated seasonal surface nitrogen (NO<sub>2</sub> and HNO<sub>3</sub>) concentrations for the BASE run over the domain, in comparison with the CAMS reanalysis (Inness et al., 2019; Wagner et al., 2021) and outputs ~~coming from Geos-Chem model.~~ Simulated from the GEOS-Chem model. The variability of simulated NO<sub>2</sub> concentration ~~'s variability~~ over the domain of interest is primarily driven by regional biomass burning emissions ~~.We thus note (see Figure 1).~~ We hence observe consistent spatial and seasonal patterns between ~~RegCM~~RegCM5 simulations, CAMS and the ~~Geos-Chem~~GEOS-Chem model (Fig-  
460 ure 6) reflecting the ~~broad-general~~ spatial agreement between the different biomass burning emission inventories considered in these models. However, sub-regional details, for instance over west Africa, can be clearly distinguished in the higher resolution models ~~against coarse Geos-Chem~~(RegCM5 and CAMS) but not in the coarser GEOS-Chem model. Compared to the CAMS reanalysis and to ~~Geos-Chem, the RegCM-BASE shows~~GEOS-Chem, the RegCM5-BASE estimates lower surface NO<sub>2</sub> concentrations (about 0.7-0.9 ppb ~~below less~~), especially in the Sahel regions during the summer. In the Biomass burning regions  
465 (see Figure 1), these differences are less visible. The biomass burning regions, which are primarily located in the central (in DJF) and southern (in JJA) parts of Africa, are areas where extensive burning occurs.

This difference in NO<sub>2</sub> concentration ~~magnitude~~ can be attributed to ~~possible~~ differences in NO emissions (biomass burning, anthropogenic inventories and BioNO) as BioNO emissions were not accounted for in the BASE simulation (cf section 2.3).  
470 Indeed, CAMS includes BioNO emissions from a fixed climatology based on the Precursors of Ozone and their Effects in the Troposphere (POET) database for 2000 (Granier et al., 2005) inventory, while GEOS-Chem parameterizes soil NO emissions dynamically using the Hudman et al. (2012) scheme. Differences in biomass burning injection heights and nitrogen fluxes considered in ~~RegCM~~RegCM5 versus CAMS and ~~Geos-Chem~~GEOS-Chem could also explain differences in surface con-

centrations. The introduction of BioNO fills this gap to some extent, by increasing surface NO<sub>2</sub> ~~concentration, bringing it~~  
~~concentrations, bringing them~~ closer to, ~~or even and sometimes~~ exceeding CAMS values (Figure 6b,f). This is especially  
475 apparent in transitional ecosystems such as savannas and grasslands (~~see supplementary Figure S1~~). To assess the potential im-  
portance and to quantify the impact of BioNO ~~emission emissions~~ on lower troposphere NO<sub>2</sub>, ~~Figure 7 shows the we considere~~  
~~he~~ difference between the BioNO and the BASE simulations ~~previously described~~(Figure 7). The plots are shown ~~on for~~ a  
vertical cross section averaged between -10 and 10 °E, from 4 to 21 °N.

~~When comparing The comparison between~~ RegCM5 ~~results to the TROPOMI-derived annual mean ground-level simulations~~  
480 ~~and satellite-derived~~ NO<sub>2</sub> ~~concentrations (8) over the period 2010-2013, it becomes apparent that the model generally performs~~  
~~well in capturing the spatial patterns of NO2 across the region, particularly in transitional ecosystems where the impact~~  
~~of BioNO is significant. However, the model tends to overestimate data highlights both the strengths and limitations of the~~  
~~model (Figures 8 and 9). The model simulation is evaluated against two observational datasets. The first dataset corresponds~~  
~~to ground-level~~ NO<sub>2</sub> concentrations ~~compared to the TROPOMI observations. This overestimation could be attributed to~~  
485 ~~several factors, including the representation of biogenic and biomass burning emissions in the model, as well as the inherent~~  
~~uncertainties in the satellite-derived data. As detailed by Cooper et al. (2022), uncertainties in the conversion of satellite-observed~~  
~~derived from OMI (Ozone Monitoring Instrument) and TROPOMI (TROPOspheric Monitoring Instrument) satellite NO2~~  
~~observations (Figure 8), following the methodology of Cooper et al. (2022). In this approach, NO2 column densities into~~  
~~surface concentrations can lead to discrepancies. These uncertainties include potential errors of around 10% in the retrieval of~~  
490 ~~slant columns from satellite radiances and errors ranging from 23 to 37% in the calculation of air mass factors. Moreover, the~~  
~~use of ground-monitor data to constrain the model may introduce biases, particularly in regions with sparse monitoring data.~~  
~~These factors suggest that while RegCM provides a reasonable representation of NO2 distribution, the apparent overestimation~~  
~~relative to TROPOMI may also be partly due to these uncertainties in the satellite-model processed data.~~

