**Abstract.** We developed and evaluated a new method to retrieve ground surface temperatures  $T_g$  below the snowpack from Soil Moisture and Ocean Salinity (SMOS) satellite L-band brightness temperatures (BT). The study was performed over 21 reference sites providing *in situ* ground temperatures  $T_{g-insitu}$  in Northern Alaska from 2011 to 2020, representative of Arctic tundra underlined by continuous permafrost, and with various open water fractions.  $T_g$  were obtained by inverting two types of microwave emission models (MEM) tailored for winter Arctic tundra environments. The first MEM assumed homogeneous SMOS pixels and optimized the surface roughness  $H_{r,gs}$ . We observed the important influence of the frozen water bodies on  $T_g$  retrievals. Accordingly, we used a second more advanced MEM that accounts for the water surfaces within the SMOS pixels and describes their emission using an optimized water-ice interface roughness parameter,  $H_{r,wi}$ . For sites with water fraction < 0.04, our methods (median R = 0.60) outperformed the European Centre for Medium-Range Weather Forecasts reanalysis (ERA5) product (median R = 0.51) with respect to the reference sites. The bias between retrieved and *in situ* temperature was slightly negative (median bias = -0.2°C). For sites with water fraction > 0.20, our water fraction correction reduced the bias, but the correlation of the  $T_g$  retrievals remained lower than that of ERA5. This study opens a new avenue for monitoring  $T_g$  below the snowpack in the Arctic using L-band BT, by inversion of a relatively simple MEM and limited auxiliary data. Extending this study to the whole Arctic area and taking advantage of the 15 years of SMOS data to study spatio-temporal variability of winter  $T_g$  in Arctic environments is excessively promising.

## 1 Introduction

The ground surface temperature  $T_g$  is a key parameter for physical land surface processes. The observed increase in the surface air temperatures over the last decades (Druckenmiller and Jeffries, 2019) and  $T_g$  (Biskaborn et al., 2019) in the Arctic regions

induced changes in land surface energy and water balance, impacting weather and climate at local and global scales (Schuur et al., 2015; Chadburn et al., 2017; Turetsky et al., 2020). A change in  $T_g$  affect surface runoff and hydrological processes (Rouse et al., 1997; Ala-Aho et al., 2021) and the ecosystem dynamics (Wang et al., 2019). In snow-covered conditions,  $T_g$  temporal dynamics are generally decoupled from air temperature (Bartlett et al., 2004; Cao et al., 2020) because of snow thermal insulation capacity (Zhang, 2005; Domine et al., 2019). Hence,  $T_g$  modulates the permafrost active layer dynamics and its spatial distribution (Dobiński, 2020). The Arctic freeze/thaw ground state associated with  $T_g$  is a key element of Arctic climate change feedbacks as  $T_g$  is the main driver of CO<sub>2</sub> release through soil respiration during winter (Natali et al., 2019; Mavrovic et al., 2023). However, meteorological stations over the Arctic are sparse and very few  $T_g$  observations are available due to harsh conditions (Shiklomanov, 2012). Model and reanalysis data provide  $T_g$  at a global scale for decades but in Arctic areas, the results remain uncertain (Royer et al., 2021b), mostly during winter when the Arctic is covered by snow (Herrington et al., 2024). Statistical, empirical, and machine learning models (Aalto et al., 2018; Lembrechts et al., 2022; Guo et al., 2024) were proposed but the insulation properties of snow coverage remain a major challenge to estimate  $T_g$  (Lembrechts et al., 2022).

Satellite remote sensing provides opportunities to map  $T_g$  in cold environments (Westermann et al., 2015). The land surface temperature (LST) can be retrieved based on thermal radiometry (e.g. Jiménez-Muñoz et al. (2014)). However, during winter, LST corresponds to the temperature of the snow surface (Westermann et al., 2012). High-frequency ( $f > 10$  GHz) passive microwave data (Fily, 2003; Jones et al., 2007; André et al., 2015) showed limited results for determining the  $T_g$  under the snowpack (Duan et al., 2020). Moreover, Köhn and Royer (2012) and Mialon et al. (2007) showed that when using Advanced Microwave Scanning Radiometer for EOS (AMSR-E) and Special Sensor Microwave/Imager (SSM/I) observations, the derived LST corresponds to a thin layer (skin) at the air-snow interface. Marchand et al. (2018) showed the potential of using passive microwaves to retrieve  $T_g$  by combining AMSR-E and Moderate-Resolution Imaging Spectroradiometer (MODIS) satellite data to inform a land surface scheme. However, the study was performed for a unique site and the integration of remote sensing data in a land surface scheme remains complex and operationally difficult to implement. It is well known that low microwave frequencies ( $f < 10$  GHz) are less sensitive to snow properties, and L-band (protected frequency band  $f = 1400\text{--}1427$  GHz, wavelength  $\lambda \simeq 21$  cm) could provide unique information about the frozen ground under the snow (Schwank et al., 2015; Lemmetyinen et al., 2016; Roy et al., 2017).

In this study, we developed a new approach to retrieve  $T_g$  under the snowpack in tundra environments from Soil Moisture and Ocean Salinity (SMOS) observations. The emitted radiations observed by SMOS are expressed in terms of brightness temperature (BT), that are predominantly determined by the effective temperature and the emissivity of the observed scene. By considering that the Arctic ground surface remains frozen throughout winter, the ground emissivity remains constant and the BT depends mostly on  $T_g$ . However, even if the emissivity (driven by ground permittivity) remains constant, other contributions to the signal, including contributions from snow and water bodies, should be considered in retrieving  $T_g$ . We developed a microwave emission model (MEM) for Arctic tundra conditions to address the complex and heterogeneous scene observed at the SMOS footprint scale. The parameterization of central components such as the frozen ground permittivity, the snow layer, and the fraction of snow and ice covered water bodies and their impact on  $T_g$  retrievals were evaluated. The retrieved  $T_g$

were validated against *in situ* measurements from 21 sites across northern Alaska and compared with the European Centre for  
55 Medium-Range Weather Forecasts (ECMWF) reanalysis (ERA5) ground temperatures  $T_{g-ERA5}$  (Hersbach, H. et al., 2023).  
This satellite-based approach opens a new path towards soil temperatures monitoring under the snowpack in the Arctic with  
expected improvement in land and carbon cycle modeling in permafrost area.

## 2 Datasets

### 2.1 Brightness temperatures from SMOS

60 Operated by the European Space Agency (ESA), the SMOS satellite has been acquiring multi-angular BT at L-band since Jan-  
uary 2010 (Kerr et al., 2010). We used the SMOS Level 3 brightness temperatures (L3BT) version 330 provided by the Centre  
Aval de Traitement des Données SMOS (CATDS) (CATDS, 2024). The L3BT are sampled on the global Equal Area Scalable  
Earth version 2.0 (EASE 2.0 grid, Brodzik et al. (2012)) using a cylindrical projection for daily ascending and descending or-  
bits. Both vertical (V) and horizontal (H) polarizations are available for observation (off-nadir) angles  $\theta$  from  $0^\circ$  to  $60^\circ$  binned  
65 over 5-degree intervals (Al Bitar et al., 2017). The SMOS measurements are impacted by Radio Frequency Interferences (RFI)  
(Daganzo-Eusebio et al., 2013), whose consequences vary in time, so morning and afternoon orbits were considered separately.  
The revisit time is shorter than the three-day revisit at the equator and enables observations of the study area at least once a  
day. The BT are associated with the estimated radiometric accuracy and sample standard deviation obtained in the averaging  
of measurements into observation angle bins.

### 70 2.2 *In situ* measurements of ground temperatures

The 21 reference *in situ* sites are located across Alaska (US), in the Arctic region (Figure 1 and Table 1). The continuous  
permafrost landscape integrates numerous lakes and some sites are located close to the coast (Barrow, Lake 145, Fish Creek,  
Camden Bay) while others are disseminated inland. All the selected sites are located above the tree line and are representative  
of the tundra environment with vegetation characterized by low shrubs and mosses (Table 1). SMOS observations are flagged  
75 for topography (Mialon et al., 2008), but none of the 21 *in situ* sites are impacted, except for the Atigun pass site which is  
labeled as moderate topography, i.e. SMOS data quality may be impacted by topography. The study sites are part of four  
different networks. The United States Geological Survey (USGS) (Urban, 2017) provided 14 sites from 1998 to 2019 as part  
of the Global Terrestrial Network for Permafrost (GTN-P). Three other sites come from the Carbon in Arctic Reservoirs  
Vulnerability Experiment (CARVE) (Oechel et al., 2016) between 2011 and 2015. The last four sites are part of the Soil  
80 Climate Analysis Network (SCAN) (Schaefer et al., 2007) and Snowpack Telemetry (SNOTEL) (Leavesley et al., 2010) and  
were accessed thanks to the International Soil Moisture Network (ISMN) (Dorigo et al., 2021). The *in situ* data is available  
with an hourly temporal resolution and was selected from January 2011 to coincide with SMOS observations. For each site,  
ground temperatures ( $T_{g-insitu}$ ) at variable probing depth are available (Table 1). Other variables such as air temperature at 2 m  
height and snow depth are available.

**Figure 1.** Distribution of the 21 ground-based  $T_{g-insitu}$  stations used as a reference (background: the permafrost extent and tree line from Heginbottom et al. (2002). Sites coordinates are specified in Table 1.

### 85 2.3 Model reanalysis ground temperatures

The  $T_g$  retrieved from the L3BT was compared to the fifth generation ECMWF re-analysis (ERA5) ground temperature product (Hersbach, H. et al., 2023). We used the shallower soil temperature (Level 1, 0 - 7 cm depth)  $T_{g-ERA5}$  provided on a  $0.25^\circ$  resolution grid with an hourly temporal resolution.

### 2.4 Land cover

90 The land cover fraction was calculated from the ESA CCI L4 map at a 300 m spatial resolution, Version 2.0.7 (2015) (Defourny, P. et al., 2023). To obtain the fraction of a given land cover class for one grid cell, the number of ESA CCI pixels of the corresponding class was divided by the total number of ESA CCI pixels in a round buffer around the grid cell center. A 40 km

**Table 1.** *In situ* stations coordinates with the associated available probe depths. The land cover fractions extracted from the ESA CCI L4 map at 300 m, Version 2.0.7 (2015) (ESA) using a 40 km diameter buffer around the closest SMOS L3 grid cell center for each study site. Only classes with fractions above 5% for at least one site are presented.

† "5 to 120" refers to all the available depths for the USGS sites, i.e. 5 – 10 – 15 – 20 – 25 – 30 – 45 – 70 – 95 – 120 cm.

<sup>1</sup> Shrubland <sup>2</sup> Grassland <sup>3</sup> Lichens and mosses <sup>4</sup> Sparse vegetation (tree shrub herbaceous cover) (<15%)

<sup>5</sup> Shrub or herbaceous cover flooded fresh/saline/barkish water <sup>6</sup> Bare areas <sup>7</sup> Water bodies

diameter buffer zone around each SMOS L3 grid cell center roughly corresponds to a 3 dB antenna pattern cut-off assimilated to the instrumental spatial resolution. The water fraction at each site was within a 40 km buffer. The land cover classes were used for the *in situ* environment characterization and the analysis of the results. The land cover fractions are summed up in Table 1. None of the sites are significantly covered by trees or high vegetation.

### 3 Methods

#### 3.1 Pre-processing

Our retrievals were based on L-band  $T_B$  in H and V polarizations and at angles from 0 to 60°. The  $T_B$  were filtered if the RFI ratio (defined as the sum of the RFI flagged instances divided by the sum of the SMOS L1 views combined in each of the L3BT 5-degree angle bin) was more than 0.1. Due to the RFI situation in North America (Aksoy and Johnson, 2013), observations before 2012 were discarded. In winter,  $T_g$  under the snowpack is expected to be diurnally relatively stable (Bartlett et al., 2004). Consequently, we only focused on the daily morning (ascending) orbit passes (approx. 6 a.m local overpass). We used the  $T_{g-insitu}$  at 5 cm depth to focus on the same ground surface layer for all sites. An exception was made for Awuna2, Camden Bay, and Lake 145 where only 15 cm depth measurements were available. For each L3BT, we selected the closest  $T_{g-insitu}$  observed within 30 minutes of the mean satellite overpass time. The retrieval was performed only when  $T_{g-insitu} < -5^\circ\text{C}$  to ensure that ground conditions satisfy our stable frozen ground permittivity hypothesis (Pardo Lara et al., 2020). We also compared  $T_{g-ERA5}$  with respect to  $T_{g-insitu}$ . For each site, we considered the nearest neighbor ERA5 node and used the closest time to the satellite overpass time.

#### 3.2 Microwave emission model for the Arctic tundra during winter

Our proposed approach for  $T_g$  retrieval required an inversion model based on a MEM (Figure 2). The upwelling surface  $T_{B,surf}^p(\theta)$  was considered to be the linear combination of the upwelling BT from the snow-covered ground  $T_{B,G}^p(\theta)$ , from the snow and ice covered water bodies  $T_{B,WI}^p(\theta)$  weighted by the water bodies fraction  $\nu_{wi}$ :

$$T_{B,surf}^p(\theta) = (1 - \nu_{wi}) \cdot T_{B,G}^p(\theta) + \nu_{wi} \cdot T_{B,WI}^p(\theta) \quad (1)$$

$T_{B,G}^p(\theta)$  and  $T_{B,WI}^p(\theta)$  were simulated with multi-layer configurations of the Two-Stream model (Schwank et al., 2014) and the Microwave Emission Model of Layered Snowpacks (MEMLS) (Mätzler and Wiesmann, 2012) reflecting the two emission model scenarios depicted in Figure 2.  $T_{B,G}^p(\theta)$  resulted from a submodel considering the snow and the atmosphere as two horizontal layers atop the ground which is an infinite half-space. Note that the low vegetation of the tundra is not considered in the submodel. In the case of  $T_{B,WI}^p(\theta)$ , the submodel is made of three horizontal layers (ice, snow, and atmosphere) above the water as an infinite half-space. The layers and infinite half-spaces parametrizations are described in the following Sections (Sections 3.2.1, 3.2.2, 3.2.3).  $T_{B,G}^p(\theta)$  and  $T_{B,WI}^p(\theta)$  were also corrected from the atmosphere opacity  $\tau_{atm}(\theta)$ . The deep sky and atmosphere upwelling and downwelling contributions were taken into account as in (Kerr et al., 2020), depending on

$T_{\text{B,sky}}$ ,  $T_{\text{B,atm}}(\theta)$  and  $\tau_{\text{atm}}(\theta)$  (Table 2).

125 Our MEM considered microwave interactions at the interface between two layers: the reflectivity and the refractivity. The reflectivities of the smooth surface between layer  $n$  and  $n + 1$  are noted as  $s^{\text{H}*}(\theta)$  and  $s^{\text{V}*}(\theta)$  and were given by the Fresnel reflection coefficients (Ulaby and Long, 2014):

$$s^{\text{H}*}(\theta) = \left| \frac{\sqrt{\varepsilon_n} \cdot A - \sqrt{\varepsilon_{n+1}} \cdot B}{\sqrt{\varepsilon_n} \cdot A + \sqrt{\varepsilon_{n+1}} \cdot B} \right|^2 \quad s^{\text{V}*}(\theta) = \left| \frac{\sqrt{\varepsilon_{n+1}} \cdot A - \sqrt{\varepsilon_n} \cdot B}{\sqrt{\varepsilon_{n+1}} \cdot A + \sqrt{\varepsilon_n} \cdot B} \right|^2 \quad (2)$$

130 with  $A = \cos(\theta_n)$  and  $B = \sqrt{1 - (1 - A^2) \cdot \frac{\varepsilon_n}{\varepsilon_{n+1}}}$

where H and V stand for horizontal and vertical polarization,  $\theta$  account for the incidence angle and  $\varepsilon_n$  is the layer  $n$  complex dielectric constant.