Comparison of BASE and BIONO simulations of annual mean surface NO<sub>2</sub> concentrations (ppb) against OMI and OMI/Aura-derived  
495 ~~tropospheric NO2 columns over 2010-2013, and associated Pearson spatial correlation. In this study, we also compare the~~  
~~RegCM5 simulations to the~~ ~~for each year are first determined using OMI observations, then downscaled to a finer resolution~~  
~~using TROPOMI data, and finally converted into surface-level NO2 concentrations using the GEOS-Chem chemical transport~~  
~~model constrained by ground-based measurements. The resulting dataset provides annual mean NO2 concentrations at a~~  
~~resolution of approximately 1 km x 1 km. The second dataset consists of OMI/Aura-derived tropospheric NO2 columns (-)~~  
500 ~~NO2 columns (Lamsal et al., 2021) over the period 2010-2013 (Figure 9). The satellite data come from the Level-3 daily global~~  
~~gridded 0.25 x 0.25 x 0.25 degree OMI NO2 product (OMNO2d), which provides total and tropospheric NO2 columns for all~~  
~~atmospheric conditions and is cloud-screened for sky conditions where cloud cover is less than 30 %. With its high spatial~~  
~~resolution (0.25° x 0.25°), this dataset is well-suited for studying large-scale NO2 distributions in the troposphere. It becomes~~  
~~clear that the model The RegCM5 model simulation~~ captures the general spatial distribution of NO<sub>2</sub> across the region. ~~Both~~  
505 ~~the model and the satellite data Model results and satellite data both~~ show high concentrations of NO<sub>2</sub> in areas such as Sahel  
and ~~forests forested~~ regions, where biomass burning plays a ~~significant role. The preponderant role (see Figure 1). However,~~  
~~the model overestimates NO2 levels compared to both TROPOMI-derived surface NO2 and OMI-derived tropospheric NO2~~

columns, particularly when BioNO emissions are included. This overestimation could be due to several factors, including the way in which biogenic and biomass burning emissions are represented in the model, and the inherent uncertainties in the satellite-derived data. The use of ground-monitoring data to constrain models may introduce biases, particularly in regions with sparse monitoring data. On the other hand, as detailed by Cooper et al. (2022), uncertainties in the conversion of satellite-observed NO<sub>2</sub> column densities into surface concentrations can lead to errors. These uncertainties include potential errors of around 10% in the retrieval of slant columns from satellite radiances and errors ranging from 23 to 37% in the calculation of air mass factors. Thus, the apparent overestimation of NO<sub>2</sub> by RegCM5 compared to TROPOMI (Figure 8) may not only result from model biases but also from the uncertainties in the processing of satellite data. In addition, a spatial correlation analysis shows moderate agreement between the RegCM5 simulations and the ~~satellite-derived data~~ OMI/Aura-derived tropospheric NO<sub>2</sub> columns (Figure 9). Specifically, the Pearson Correlation Coefficient (PCC) indicates a correlation of ~~0.32~~ 0.41 when excluding BioNO emissions (~~No-BioNO~~ BASE run) and a correlation of ~~0.22~~ 0.37 when BioNO emissions are included in the simulation. This suggests that the addition of BioNO emissions reduces the overall correlation with the OMI observations. One potential explanation for this reduction could be ~~related to the fact~~ that OMI measures the entire tropospheric column, ~~which may not fully capture while the model's representation of NO<sub>2</sub> distribution may be influenced by uncertainties in vertical mixing and emission sources. In particular,~~ diffuse biogenic emissions or localized sources (e.g., Osohou et al., 2019) ~~that contribute to near-surface concentrations represented in the model may not be fully captured in the satellite retrievals, potentially affecting the correlation.~~ Despite some discrepancies in specific regions, the spatial correlation suggests a reasonable alignment of NO<sub>2</sub> patterns between the model and the satellite observations, particularly in regions where biomass burning and other large-scale processes dominate.

~~The effect of BioNO emissions from~~ At the regional scale, the effect of incorporating BioNO emissions using the ANN algorithm ~~at the regional scale~~, leads to an overall increase in NO<sub>2</sub> seasonal mean concentrations ranging from 0 to 2-4 ppb. This increase also ~~extends to~~ appears in the lower troposphere, as illustrated in Figure 7. The maximum increase occurs over the Sahel region (especially 10-21°N) and can reach up to 3 ppb in JJA, ~~consistently~~ consistent with increased BioNO fluxes in this region. We ~~can~~ note a general positive correlation between the BioNO ~~fluxes~~ emissions (Figure 5a,d) and the difference ~~BIONO-BASE~~ between the BIONO and BASE simulations at the surface level (Figure 16a,d). This increase in surface NO<sub>2</sub> concentrations over the domain is consistent with Delon et al. (2008) ~~results who report that,~~ who report a local BioNO induced NO<sub>2</sub> increase by up to 0.9 ppb at 4°E and between 7°N-21°N for August. Based on global simulations, Steinkamp et al. (2009) found an increase in global NO<sub>x</sub> mean mixing ratio in the lower troposphere reaching 7 and 17 % for DJF and JJA respectively.