The H-Q-N model (Wang and Choudhury, 1981) was proposed to empirically consider surface effects (including roughness) in the reflectivity and can be expressed as:

135  $s^p(\theta) = [(1 - Q_r)s_n^{p*}(\theta) + Q_r s^{q*}(\theta)] \cdot \exp\left(-H_r \cos^{N_r^p}(\theta)\right)$  (3)

where  $p$  and  $q$  are the two polarizations ( $q$  is H (resp. V) when  $p$  is V (resp. H)). The surface effects were taken into account with four parameters: the polarization mixing ratio  $Q_r$ , the angular effect parameters  $N_r^{\text{H}}$ , and  $N_r^{\text{V}}$  and the effective roughness parameter  $H_r$ . These four parameters account for not only the geometric roughness effects but also the spatial heterogeneity of the surface characteristics. For instance, Escorihuela et al. (2007) showed a  $H_r$  dependence on soil moisture content for a  
140 ground-air interface. Our values for those parameters are detailed in the following sections and summed up in Table 2.

The angle deviation due to refractivity at the interface between the layers  $n$  and  $n + 1$  is given by Snell-Descartes law:

$$\theta_n = \arcsin\left(\sqrt{\frac{\varepsilon_{n+1}}{\varepsilon_n}} \sin \theta_{n+1}\right) \quad (4)$$

where  $\varepsilon_n$  is the layer  $n$  complex dielectric constant Ulaby et al. (1984).

### 145 3.2.1 Frozen ground parametrization

The bottom-most infinite half-space representing the ground was described using the following parameters:  $T_g$ ,  $\varepsilon_{\text{frozen}}$ ,  $H_{\text{r,gs}}$ ,  $Q_{\text{r,gs}}$ ,  $N_{\text{r,gs}}^p$  (see Figure 2). The ground-snow interface reflectivity  $s_{\text{gs}}^p$  was obtained from equations 2 and 3. This study aimed to retrieve the ground surface temperature  $T_g$  by considering a fixed and constant ground permittivity in frozen conditions. Various models describe the ground permittivity at 1.4 GHz (Mironov et al., 2009; Bircher et al., 2016; Park et al., 2017), but  
150 very few in the case of frozen ground (Hallikainen et al., 1985; Mironov et al., 2015). The permittivity of a frozen ground was set to  $\varepsilon_{\text{frozen}} = 5.0 + 0.5 i$ , similar to past studies (Schwank et al., 2014; Holmberg et al., 2024) and SMOS algorithm (Kerr et al., 2020). We considered the ground surface reflectivity as in Equation 3 accounting for various effects including roughness

using four parameters ( $H_{r,gs}$ ,  $Q_{r,gs}$ ,  $N_{r,gs}^H$  and  $N_{r,gs}^V$ ). The polarization mixing ratio  $Q_{r,gs}$  (Wang and Choudhury, 1981) as well as the angular effects parameters  $N_{r,gs}^H$  and  $N_{r,gs}^V$ ) were set to 0, as suggested by several studies (Kerr et al., 2020; Wigneron et al., 2011; Lawrence et al., 2013).  $H_{r,gs}$  value was optimized for all the sites using a range of 0 to 1 with 0.1 increments.

### 3.2.2 Dry snow parametrization

The layer accounting for the snow was defined by its effective temperature  $T_s$ , its permittivity  $\varepsilon_s$ , and the layer internal transmissivity  $t_s$  and reflectivity  $r_s$  (Figure 2). According to Schwank et al. (2015) and Rautiainen et al. (2016), dry snow is considered transparent at L-band, i.e. its internal transmissivity and reflectivity are  $t_s = 1$  (no absorption) and  $r_s = 0$  (no volume scattering). Consequently, our model became independent of  $T_s$ . However, Schwank et al. (2015) showed that air-snow interface impacts on impedance matching can not be ignored, i.e. the snow surface reflectivity  $s_s^{p*} \neq 0$ . We considered refraction (Equation 4) and reflection for a smooth air-snow interface (Equation 2). The dry snow permittivity was set to  $\varepsilon_s = 1.53$  according to Equation 4 of Schwank et al. (2015) for a mean snow density  $\rho_s = 300 \text{ kg m}^3$ , which corresponds to the high Arctic snowpack average density observed by Derksen et al. (2014) and Roy et al. (2017). We assume a snowpack with the same parameters above the ground and the ice-covered water bodies.

### 3.2.3 Snow and ice covered water bodies parametrization

During winter, water bodies are fully covered by an ice layer with liquid water remaining below the ice layer (Adams and Lasenby, 1985; Jeffries et al., 2013). The ice layer was defined by its permittivity  $\varepsilon_i = 3.18$  (Mätzler, 2006) and considered transparent (internal transmissivity  $t_i = 1$  and internal reflectivity  $r_i = 0$ ). However, smooth surface refraction (Equation 4) and reflection  $s_{is}^{p*}$  (Equation 2) were taken into account at the ice-snow interface. Similarly to the ground layer, the liquid water layer was defined with  $T_w$ ,  $\varepsilon_w$ ,  $H_{r,wi}$ ,  $Q_{r,wi}$  and  $N_{r,wi}^P$  (Figure 2). The water temperature  $T_w$  was considered constant throughout winter and equal to  $2^\circ\text{C}$  (Oveis et al., 2012). We consider fresh water whose L-band permittivity  $\varepsilon_w$  was fixed to  $86 + 13i$  (Liebe et al., 1991; Mätzler, 2006; Ulaby and Long, 2014). The water-ice interface reflectivity  $s_{wi}^p$  was obtained from equation 3, accounting for the water-ice interface heterogeneity.  $Q_{r,wi}$ ,  $N_{r,wi}^H$  and  $N_{r,wi}^V$  were set to 0 (Choudhury et al., 1979).  $H_{r,wi}$  value was optimized for all the sites on a range of 0 to 2 with an iteration step of 0.1. The water body  $\nu_{wi}$  accounted for the area percentage of the considered SMOS node covered by water bodies based on the water class from ESA CCI landcover (Table 1).

### 3.2.4 Microwave emission model configurations

Figure 2 depicts a schematic of the MEMs and Table 2 summarizes the input parameters. This study tested two configurations: one considering a homogeneous scene with only ground (hereafter named MEM<sub>G</sub>) and one with a heterogeneous scene composed of ground and snow and ice covered water bodies (hereafter named MEM<sub>G+WI</sub>).

**Figure 2.** Schematic representation of the MEMs for modeling a winter tundra scene at L-band.

MEM<sub>G</sub> only considers the left side of the sketch, MEM<sub>G+WI</sub> considers both sides.