~~DJF and JJA differences (BIONO-BASE) in NO<sub>2</sub> (a, d), HNO<sub>3</sub> (d, e) and O<sub>3</sub> (e, f) concentrations, on the transect 4-21°N averaged between 10°W-10°E. Units are in ppb.~~ To further examine the simulated NO<sub>2</sub> concentrations, we compare the simulated results with monthly ~~averaged~~ average surface concentrations from the INDAAF stations. Simulated outputs at the lower model level (around 40 m above the ground level) are interpolated to the site locations for the simulated period. BIONO and BASE biases (based on the 3-years monthly-averaged mass concentration) (Table 5) and correlation with observations (Figure 11) were calculated for the pollutant NO<sub>2</sub> at the corresponding stations.

Figures 10 and 11 show that the BASE model ~~experiment tends to generally underestimate the~~ simulation tends to underestimate NO<sub>2</sub> concentrations except for december-january in wet savannas (Lamto, Djougou). This is also ~~generally~~ the case for the CAMS reanalysis (Figure 10). RegCM5-BASE NO<sub>2</sub> concentrations ~~tend to be underestimated especially are especially~~ underestimated over dry savannas (Banizoumbou, Katibougou) in the wet season, where the maximum negative bias recorded ~~could reach is~~  $\approx -4$  ppb in June and October at the Banizoumbou site. Mostapha et al. (2019) used the ~~RegCM4-CHEM~~ RegCM4 model and also showed that the model mostly underestimates, compared to the Greater Cairo observation data (Egypt), the monthly averages of NO<sub>2</sub> concentrations at four representative sites, with maximal underestimation in April. Taking into account BioNO emissions has a very ~~significant~~ considerable impact on reducing the dry savanna's wet season bias, as illustrated ~~on in~~ figures 10 and 11. Figure 10 suggests that this reduction can ~~bring for instance the model reduce the~~ model's maximum negative bias to  $\approx -3.94$  ppb when BioNO are accounted for, vs -4.62 ppb in the BASE run, in ~~July-June~~ at Banizoumbou. ~~We can however notice on figure 9~~ Even though this reduction lowers the bias, it remains high and is also observed in the CAMS reanalysis (-3.85 ppb) and the state-of-the-art model (GEOS-Chem : -4.54 ppb) for the same month and site (See Table 5). We can observe in figure 10 that the model (BIONO run) tends to produce maximum ~~concentration~~ concentrations in the middle of the rainy season, while the observations ~~tend to~~ show that maximum ~~NO2-NO<sub>2</sub>~~ concentrations occur at the beginning and end of the wet season (in a sort of bi-modal pattern). This could be due to a nitrogen pool limitation not accounted for by the ANN approach, which reacts only to environmental conditions. Indeed, soil N content in the Sahel shows a maximum at the end of the ~~rain-rainy~~ season when senescent herbaceous biomass begins to decompose, leading to increased BioNO fluxes (not represented ~~by in~~ the model). The temporal distribution of rain events might ~~be also at play here;~~ with peak of emissions occurring preferentially also be at play, with emission peaks occurring for rainfall events consecutive to a dry period, which are more likely at the beginning and end of the rainy season (Gasche and Papen, 1999; Hickman et al., 2018; Johansson et al., 1988; Jaeglé et al., 2005; Yienger and Levy, 1995).

For wet savannas, the model ~~and measurements are rather consistent in the BASE run is consistent with observed measurements~~ for the BASE simulation. During the dry season, positive biases are present in the BASE run for wet savannas (unlike dry savannas), ~~ranging and range~~ between 0.2 and 1.6 ppb. The highest NO<sub>2</sub> surface concentrations in the dry season are linked to biomass burning emissions (Oppenheimer et al., 2004; Van Marle et al., 2017). Moreover, Ossohou et al. (2019) ~~suggested~~ suggest that NO<sub>2</sub> concentrations in the dry season could be ~~mainly attributed due~~ to the intensity of biomass burning sources in all of the six sites except Banizoumbou and Katibougou. This ~~context~~ helps to explain the observed positive biases, which ~~might may~~ be enhanced by ~~the addition of BioNO emissions. While BioNO emissions lead including BioNO emissions in~~ the model. While including BioNO emissions leads to a small improvement in ~~simulations~~ simulation results, especially for the Lamto station ~~during both wet and dry seasons~~, they tend to worsen ~~these biases~~ biases at wet savanna sites. For instance, the maximum positive bias is increased by 1.2 ppb in January at the Djougou site ( 79.9% increase in bias). The BioNO emissions are possibly overestimated due to ~~larger, and excessive ,~~ a larger and excessive response of the ANN to soil moisture in wet savanna compared to dry savanna in both seasons (Figure 5), ~~which can also combine with and which may be accentuated by a~~ smaller canopy reduction factor when compared to forested regions. Similarly, GEOS-Chem model also displays positive biases in the dry season of wet savannas, particularly in Djougou, where the bias reaches 0.99 ppb in January. This suggests that the

~~overestimation could be a systematic issue across models, potentially due to uncertainties in emissions or local photochemistry.~~

For tropical/transition forest ecosystems, both the BASE simulation and CAMS reanalysis show a ~~significant-notable~~  $\text{NO}_2$  underestimation compared to INDAAF measurements. The discrepancies observed in the BASE and CAMS simulations could be ~~influenced-by~~ due to several factors, including the representation of  $\text{NO}_x$  sources, such as anthropogenic emissions, near the surface and regional chemical processes. ~~GEOS-Chem also underestimates  $\text{NO}_2$  concentrations in these sites, with biases reaching -1.94 ppb in January at Bomassa, which are comparable to the BASE (-0.80 ppb) and CAMS (-2.15 ppb) biases.~~ Furthermore, INDAAF stations are often located in areas with strong simulated  $\text{NO}_2$  gradients (~~BIONO-run~~ Figure 6b and 6f), particularly in DJF, where even slight spatial discrepancies could lead to ~~significant-notable~~ differences between simulated and observed levels (This is the challenge of regional representativity of the INDAAF stations). The ~~introduction-inclusion~~ of BioNO emissions in the simulation helps to reduce these discrepancies by ~~enhancing-increasing~~  $\text{NO}_x$  concentrations, which in turn brings the simulated ozone levels closer to ~~those-observed~~ observed levels (Figures 10 and 11).

### 6.1.2 $\text{HNO}_3$ concentration

~~On Figure 12, simulations exhibit in general~~ Simulations exhibit a consistent representation of  $\text{HNO}_3$  spatial distributions between the different models. ~~While RegCM concentrations are rather~~ (Figure 12). While RegCM5 concentrations are quite close to CAMS in magnitude, both are ~~significantly smaller than Geos-Chem~~ substantially smaller than GEOS-Chem, in relation to the  $\text{O}_3$  fields as discussed later. Over the Sahel, the lower ~~JJA~~ simulated  $\text{HNO}_3$  concentrations for JJA (BASE run) are likely associated with the previously discussed underestimation of modelled  $\text{NO}_2$  in the regions ( $5^\circ$ - $20^\circ\text{N}$ ), since  $\text{HNO}_3$  is a product of  $\text{NO}_2$  oxidation. In general ~~for both seasons, BioNO contribute to~~ including BioNO emissions results in increased spatial concentrations of  $\text{HNO}_3$ , bringing ~~RegCM simulations closer to reanalysis and Geos-Chem as shown by Figure 12~~ RegCM5 simulation results closer to CAMS and GEOS-Chem (Figure 12).

~~According to Figure 7, When BioNO emissions are included in the model,~~ (the lower troposphere  $\text{HNO}_3$  increase can reach values increase by up to 0.3 ppb ~~with maximum increases correlated with strong~~ (Figure 7), and are correlated with large BioNO emissions (Figures 5a, 5d), as for  $\text{NO}_2$ . The effect of BioNO on  $\text{HNO}_3$  is ~~somehow less sensitive~~ smaller compared to  $\text{NO}_2$ . This sensitivity difference is likely due to chemical controls occurring through OH and  $\text{O}_3$  formation (Steinkamp et al., 2009).  $\text{HNO}_3$  formation pathways from  $\text{NO}_2$  involve the presence of oxidants such as OH and  $\text{O}_3$ , which are controlled by regional photo-oxidant chemistry and emissions. As a result, the impact of BioNO on simulated  $\text{HNO}_3$  is not as straightforward as for  $\text{NO}_2$ .

As for  $\text{NO}_2$ , both RegCM5 and CAMS show an overall large underestimation of  $\text{HNO}_3$  concentrations compared to available measurements ~~over for~~ nearly all INDAAF stations (Figure 13). The corresponding biases are large in the wet season and ~~smaller-small~~ in the dry season, when the contribution of biomass burning is more important relative to BioNO emissions (Figure 13/Table 6). The maximum bias, also obtaining in late June for wet season over dry savannas ~~is likely to be partially due, is likely due, at least in part,~~ to the same reasons ~~as~~ discussed previously for the monthly-averaged  $\text{NO}_2$  concentrations.

Lin et al. (2013) argue that enhanced soil emissions and higher  $\text{NO}_x$  oxidation ~~rate under warmer~~ rates under warm conditions

can generate high atmospheric  $\text{HNO}_3$ . Despite the ~~large remaining remaining large~~ underestimation, due to ~~the less sensitive smaller changes~~ improvement across all ecosystems, the addition of BioNO ~~emissions~~ in RegCM5 helps reduce the biases and brings the model ~~results~~ closer to the ~~observations-observed data~~ (Figure 13). Figure 13 indicates an overall increase at all ~~the~~ study sites and a reduction in negative bias: a maximum of -1.67 vs -1.73 ppb in June (3.51% reduction in negative bias) in dry savannas. ~~This underestimation is also observed in CAMS and GEOS-Chem models, particularly for June, where CAMS and GEOS-Chem biases reach -1.67 ppb and -1.11 ppb, respectively, in Katibougou. In wet savannas, we obtain a maximum negative bias of -0.77 vs -0.8 ppb in April (4.56% reduction in negative bias) in wet savannas, and around, and a~~ 2.27% reduction in negative bias over forests.

In addition to improving the ~~amplitude-magnitude~~ of surface concentrations at the six remote sites and across the region, the introduction of ANN on-line emissions also improves the spatial correlation between the simulated (~~RegCM~~RegCM5) and observed (INDAAF) concentrations. The BioNO induced enhancement is also associated with a more realistic seasonal evolution of  $\text{NO}_2$  and  $\text{HNO}_3$  surface levels when compared to INDAAF observations (Figures 11 and 14).