**Table 2.** Input parameters values of the MEM for modeling a winter tundra scene at L-band.

| Layer      | Parameter              | Description                                 | Value                       |
|------------|------------------------|---------------------------------------------|-----------------------------|
| Atmosphere | $T_{B,sky}$            | Deep sky BT                                 | 2.7 K                       |
|            | $T_{B,atm}$            | Atmosphere BT                               | 2.2 K at nadir <sup>†</sup> |
|            | $\tau_{atm}$           | Atmosphere opacity                          | 0.01 at nadir <sup>†</sup>  |

|            | $s_{is}^{p*}$          | Ice-snow reflectivity                       | Equation 2                  |
|            | $r_i$                  | Ice internal reflectivity                   | 0                           |
|            | $t_i$                  | Ice internal transmissivity                 | 1                           |
|            | $\varepsilon_i$        | Ice permittivity                            | 3.18                        |
|            | $s_{wi}^p$             | Water body-ice reflectivity                 | Equation 3                  |
|            | $H_{r,wi}$             | Water body roughness                        | [0-1]                       |
|            | $Q_{r,wi}$             | Water body polarization ratio               | 0                           |
|            | $N_{r,wi}^H$           | Water body angular dependent effects (in H) | 0                           |
|            | $N_{r,wi}^V$           | Water body angular dependent effects (in V) | 0                           |
|            | $\varepsilon_w$        | Water permittivity                          | 86 + 13 i                   |
|            | $T_w$                  | Water temperature                           | 2°C                         |

<sup>†</sup> Example value for  $\theta = 0^\circ$ . For all the angles,  $T_{B,atm}$  and  $\tau_{atm}$  are calculated as in Kerr et al. (2020).

### 3.3 Cost function for frozen ground temperature retrievals

Both  $\text{MEM}_G$  and  $\text{MEM}_{G+\text{WI}}$  described in Section 3.2 were inverted to retrieve the frozen ground temperature  $T_g$ , by minimizing the following cost function:

$$185 \quad \text{CF}(T_g) = \sum_{p, \theta_k} \left( \frac{T_{B, \text{obs}}^p(\theta_k) - T_{B, \text{sim}}^p(\theta_k, T_g)}{\sigma T_B^p(\theta_k)} \right)^2 \quad (5)$$

where  $T_{B, \text{obs}}^p(\theta_k)$  and  $T_{B, \text{sim}}^p(\theta_k, T_g)$  are the observed and simulated BT for both H and V polarizations and at various incidence angle bins  $\theta_k$ . The BT standard deviation  $\sigma T_B^p(\theta_k)$  is computed from the estimated radiometric accuracy and sample standard deviation obtained in the averaging of measurements into observation angle bin  $k$ .

### 3.4 Post-processing

190 The first aim of the post-processing was to reduce the influence of outliers. The retrieved  $T_g$  below the first 1% quantile and above the last 99% quantile of each site were considered outliers and discarded. We removed the  $T_{g-\text{ERA5}}$  at these dates in the ERA5 time series to ensure that we compared a data pull with the same size. A low short-term variability is expected between  $T_g$  under the snowpack that acts like a thermal insulator. The final step smoothed the  $T_g$  time series to reduce the impact of the noise in SMOS BT to the retrievals. We used a z-score smoothing, to limit the variations of  $T_g$  to 1 standard deviation for a  
 195 5-day window. At a date  $t$ , the local average  $\overline{T_g^t}$  and standard deviation  $\sigma(T_g^t)$  are calculated for a 5-day window around each  $T_g^t$ . If  $T_g^t > \overline{T_g^t} + 1 \cdot \sigma(T_g^t)$ ,  $T_g^t$  is replaced by  $\overline{T_g^t}$ .

### 3.5 Metrics

Three statistical indicators were used to assess the comparison between the retrieved  $T_g$  and the reference temperatures  $T_{g-\text{insitu}}$  ((Entekhabi et al., 2010; Gruber et al., 2020)). The unbiased Root Mean Square Deviation (ubRMSD) is used for uncertainty  
 200 estimation as it is corrected from the bias between the two time series (Kerr et al., 2016a; Benninga et al., 2020). The bias corresponds to the mean difference between the compared time series of  $T_g$  and  $T_{g-\text{insitu}}$ . The Pearson correlation coefficient (R) accounts for the similarities in temporal dynamics of the two time series. Each metric was computed for the whole time series for each site. Each metric was computed for the whole time series for each site and was provided with its confidence intervals (CI) at 5 and 95%. Analytical solutions enabled us to find the CI of the bias, the ubRMSD and the R (Gruber et al.,  
 205 2020). We also evaluated  $T_{g-\text{ERA5}}$  with respect to  $T_{g-\text{insitu}}$  with similar metrics.

## 4 Results

The metrics (bias, R and ubRMSD) for all sites and obtained with both  $\text{MEM}_G$  and  $\text{MEM}_{G+\text{WI}}$  are summarized in Appendix D. This results section first focuses on the  $H_{r, \text{gs}}$  and  $H_{r, \text{wi}}$  optimization based on the biases (Section 4.1) and then evaluates the  $T_g$  retrievals (Section 4.2).

4.1.1  $H_{r,gs}$  optimization

In the MEM<sub>G</sub> configuration, we retrieved  $T_g$  by testing  $H_{r,gs}$  values from 0 to 1 with 0.1 increments. Figure 3 shows the biases obtained with all tested  $H_{r,gs}$  and biases obtained with  $T_{g-ERA5}$  for each site, with respect to  $T_{g-insitu}$ . For all sites, the bias changed in the negative direction with increasing  $H_{r,gs}$ . For sites with  $\nu_{wi} \leq 0.04$ , the biases went from positive down to negative values with increasing  $H_{r,gs}$ , except for Awuna2 and Umiat whose biases remained positive. For sites with  $\nu_{wi} \geq 0.20$ , the biases of numerous sites remained negative and went down close to  $-30^\circ\text{C}$ . This suggests that the water bodies strongly impact the  $T_g$  retrieval bias. That is why we optimized the value of  $H_{r,gs}$  only on sites less affected by water bodies. For sites with  $\nu_{wi} \leq 0.04$ , the bias was minimized with  $H_{r,gs} = 0.8$  (average =  $0.2^\circ\text{C}$ , median =  $-0.2^\circ\text{C}$ , Q1 =  $-1.6^\circ\text{C}$ , Q3 =  $0.8^\circ\text{C}$ , range =  $2.4^\circ\text{C}$ ). Surprisingly, the sites with the highest  $\nu_{wi}$  (between 0.44 and 0.59) showed positive biases for some  $H_{r,gs}$ .

**Figure 3.** Bias per site for each  $H_{r,gs}$  used in the inversion with the MEM<sub>G</sub> model. Each graph corresponds to one site.  $H_{r,gs}$  values are represented by a unique color and are ranged from 0 to 1 on the x-axis. The last point of each graph, in black, is obtained with  $T_{g-ERA5}$ . The y-axis corresponds to the bias  $T_g - T_{g-insitu}$ . Each point is symbolized with error bars that correspond to the confidence interval. The sites are ordered in ascending order of water fraction ( $\nu_{wi}$  in the light blue box).

220 4.1.2  $H_{r,wi}$  optimization

The results in Section 4.1.1 showed that the  $T_g$  retrieval bias strongly depends on water fraction. The MEM<sub>G+WI</sub> model accounted for the presence of frozen water bodies (i.e.  $\nu_{wi} \neq 0$ ) in the  $T_B$  calculation (Figure 2). In this configuration,  $T_g$  was retrieved with different tested  $H_{r,wi}$  values from 0 to 1 with 0.1 increments.  $H_{r,gs}$  was set to 0.8 as shown in Section 4.1.1. For each site, Figure 4 shows the biases obtained with various  $H_{r,wi}$  and compared with  $T_{g-ERA5}$  bias with respect to  $T_{g-insitu}$ . The

225 higher  $H_{r,wi}$  the more negative the bias, while slope of the variations is linked to  $\nu_{wi}$ . As expected, for sites with  $\nu_{wi} \leq 0.04$ , the biases showed little variations for all  $H_{r,wi}$ . At Piksiksak ( $\nu_{wi} = 0.04$ ) bias went from 5.2°C ( $H_{r,wi} = 0$ ) down to 2.0°C  $H_{r,wi} = 1$ . For sites with  $\nu_{wi} \geq 0.20$ , the biases highly varied with increasing  $H_{r,wi}$ . For instance at Atqasuk ( $\nu_{wi} = 0.24$ ), the bias decreased from 16.5°C to -7.8°C with  $H_{r,wi} = 0$  and  $H_{r,wi} = 1$ . At East Teshekpuk ( $\nu_{wi} = 0.41$ ), the bias for the  $H_{r,wi}$  extrema decreased from 37.0°C to -16.7°C. For the sites with the highest  $\nu_{wi}$  (between 0.44 and 0.59), all the biases remained  
 230 larger than 15°C for the tested  $H_{r,wi}$  range. Consequently, we do not consider them in the following analysis of the water body correction method. For the sites with  $0.20 \leq \nu_{wi} \leq 0.41$ , the bias was minimized with  $H_{r,wi} = 0.7$  (average = 0.7°C, median = 0.2°C, Q1 = -2.9°C, Q3 = 2.8°C, range = 5.7°C).