## 6.2 Regional and local Ozone

Together with transport, emission and deposition processes, ozone photo-chemistry regulates the content of nitrogen compounds in the atmosphere. Tropospheric Ozone simulation is ~~in general~~ very challenging due to numerous sources of variability and ~~uncertainties-uncertainty~~ (Young et al., 2018). Such simulations involve complex and interrelated factors, including precursor emissions, meteorological variability, ozone photochemical production and loss, surface deposition, long-range transport influence and stratosphere-troposphere exchange (Lelieveld and Dentener, 2000). In this section we discuss the ability of the model to represent regional ozone and the subsequent impact of BioNO emissions on regional ozone production. Figure 15 displays the regional surface ozone simulated by ~~RegCM5-CHEM~~RegCM5 for BASE and BioNO runs, compared to the CAMS chemical reanalysis and the ~~Geos-Chem model. The~~GEOS-Chem model.

A strong seasonality of surface ozone concentrations (winter vs summer) ~~is first highlighted-~~ can be observed (Figure 15). In the DJF season, strong ozone production occurs between  $5^\circ\text{N}$  and  $15^\circ\text{N}$  as a result of biomass burning activities. ~~RegCM5-CHEM shows a consistent spatial pattern (Figure 1). RegCM5 shows spatial patterns consistent~~ with CAMS and ~~Geos-Chem~~GEOS-Chem in terms of simulated surface concentrations, but with lower values in the source zones (~~Geos-Chem showing the larger concentrations with~~GEOS-Chem showing the largest concentrations among them). In areas where local chemical production is low, such as over the Sahara, long range and vertical ozone transport ~~essentially~~ primarily determines the background ozone level (e.g., Sauvage et al., 2005). We can outline here the added ~~values-value~~ of improved chemical boundary conditions, which set up a more realistic and climatically relevant seasonal ozone background ~~compared to CAMS reanalysis, while also accounting when benchmarked against the default approach, and also better account~~ for long range transport events at shorter time scale.

During summer months (JJA), we also observe consistency between the continental-scale surface ozone gradients simulated by RegCM5 and those from CAMS and ~~Geos-Chem~~GEOS-Chem. In northern Africa, there is a ~~only a~~ slight overestimation of ozone, which can be attributed to ~~enhanced-greater~~ vertical transport and mixing during the African mon-

645 soon(~~the south-to-north transport more effective, Sauvage et al., 2007~~). It can also be linked to the south-to-north transport being more effective during JJA (Sauvage et al., 2007), potentially combined with an overrepresentation of stratosphere-troposphere exchange and local photochemical production under strong solar radiation (Li et al., 2019). However, in the southern biomass burning regions, where ozone “hot-spots” are found (Sauvage et al., 2007), RegCM5 tends to simulate lower surface ozone concentrations compared to CAMS and more noticeably, to ~~Geos-Chem~~GEOS-Chem.

650 Focusing ~~here~~ on surface concentration ~~only~~ offers a limited view of actual model to model differences, and a deeper tropospheric ozone budget assessment would be required for a more systematic quantitative analysis, ~~which~~ but this is beyond the scope of this paper. Studies have shown that discrepancies in model ozone simulations ~~are in general~~ tend to be large in tropical regions. For example, a comprehensive ~~interecomparison between Geos-Chem~~ comparison between GEOS-Chem and CAM-chem (e.g., Lin et al., 2024) ~~highlighted significant~~ (Community Atmosphere Model-chemistry) (e.g., Lin et al., 2024)  
655 highlighted important differences in ozone budgets and vertical profiles due to variations in photolysis schemes, aerosol interactions, and convective transport processes. These differences can lead to variations in how ozone is transported vertically, impacting surface concentrations (e.g., Li et al., 2019). ~~Moreover, recent intercomparison~~ Recent comparative studies focusing on tropospheric ozone in various tropical regions, including Africa, confirm that such discrepancies are common and often linked to model-specific handling of emissions, injection heights and vertical dynamics (Huijnen et al., 2020; Lin et al., 2024).  
660 ~~For instance,~~ Tsvilidou et al. (2023) argue that it is essential to consider the combination of injection height of ozone precursors and the strong vertical mixing in the tropics which largely determine the surface ozone values. These factors, ~~along with the~~ together with non-linear interactions between  $\text{NO}_x$  and VOCs, including ~~the~~ uncertain biogenic emissions, must be carefully analysed when assessing model outputs.

Figures 16c and 16f illustrate the influence of BioNO emissions on the RegCM5 simulated surface  $\text{O}_3$  field. The consecutive production or depletion of  $\text{O}_3$  is not solely dependent on  $\text{NO}_x$  concentrations but also on the  $\text{NO}_x/\text{VOCs}$  ratio, which determines the ozone chemical regime ~~variable~~ in different subregions of the domain. At the regional to continental scale,  
665 and for both seasons, the introduction of BioNO leads to both an increase and a decrease in surface ozone production, with a predominantly increasing effect in the lower troposphere (Figures 7c,f and 16c,f). In regions coinciding with ~~intense BioNO emissions and large BioNO emissions,~~ for both seasons ~~there is however~~ there is, however, a notable negative impact on surface  
670  $\text{O}_3$ . This ~~decrease~~ reduction in ozone levels, which can reach up to 2 ppb, is likely due to ozone titration processes, ~~more~~ characteristic of VOC-limited conditions. In areas with ~~higher proportion of large~~  $\text{NO}_x$  emissions (here BioNO source areas),  $\text{O}_3$  formation can be VOC-limited or may shift between chemical regimes (~~Kleinman, 1994; Sillman and He, 2002~~) e.g depending on depending on, for example, the time of the day (~~Kleinman, 1994; Sillman and He, 2002~~).

As one moves away from these intense sources ~~towards the regional scale, the ozone average of  $\text{NO}_x$ , the average ozone~~ re-  
675 sponse shifts to being positive, reflecting the classical change in chemical regime downwind of the sources. An illustration of this process can be seen in JJA in the vertical wind (wa) monsoon region where intense Sahelian BioNO sources ~~decrease~~ locally locally decrease surface ozone but contribute to ~~a relative~~ an increase in downwind surface ozone ~~increase~~ in northern Sahel/southern Sahara (dipole pattern on Figure 16f). For this situation, the  $\text{NO}_x/\text{VOC}$  ratio decreases and the chemical regime becomes more  $\text{NO}_x$ -limited (Delon et al., 2008; Stewart et al., 2008). In DJF, the ~~surface ozone increase can reach~~

680 ~~approximately increase in surface ozone can reach up to~~ 4 ppb in the southern part of the domain, while in JJA, we observe increases of up to 3 ppb over the Sahel region and in eastern Africa. Over West Africa, ~~this influence extends into the the effects of the NO<sub>x</sub>-limited extend to the~~ lower troposphere, where an average increase in ozone concentration of up to 4 ppb is noted (Figure 7c,f). This pattern ~~aligns agrees~~ with findings by Delon et al. (2008), who observed that a moderate increase in NO<sub>x</sub> concentrations leads to a ~~sensitive small~~ increase in simulated ozone across all altitudes (0-15 km), characteristic of  
685 a NO<sub>x</sub>-limited regime. Several studies have shown that throughout much of the troposphere in a variety of tropical regions, including Africa, O<sub>3</sub> formation is predominantly NO<sub>x</sub>-limited ~~, meaning it largely depends on the availability of NO<sub>x</sub>~~ (e.g., Li et al., 2021; Tadic et al., 2021).

~~Regarding comparison with the INDAAF ozone ground measurements, Figure 17 indicates that, unlike the improvements observed for other species, the~~ A comparison with INDAAF ground measurements shows that the inclusion of BioNO emis-  
690 sions results in ~~minimal to no enhancement very little improvement~~ in simulated ozone concentrations at the local ~~level scale,~~ in contrast to the better performance observed for other species (see section 6.1) (Figure 17). However, a general reduction in bias, leading to better alignment between simulated and observed values, is observed for nearly all of the sites during the period from June to August. ~~In For example, in~~ dry savannas the maximum negative bias is ~~for instance~~ reduced by 83.38 % in June ~~over in~~ Banizoumbou (Table 7) ~~while the ozone increase can also contribute to worsen the positive bias(.~~ Nevertheless,  
695 BioNO emissions in some cases lead to an increased positive bias, for example +2.4 % in march ).-We at Banizoumbou. For the JJA period, in wet savannas and equatorial forests we observe an overall slight decrease in O<sub>3</sub> amplitude induced by BioNO over wet savannas and equatorial forests from June to August, which tends to only very moderately improve simulations concentrations when BioNO is included, corresponding to a very slight improvement in the simulated results. Over tropical ~~forest forests,~~ surface ozone concentrations are influenced by regional transport from burning areas, ~~and as well~~ as  
700 as local vertical exchanges between ~~surface and the surface and the~~ lower troposphere. ~~Model-measurement~~ A comparison with CAMS and GEOS-Chem shows that both models also struggle to accurately capture the observed ozone concentrations at INDAAF sites. For instance, in January over Zoétélé, CAMS and GEOS-Chem exhibit biases of 24.77 ppb and 49.95 ppb, respectively, which are noticeably high despite the models' advanced chemistry and assimilation techniques. This suggests that the discrepancies could be the result of broader model limitations in representing regional ozone dynamics. Comparing model  
705 O<sub>3</sub> ~~comparisons are not straightforward results to on-site measurements is straight-forward~~ due to the presence of an important tree canopy on measurement sites (~~;-~~) which can potentially ~~affects affect~~ both local dynamics and chemistry (e.g., Bryan and Steiner, 2013). Big leaf dry deposition schemes for ozone over tropical forests can only ~~crudely roughly~~ represent deposition processes, ~~while extra and other~~ chemical sinks within the canopy layer are ~~simply~~ not properly parametrized (Ganzeveld and Lelieveld, 2004; Sun et al., 2022). These deposition and chemical processes in the canopy should ~~potentially ideally~~ be ac-  
710 counted for to better explain the discrepancy between the simulations and the in situ observations, ~~and notably in particular~~ the fact that ozone observations are systematically much lower than model results ~~in general~~ (Figures 17 and 18).