**Figure 4.** Bias per site for each  $H_{r,wi}$  used in the inversion. Each graph corresponds to one site.  $H_{r,wi}$  values are represented by a unique color and marker combination (see Legend) and are ranged from 0 to 1 with a 0.1 step on the x-axis. The last point of each graph, in black, is obtained with  $T_{g-ERA5}$ . The y-axis corresponds to the bias  $T_g - T_{g-insitu}$ . Note that the y-axis scale is variable. Each point is symbolized with error bars that correspond to the 5-95% confidence interval. The sites are ordered in ascending order of water fraction ( $\nu_{wi}$  in the light blue box).

## 4.2 $T_g$ retrievals evaluation

### 4.2.1 $T_g$ retrievals for sites with $\nu_{wi} \leq 0.04$

235 The R, bias, and ubRMSD using  $MEM_G$  with  $H_{r,gs} = 0.8$  and  $MEM_{G+WI}$  with  $H_{r,wi} = 1$  were compared to  $T_{g-ERA5}$  metrics in Figure 5. For the sites with  $\nu_{wi} \leq 0.04$ , when accounting for the water bodies with  $MEM_{G+WI}$ , we selected  $H_{r,wi} = 1$  for the ice-water interface as it minimized the bias average of these sites (average = 0.6°C). Each metric (in grey) is given with its confidence limits at 5% (orange) and 95% (blue). This representation enables us to show the dispersion of the metrics for all the considered sites. The R values of the retrieved  $T_g$  (median = 0.60 for both  $MEM_G$  and  $MEM_{G+WI}$ ) were better than

240 ERA5 (median = 0.51). Moreover, in the case of ERA5, the interquartile range was larger ( $Q1 = 0.33$ ,  $Q3 = 0.55$ , range = 0.22) and the 5% confidence limit went down negative values. All the biases are centered around zero (mean =  $0.2^\circ\text{C}$  for  $\text{MEM}_G$ ,  $0.6^\circ\text{C}$  for  $\text{MEM}_{G+WI}$  and  $-0.8^\circ\text{C}$  for ERA5), and all the absolute biases were lower than  $5^\circ\text{C}$ , except an outlier for ERA5 with a strong negative bias =  $-13.1^\circ\text{C}$  (Kelly Station, according to Figure 3). The ubRMSD from both inversions (median =  $2.1^\circ\text{C}$  for both  $\text{MEM}_G$  and  $\text{MEM}_{G+WI}$ ) were significantly smaller than the ones from ERA5 (median =  $3.9^\circ\text{C}$ ).

**Figure 5.** Summary statistics of R, bias and ubRMSD for sites with  $\nu_{wi} \leq 0.04$ . The boxes show the median and interquartile range and whiskers show the 5 and 95 percentiles obtained from all the considered sites. The boxes correspond to the skill estimate (R, bias, or ubRMSD). The associated 5% and 95% CI are provided in Figure B1. The x-axis corresponds to the  $H_{r,wi}$  used in the inversion. The boxes are respectively obtained from:  $\text{MEM}_G$  with  $H_{r,gs} = 0.8$  (left),  $\text{MEM}_{G+WI}$  with  $H_{r,wi} = 1$  (center) and ERA5 (right).

#### 245 4.2.2 $T_g$ retrievals for sites with $0.20 \leq \nu_{wi} \leq 0.41$

The overall R, bias and ubRMSD for  $\text{MEM}_{G+WI}$  with different  $H_{r,wi}$  are summarized in Figure 6 with the corresponding  $\text{MEM}_G$  (with  $H_{r,gs} = 0.8$ ) and ERA5 metrics. Similarly to Figure 5, the boxes show the metrics dispersion. The R values remained the same for all  $H_{r,wi}$  and equal to the R reached with  $\text{MEM}_G$  (median R = 0.21), but lower than ERA5 (median R = 0.62). The biases went more negative with increasing  $H_{r,wi}$  values. The bias was minimized for  $H_{r,wi} = 0.7$  (Section 4.1.2),  
250 with a median value ( $0.2^\circ\text{C}$ ) which was closer to 0 than the bias with  $\text{MEM}_G$  (median =  $-13.0^\circ\text{C}$ ) and with ERA5 (median =  $2.3^\circ\text{C}$ ). Yet, for bias, the interquartile range for  $H_{r,wi} = 0.7$  ( $Q1 = -2.9^\circ\text{C}$ ,  $Q3 = 2.8^\circ\text{C}$ , range =  $5.7^\circ\text{C}$ ) remained much larger than ERA5 ( $Q1 = 0.8^\circ\text{C}$ ,  $Q3 = 3.2^\circ\text{C}$ , range =  $2.4^\circ\text{C}$ ), which meant that the bias remained higher for some of the sites. A wider

range ( $Q1 = 4.4^{\circ}\text{C}$ ,  $Q3 = 6.6^{\circ}\text{C}$ , range =  $2.2^{\circ}\text{C}$ ) was also observed for the ubRMSD for all the  $H_{r,wi}$  and  $\text{MEM}_G$  ( $Q1 = 3.7^{\circ}\text{C}$ ,  $Q3 = 5.3^{\circ}\text{C}$ , range =  $1.6^{\circ}\text{C}$ ) with respect to ERA5 ( $Q1 = 3.2^{\circ}\text{C}$ ,  $Q3 = 3.5^{\circ}\text{C}$ , range =  $0.2^{\circ}\text{C}$ ).

**Figure 6.** Summary statistics of  $R$ , bias and ubRMSD for sites with  $0.20 \leq \nu_{wi} \leq 0.41$ . The associated 5% and 95% CI are provided in Figure B2. Boxes represent the site median and interquartile range ( $Q_3 - Q_1$ ) and whiskers represent the 5 and 95 percentiles. The x-axis corresponds to the  $H_{r,wi}$  used in the inversion. The rightmost boxes are obtained with ERA5.

## 255 5 Discussion

The SMOS satellite was originally designed to focus on soil moisture and ocean salinity, but the applications extend to biomass monitoring (Kerr et al., 2010, 2016b; Mialon et al., 2020) and soil freeze-thaw state (Rautiainen et al., 2014, 2016). Recently, cryosphere applications have been increasingly investigated (Leduc-Leballeur et al., 2020; Schwank et al., 2021; Holmberg et al., 2024). The synergy between these studies should be further explored. For instance, producing  $T_g$  maps over the Arctic  
260 could complement the information from the freeze-thaw state products. In addition, this satellite-based approach is a first attempt to monitor the soil temperatures under the snowpack in the whole circumarctic permafrost area. Based on L-band

observations of SMOS since 2010, continuing efforts in long-term and operational permafrost state monitoring would be made possible by the upcoming satellite missions CIMR and CryoRad (Donlon et al., 2023; Macelloni et al., 2018). Such soil temperature measurements would be highly beneficial for climate monitoring and carbon cycle modeling. Future work will  
 265 look at integrating our approach to assimilation approaches such as the SMAPLv4 to improve soil temperature in winter and winter soil CO<sub>2</sub> emission.