## 7 Conclusion

RegCM5 is the latest released version of the ICTP regional climate model designed to conduct high-resolution regional climate simulations. In the broader context of on-going programs targeting the regional nitrogen cycle over Africa, we more specifically use and assess the related atmospheric chemistry module (~~RegCM5-Chem~~RegCM5), which has been substantially updated relative to previous versions. ~~Doing so, we~~ We also conduct a specific study targeting the impact of BioNO emissions on regional chemistry over Africa. ~~The sensitivity~~ This comparative study consists of ~~two experiments of 3-years coupled climate chemistry runs considering or not BioNO emissions, simulated through an original parameterization simulating a coupled climate-chemistry model, with and without BioNO emissions. The simulation model is parameterized using an original method~~ based on ANN. ~~These runs, and the impact of BioNO are evaluated in the light of various data and is run over a three year period. The model performance is evaluated by comparing the simulation outputs to various data,~~ including satellite observations for climate, ground-based observations, reanalysis and alternative ~~state-of-the-art~~ state-of-the-art model outputs for key atmospheric compounds.

~~Obtained results~~ The results obtained show evidence that ~~RegCM5-CHEM~~RegCM5 can capture the main features of the regional climate over the region, ~~for instance in terms of~~ considered, for example the seasonal and daily mean ~~of~~ temperature, precipitation and wind circulation relevant for regional atmospheric chemistry and emission processes.

Simulated NO<sub>2</sub>, HNO<sub>3</sub> and O<sub>3</sub> ~~fields-values~~ show consistency with ~~reanalysis and Geos-Chem~~ CAMS reanalysis and GEOS-Chem simulations in terms of spatio-temporal distribution and gradients. Local comparison with surface concentrations measured over the six INDAAF sites indicates that the coupled chemistry-climate model can reproduce the seasonal cycle of all species over all sites. However, these comparisons strikingly ~~outline an overall~~ show an systematic overestimation of simulated O<sub>3</sub> and, to a lesser extent, an underestimation of NO<sub>2</sub> and HNO<sub>3</sub>, especially in the wet season over dry ~~savannas~~ savanna stations. These large biases are present not only in ~~RegCM~~RegCM5 simulations but also in ~~reanalyses, and Geos-Chem~~ CAMS reanalysis, and GEOS-Chem outputs. In the BASE simulation, the O<sub>3</sub> biases range from -2.64 to 34.2 ppb (dry savannas), -2.63 to 28.72 ppb (wet savannas) and 1.96 to 23.05 ppb (forests) while for NO<sub>2</sub>, we obtained biases from -4.97 to -0.41 ppb (dry savannas), -0.84 to 1.59 ppb (wet savannas), -1.64 to 1.14 ppb (forests), and -1.73 to 0.02 ppb (dry savannas), -0.8 to 0.26 (wet savannas) and -0.54 to 0.05 ppb (forests) for HNO<sub>3</sub>. These differences are attributed to potential deficiencies in chemical emissions and mechanisms, deposition, boundary layer dynamics and transport from the upper layer, which are particularly challenging to ~~be reproduced in~~ reproduce for tropical regions. It is well known that regional models often struggle to accurately capture local-scale emissions and processes due to the coarse resolution (Valari and Menut, 2008; Wang et al., 2023) of their grids (in this case, 30 km x 30 km), which can lead to discrepancies when comparing with point measurements. Nevertheless, despite ~~a substantial room for potential improvements~~ room for improvement, our conclusion is that ~~RegCM5-Chem performance turns out to be consistent with state-of-the-art in regards to regional photo-oxidant chemistry, RegCM5 performance is consistent with both state-of-the-art~~ chemical reanalysis and chemistry transport model ~~regarding regional photo-oxidant chemistry.~~

745 When integrating BioNO emissions, we estimate ~~that~~ seasonal averaged BioNO ~~flux-to-be-ranging-fluxes range~~ from 0.02 to 7 mg m<sup>-2</sup> day<sup>-1</sup> ~~and a~~, and that the total amount of nitrogen emitted from BioNO ~~ranging-from-ranges between~~ 0.01 to ~~and~~ 4.4 TgN. month<sup>-1</sup> ~~on the whole~~, over the domain. The regional distribution of BioNO ~~is essentially determined by emissions is determined primarily from~~ the environmental predictors considered in the ANN based parameterization, with ~~an important role of~~ soil moisture variability ~~. When taken into account, BioNO emissions lead playing a particularly important~~

750 ~~role. Incorporating BioNO emissions leads~~ to increased concentration levels of surface NO<sub>2</sub> (ranging from 0.05 to 4 ppb) and HNO<sub>3</sub> (from 0.05 to 0.3). A decrease in surface ozone (until 2 ppb likely in the Sahel) is also obtained ~~as a likely result of predominant~~, most likely as a result of NO induced titration ~~effect-effects~~ in the surface layer, ~~while~~. Meanwhile, the O<sub>3</sub> concentrations ~~relatively show a relative~~ increase in altitude ~~and~~, downwind from BioNO sources, and towards the regional scale (up to 4 ppb).