The retrieval model parametrization evaluation showed clear contrasting results according to the water bodies' fraction over sites.  $T_g$  retrievals outperformed ERA-5 when  $\nu_{wi} \leq 0.04$  but are mitigated when  $\nu_{wi} \geq 0.20$ . Improvement of the  $T_g$  retrievals may be further explored with more complex modeling, auxiliary data, or a 2-parameter inversion. Previous studies have shown  
 270 the effects of ground permittivity and snow density to L-band BTs at theoretical, tower-based radiometer, and satellite scales, Schwank et al. (2014); Lemmetyinen et al. (2016); Roy et al. (2017); Holmberg et al. (2024). We can expect the same for snow density and ground temperature. So a joined retrieval of  $T_g$  and snow density may remove some artifacts due to the snow signal in the retrieved  $T_g$  time series. However, additional prior information may have to be needed to ensure inversion stability. In the high-latitude areas, the revisit time is short. For all the sites, the median value of the difference between  $T_{g-insitu}$  at days  $t$   
 275 and  $t + 1$  is 0.03°C. This difference remains at 0.1°C for a 3-day lag. Thus,  $T_{g-insitu}$  is very stable for short time range, which supports the thermal insulation of the snowpack. Considering a small temporal variation of  $T_g$  due to the snowpack thermal insulation, retrievals could be based on observations from multiple orbits (Konings et al., 2016). This could decrease the impact of the instrumental noise on the retrievals.

## 5.1 $T_g$ retrievals under the snowpack for sites with $\nu_{wi} \leq 0.04$

280 For sites with  $\nu_{wi} \leq 0.04$ , correlation, bias and ubRMSD of the retrieval were superior to ERA5. A slightly negative bias was observed when the  $\nu_{wi}$  was ignored (using the model MEM<sub>G</sub>) but was successfully corrected with a model that accounts for snow and ice covered water bodies MEM<sub>G+WI</sub>.

### 5.1.1 Frozen ground parametrization

We used a frozen ground permittivity of  $\varepsilon_{frozen} = 5 + 0.5 i$ , as defined by Hallikainen et al. (1985) and which was commonly  
 285 used in various studies (Schwank et al., 2014; Kerr et al., 2020; Holmberg et al., 2024). The emission depth of L-band observations is usually associated with the first 5 cm of the ground (Schmugge, 1983). However, the emission depth varies with the ground state and texture, based on the ground attenuation constant  $\alpha$  ( $\delta_e = 1/2\alpha$  Ulaby and Long (2014)), and consequently the ground complex dielectric constant  $\varepsilon_g$ . For  $\varepsilon_{frozen} = 5.0 + 0.5 i$ , the calculation based on Ulaby and Long (2014) shows that the associated emission depth  $\delta_e \simeq 15$  cm. When it comes to frozen ground, the effective depth is still not well defined and  
 290 it becomes even more complex with a snow layer on top of the ground. Rautiainen et al. (2012) estimated the emission depth of frozen ground at a maximum of 50 cm, but observed a  $T_B$  saturation only when reaching a 30 cm frost depth. By computing metrics for  $T_{g-insitu}$  at all the available depths for the sites with  $\nu_{wi} \leq 0.04$ , we found that R was better than ERA5 (median = 0.51) for depth down to 30 cm (median range from 0.57 to 0.74) (Figure 7). For *in situ* measurements down to 45 cm, the median absolute biases were smaller than 1.5°C and the median ubRMSD were smaller than 2.5°C. These results suggest that

the sensitivity depth is in fact down to 50 cm or less. For deeper  $T_{g-insitu}$ , the correlation decreased to negative values (median  $R = -0.18$  for depth = 120 cm). Note that for the period of this study (focused on  $T_{g-insitu} < -5^{\circ}\text{C}$  at 5 cm depth) the ground was fully frozen down to 50 cm for the 11 USGS sites that provide ground temperatures down to 120 cm. Due to potential shallow frozen soil, emissions from the underlying unfrozen soil should be taken into account in the early winter (Rautiainen et al., 2012). As observed by Schwank et al. (2004), the observed signal can encompass a contribution of the boundary between frozen and unfrozen soil, which was not taken into account in our modeling.

**Figure 7.** Summary statistics of  $R$ , bias and ubRMSD for sites with  $\nu_{wi} \leq 0.04$ . The associated 5% and 95% CI are provided in Figure 7. Boxes represent the site median and interquartile range ( $Q_3 - Q_1$ ) and whiskers represent the 5 and 95 percentiles. The x-axis corresponds to the *in situ* probing depths used for the validation. The extreme right boxes are obtained with ERA5 and  $T_{g-insitu}$  at 5 cm depth.

Concerning the ground surface parameters, the commonly used H-Q-N empirical model has been tuned for SM and VOD retrievals in many studies (Parrens et al., 2017; Chaubell et al., 2020; Preethi et al., 2024). Hence, its parametrization should be optimized for  $T_g$  retrievals in arctic environment. We found the optimized set of values  $H_{r,gs} = 0.8$ ,  $Q_{r,gs} = 0$ ,  $N_{r,gs}^H = 0$ ,  $N_{r,gs}^V = 0$  for the snow-ground interface, which is consistent with Holmberg et al. (2024). This parametrization depends on the

305 chosen ground permittivity value. According to the Fresnel reflection coefficients (Equation 2), increasing ground permittivity leads to a decrease of the emissivity. Using the H-Q-N model (Equation 3), increasing  $H_{r,gs}$  means an increase of the emissivity. Thus, the soil parametrization requires a joint optimization of  $\varepsilon_g$  and  $H_{r,gs}$ .

We optimized  $H_{r,gs}$  based on a permittivity of a frozen ground value of  $\varepsilon_{frozen} = 5 + 0.5 i$ , but this value could be re-evaluated. The soil permittivity depends on the soil liquid water content and other characteristics (e.g. texture and bulk density).  
310 Based on a review of ground permittivity models (see Section 5.1.1), we investigated other potential values for frozen soil permittivity. For a frozen ground ( $T_g < -5^\circ\text{C}$ ), we assumed the water to be completely frozen and thus SM negligible, i.e.  $SM \simeq 0 \text{ m}^3 \text{ m}^{-3}$  (Zhang et al., 2010; Mavrovic et al., 2023). Soil property information (clay fraction, sand fraction, soil organic content, and bulk density) was extracted at each site location from the SoilGrids 250 m v2.0 database (Poggio et al., 2021) for the 0–5 cm soil layer (Table A1 in the appendices). The Soil Organic Carbon (SOC) content was very high at all the  
315 sites, as expected in the Arctic region, i.e five to ten times higher than the global mean  $40 \text{ g kg}^{-1}$  (according to SoilGrid v2.0), and so was the bulk density. Dielectric constant models like the commonly used Mironov model do not use the SOC information to compute the permittivity. It was first designed considering SM and clay content (Mironov et al., 2009). It was then further developed to use SM,  $T_{sg}$  (here set as  $-20^\circ\text{C}$ ), and bulk density (Mironov et al., 2015). Park et al. (2017) was based on silt, clay, and sand contents, and bulk density. Bircher et al. (2016) defined a soil permittivity model tailored for high organic content  
320 soils, whereas Park’s model was updated to consider soil organic content (Park et al., 2019). The permittivities computed with these models for our sites are summarized in Table A2 in the appendices. The obtained  $\varepsilon_{frozen}$  real parts went from 1 to 4, while the imaginary parts ranged from 0 to 0.1. This comparison of various permittivity models that depend on soil texture showed that the permittivity variability for frozen arctic soils was low and legitimate the use of a fixed value for the ground permittivity. However, the obtained permittivities were significantly lower than  $\varepsilon_{frozen} = 5.0 + 0.5 i$ . This could be an evidence  
325 that  $SM > 0 \text{ m}^3 \text{ m}^{-3}$ , even in frozen ground conditions ( $T_g < -5^\circ\text{C}$ ). In addition, a permittivity equal to  $\varepsilon_{frozen} = 5.0 + 0.5 i$  may result from a soil surface which was saturated with water at freezing time. But, as the Arctic soil shows high SOC and high bulk density (Table A1), it may not satisfy this water saturation condition. For the imaginary part of the permittivity, Mironov et al. (2015) showed a decrease with decreasing temperatures. *In situ* measurements of frozen ground permittivity could be valuable, simultaneously to tower-based radiometer observations in the Arctic tundra environment. Some probes seem efficient  
330 for this task, such as the one described in Gélinas et al. (2025). Using a constant permittivity, calculated under the assumption of a homogeneous ground, is a practical solution for our model, as it reduces the number of free parameters and auxiliary data. However, dielectric mixing models enable to characterize heterogeneous materials (Ulaby and Long, 2014) and could better fit the Arctic soils local behaviour.

### 5.1.2 Effects of the snow layer

335 Snow cover was present for all ground temperature observations used in  $T_g$  retrievals (i.e., the observed snow depth was above 10 cm), motivating the use of a snow layer in the MEM model. Lemmetyinen et al. (2016) and Roy et al. (2017) suggested that snow emissions at L-band are related to the bottom 10 cm of the snow layer. The typical Arctic snow profile consists of a dense windslab of high density ( $\rho \simeq 300 - 400 \text{ kg m}^{-3}$ ) but with a depth hoar underneath with lower density ( $\rho \simeq 250 \text{ kg m}^{-3}$ ) (?).

However, the impact in terms of  $\varepsilon_s$  is low in the model of Wiesmann and Mätzler (1999) that we used in the present study  
 340 ( $\varepsilon_s(\rho = 300 \text{ kg m}^{-3}) \simeq 1.5$  and  $\varepsilon_s(\rho = 250 \text{ kg m}^{-3}) \simeq 1.4$ ). In addition, our model does not account for the inclusion of ice  
 crusts in the snowpack (e.g. after rain-on-snow (ROS) events) (Bartsch et al., 2023), nor low vegetation (e.g. shrubs or mosses)  
 that could be observed in the tundra environment (Royer et al., 2021a) and might add complexity to the snowpack microwave  
 emission. In fact, Roy et al. (2015) observed a decrease in horizontal polarization as the impact of ice crust formation, but Roy  
 et al. (2018) underlined the difficulty of modeling and quantifying such event at L-band. As for the vegetation, multiple effects  
 345 may mitigate the  $T_g$ . The presence of shrubs leads to a snow accumulation with a lower density than on herbaceous areas,  
 which means more thermal insulation from the snowpack (Grünberg et al., 2020; Liston et al., 2002). However, Domine et al.  
 (2022) also observed thermal exchanges between air and soil through the branches. As these effects are observed at local scale,  
 it is difficult to model it at the SMOS scale ( $\simeq 40 \text{ km}$ ). Various temporal matching between *in situ* measurements  $T_{g\text{-insitu}}$  and  
 the retrieved  $T_g$  were tested (not shown): closest measurement to the satellite overpass time (Catherinot et al., 2011) or daily  
 350 maximum, minimum (Jones et al., 2007) or mean. The metrics remained similar because we observed very few daily variations  
 of  $T_g$  due to the snow insulation effect.

## 5.2 $T_g$ retrievals under the snowpack for sites with $\nu_{wi} \geq 0.20$

For sites with  $0.20 \leq \nu_{wi} \leq 0.41$ , the retrievals showed a strong negative bias when ignoring the snow and ice covered water  
 bodies with  $\text{MEM}_G$ . We corrected the bias with the model  $\text{MEM}_{G+WI}$  accounting for water bodies' contribution by optimizing  
 355 the  $H_{r,wi}$  parameter. A single  $H_{r,wi}$  value did not suit all the sites. Validating  $T_g$  retrievals for sites with water body fractions  
 between 0.04 and 0.20 may help to understand the water bodies' effects in the retrievals and how to account for them. For sites  
 with  $\nu_{wi} \geq 0.44$ , the bias was larger with  $\text{MEM}_{G+WI}$  than with  $\text{MEM}_G$ . In fact, the bias could already be minimized using an  
 appropriate  $H_{r,gs}$ . However, the correlation remained poor for these sites ( $R < 0.3$ ). For ERA5, the bias median was larger for  
 sites with  $\nu_{wi} \geq 0.20$  (median =  $1.0^\circ\text{C}$ ) than for sites with  $\nu_{wi} \leq 0.04$  (median =  $-0.1^\circ\text{C}$ ). For sites with higher biases (namely  
 360 Niguanak, Marsh Creek, Camden Bay and Fish Creek), no correlation could be made with surface characteristics, such as land  
 cover (Table 1) and soil content (Table A1). However, we noticed that those sites correspond to coastal pixels, i.e. made of BT  
 measured on the continent and the ocean. Kerr et al. (2020) highlighted the retrieval difficulties for coastal BT that result from  
 mixed pixels. In fact, the observation geometry variations that lead to various water fractions are not taken into account in the  
 MEM.

### 365 5.2.1 Effects of the snow and ice covered water bodies

We used the water fraction for a 40 km resolution, but Kerr et al. (2020) showed that a working area of  $\sim 123 \text{ km} \times 123 \text{ km}$  is  
 required to capture all the microwave signal that contributes to the SMOS observed BT. In fact, due to the multiple observation  
 angles, the size and shape of the elliptical footprint vary. Using an average single round buffer for all the angles is a potential  
 error source. For sites located near the coast, the nearby presence of the ocean is non-negligible. The considered water body  
 370 areas may also vary over time. Dynamic water maps could improve the  $T_B$  correction, even more if they provide us with  
 information on the water state (e.g. frozen, snow and ice covered, etc.). The water bodies highly impact the passive microwaves

observations in summer in the Arctic area (Ortet et al., 2024). Including water bodies in the MEM in winter is even more difficult because even if their surface is fully covered with ice, they may not be completely frozen in depth (Lemmetyinen et al., 2011). We tested various modeling configurations for the water bodies (ice only, liquid water only, ice on top of liquid water with a smooth interface, not shown). None were fully satisfying, but introducing the  $H_{r,wi}$  parameter worked better. Indeed, it represents the surface roughness at the ice-water interface, which is not flat and significantly impacts microwave observations. Yet, different models should be applied depending on water bodies characteristics (e.g. depth) as shallower lakes could freeze down to bottom or sea ice may be formed on the coastal areas.

### 5.2.2 Analysis of a site with high water fraction (Inigok)

Figures 4 and 6 show that using a unique  $H_{r,wi}$  for all the sites does not allow to get fully optimized  $T_g$ . To better understand the possible impact of snow and ice covered water bodies and model configuration, we present the Inigok site with a high water fraction of  $\nu_{wi} = 0.23$ . Figure 8 shows varying performance of the timeseries of  $T_{g,MEM_G}$ ,  $T_{g,MEM_{G+WI}}$  and  $T_{g-ERA5}$  compared to  $T_{g-insitu}$ . The  $T_{g,MEM_G}$  time series showed a negative bias that was well corrected in the  $T_{g,MEM_{G+WI}}$  time series. The  $T_{g-ERA5}$  time series did not show a systematic bias with the  $T_{g-insitu}$  time series. However, the ERA5 dynamic was quite different from the *in situ* measurements. While  $T_{g-insitu}$  and  $T_g$  seemed linked to air temperature when it rises above  $-10^\circ\text{C}$  (e.g. in early 2014), but with a lag. This was not observed for  $T_{g-ERA5}$ , while it appeared in the retrieved  $T_{g,MEM_G}$  and  $T_{g,MEM_{G+WI}}$ . This could be linked to wet snow events, that increase the snowpack thermal conductivity and consequently the link between air temperatures and  $T_g$ . They also challenge the snowpack transparency hypothesis (Kumawat et al., 2022), that could be not valid anymore, and could lead to an increase in the retrieved  $T_g$  values. Using  $MEM_G$  or  $MEM_{G+WI}$  did not affect the time series dynamic, as shown by the similar R and ubRMSD in Figure 6. However, a strong interannual difference is observed. In winter 2014, we found  $R = 0.46$  for  $T_{g-ERA5}$ , while we obtained  $R = 0.29$  for both  $T_{g,MEM_G}$  and  $T_{g,MEM_{G+WI}}$  (see Figure C1 in the appendices). On the contrary, in winter 2019, a correlation of  $R = -0.03$  is obtained with ERA5, while  $R = 0.61$  using  $MEM_G$  or  $MEM_{G+WI}$ . These discrepancies between years suggest that ice conditions change throughout the years and further ice parametrization would be needed to obtain satisfactory  $T_g$  retrievals for scenes with high water body fractions.