755 ~~In terms of model performance compared to INDAAF stations~~ ~~When comparing model performance to observations from INDAAF sites~~, the inclusion of BioNO emissions improves the representation of O<sub>3</sub>, NO<sub>2</sub>, and HNO<sub>3</sub> seasonal cycles and concentration ~~magnitudes, particularly by reducing values, and reduces~~ biases in some cases. However, in certain conditions, it can also lead to an increase in biases, highlighting the complex interactions at play across different regions and ecosystems.

Overall, our study ~~points-out-highlights~~ an added value of including interactive BioNO emission representations, especially

760 over the dry savannas of northern Sahel, ~~where-since~~ atmospheric nitrogen cycle and ~~deposition-inputs-nitrogen deposition~~ are particularly important for these ecosystems where N content is low and sensitive to small variations ~~in deposition rates~~. One limitation of the ANN approach is that it does not account for limitations in the nitrogen pool ready to be emitted, which could be ~~at-play-especially-in-dryer-an important factor in dry~~ and unfertilized ecosystems. A deeper look at such limitations ~~; using-for-example-is anticipated, for example by using~~ constraints from explicit soil nitrogen modules, ~~is-foreseen. Perspective~~

765 ~~to-Perspectives of~~ this work also include improving the representation of atmospheric chemistry processes important for the regional nitrogen budgets, such as LiNO<sub>x</sub> emissions and relevant heterogeneous chemistry processes (e.g. dust - HNO<sub>3</sub>), ~~which will have a significant HNO<sub>3</sub>~~. This is likely to have a notable impact on deposition processes, while ~~keeping-maintaining the~~ numerical efficiency required ~~by-for a~~ climate scale simulation. ~~Extended-It is also anticipated to perform~~ multi-decadal simulations ~~aiming-at-investigating-in order to investigate~~ the impacts of regional climate variability and direct anthropogenic

770 perturbations on the regional nitrogen cycle over Africa, which may ~~bring-a-more-thorough-insight-in-provide deeper insight into~~ future trends of these processes in Africa.

*Code and data availability.* The RegCM5 model code can be accessed at the web site: <https://zenodo.org/record/7548172#.Y8gVV7TM-KUK>. INDAAF measurement network data is available at <https://indaaf.obs-mip.fr>. <sup>c</sup> Reduction/Increase Bias by BioNO emissions

<sup>d</sup> Bias with CAMS reanalysis

<sup>e</sup> Bias with GEOS-Chem model

**Figure 15.** Comparison of BASE and BioNO simulations of surface  $O_3$  concentrations (in ppb) against the CAMS reanalysis and the model ~~Geos-Chem~~GEOS-Chem for DJF and JJA season. The INDAAF measurement values are overplotted and represented by small circles on the map.

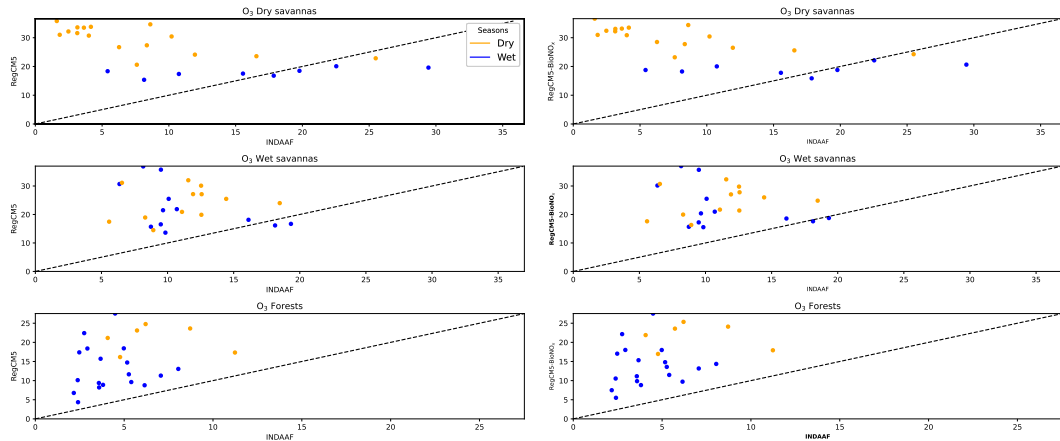

**Figure 16.** DJA and JJA differences (BIONO - BASE) in surface  $\text{NO}_2$  (left),  $\text{HNO}_3$  (middle) and  $\text{O}_3$  (right) concentrations. Units are in ppb.

**Figure 17.** Simulated monthly-averaged concentrations of  $O_3$  by BASE, BIONOX runs and the CAMS reanalysis in comparison with INDAAF observation at its representative remote sites.

**Figure 18.** Surface observed  $O_3$  concentrations (INDAAF) vs simulated with RegCM5. BioNO emissions are considered in the right panel.

**Table 7.** BASE~~and~~, BIONO, CAMS and GEOS-Chem Biases (ppb) for O<sub>3</sub>. The Reduced/Increased (Red/Inc) biases given by BIONO run is in %.Ba: Banizoumbou, Ka: Katibougou, La: Lamto, Dj: Djougou, Bo: Bomassa, Zoétélé: Zo