**Figure 8.** Time series of the ground temperatures (in °C, left axis) at Inigok from 2012 to 2020:  $T_{g-insitu}$  (in black),  $T_{g, MEM_G}$  (in orange),  $T_{g, MEM_{G+WI}}$  (in blue) and  $T_{g-ERA5}$  (in red). The snow depth (in cm, right axis) is displayed as dark grey bar plots. In the background, stripes from blue to red account for the *in situ* air temperature (in °C).

395 The similarities of behaviors of *in situ* and retrieved time series also varied during a single season. Figure 9 focuses on the retrievals using  $MEM_{G+WI}$  with different  $H_{r,wi}$  at Inigok from December 2016 to May 2017. This period corresponds to the winter season with best correlation according to Figure C1 ( $R = 0.74$ ). The retrieved  $T_g$  and  $T_{g-insitu}$  were averaged per month and plotted with their standard deviation. Each graph of Figure 9 corresponds to a different  $H_{r,wi}$  used in the modeling. The difference between the monthly averaged  $T_g$  and the monthly averaged  $T_{g-insitu}$  is noted  $\Delta\bar{T}$ . December ( $\Delta\bar{T} = -0.5^\circ\text{C}$ ),  
400 January ( $\Delta\bar{T} = -1.8^\circ\text{C}$ ) and February ( $\Delta\bar{T} = 0^\circ\text{C}$ )  $T_g$  are in good agreement with  $T_{g-insitu}$  for  $H_{r,wi} = 0.7$ . However, in March,  $H_{r,wi} = 0.8$  provide better results ( $\Delta\bar{T} = -0.2^\circ\text{C}$ ). The best  $H_{r,wi}$  is 0.9 for April ( $\Delta\bar{T} = -0.5^\circ\text{C}$ ) and May ( $\Delta\bar{T} = -0.5^\circ\text{C}$ ). This suggests a possible evolution of the ice conditions throughout the winter, that impacts the ice-water surface rugosity and  $T_g$  inversion. This is in agreement with SAR studies (Duguay and Lafleur, 2003; Murfitt et al., 2023) which take into account roughness parameters over lakes to represent the impact of the roughness at the water-ice interface on microwave  
405 signal. Murfitt et al. (2023) linked the water-ice interface roughness with the growth of tubular bubbles during ice formation, leading to higher roughness. Slushing water in ice cracks at the end of the freezing season induces more complexity than our three horizontal layers modeling for water bodies (Adams and Lasenby, 1985). Ground-based radiometric observations would be highly beneficial to better understand the seasonal effect of water-ice interface roughness on  $T_B$  in Arctic regions. Such observations may also help the development of a more complex model to better describe the L-band emissions of the  
410 circumarctic lakes and their variations through the seasons.

**Figure 9.** Scatter plots of the retrieved monthly average  $T_g$  (in  $^{\circ}\text{C}$ ) against *in situ* averaged  $T_{g\text{-insitu}}$  (in  $^{\circ}\text{C}$ ) at the Inigok site from December 2016 to May 2017

. The error bars show the standard deviation of the retrieved and measured temperatures.  $H_{r,wi}$  values used in the inversion are 0.7 (left), 0.8 (middle), and 0.9 (right). The grey dashed line corresponds to the 1:1 identity line.

## 6 Conclusions

This study aimed to expand the previous studies on L-band passive microwave modeling and ground-based observations of snow-covered scenes by retrieving ground temperatures from satellite measurements in winter conditions. Our approach is based on SMOS L-band observations from 2012 to 2019. Two MEM configurations were explored to retrieve the  $T_g$  below the snowpack in the Arctic: one considering a homogeneous scene ( $\text{MEM}_G$ ) and another one correcting the scene for the snow and ice covered water body fraction ( $\text{MEM}_{G+WI}$ ).  $T_g$  retrieved with both MEM were validated with *in situ* measurements of 21 sites across northern Alaska and compared to  $T_{g\text{-ERA5}}$ . Several conclusions can be drawn from our results:

- $T_g$  under the snowpack can be retrieved from SMOS observations with a relatively simple MEM and limited auxiliary data.
- For sites with low water fraction ( $\leq 0.04$ ),  $T_g$  were retrieved with a median correlation R of 0.60 and a median bias of  $-0.2^{\circ}\text{C}$ . For the same sites, the ERA5 median R was 0.51 and median bias was  $-0.8^{\circ}\text{C}$ .
- For sites with a higher water fraction ( $\geq 0.20$ ), ignoring the water fraction ( $\text{MEM}_G$ ) leads to strong negative biases. The bias can be reduced using an ice-water roughness parameter  $H_{r,wi}$ , but correlation with *in situ* remains low ( $< 0.5$  and worse than ERA5).
- Further work needs to be done to assess the impact of the snow and ice covered water bodies on L-band  $T_B$  evolving through the winter season.

With its launch in 2010, SMOS has offered observations for almost 15 years to this day. Producing  $T_g$  maps over the Arctic for the whole period would improve monitoring of the permafrost state in space and time and would be highly beneficial for carbon models.

## Appendix B: Results: Figures with confidence intervals

The Figures B1, B2 and B3 below are respectively similar to the Figures 5, 6 and 7 but with the confidence intervals (CI) of each metric. The 5% and 95% CI are respectively represented in orange and blue, the metric in grey. As for each metric, the CI distribution of all sites is represented with a boxplot.

**Figure B1.** Summary statistics of  $R$ , bias and ubRMSD for sites with  $\nu_{wi} \leq 0.04$ . The boxes show the median and interquartile range and whiskers show the 5 and 95 percentiles obtained from all the considered sites. The grey box corresponds to the skill estimate ( $R$ , bias, or ubRMSD). Respectively, the orange and blue boxes correspond to the associated 5% and 95% confidence interval limits obtained from all the considered sites. The x-axis corresponds to the  $H_{r,wi}$  used in the inversion. The boxes are respectively obtained from:  $\text{MEM}_G$  with  $H_{r,gs} = 8$

(left),  $\text{MEM}_{G+WI}$  with  $H_{r,wi} = 1$  (center) and ERA5 (right).

**Figure B2.** Summary statistics (in grey) of  $R$ , bias and ubRMSD and their 5% (in orange) and 95% (in blue) confidence intervals for sites with  $0.20 \leq \nu_{wi} \leq 0.41$ . Boxes represent the site median and interquartile range ( $Q_3 - Q_1$ ) and whiskers represent the 5 and 95 percentiles. The x-axis corresponds to the  $H_{r,wi}$  used in the inversion. The rightmost boxes are obtained with ERA5.

**Figure B3.** Summary statistics (in grey) of  $R$ , bias and ubRMSD and their 5% (in orange) and 95% (in blue) confidence intervals for sites with  $\nu_{wi} \leq 0.04$ . Boxes represent the site median and interquartile range ( $Q_3 - Q_1$ ) and whiskers represent the 5 and 95 percentiles. The x-axis corresponds to the *in situ* probing depths used for the validation. The extreme right boxes are obtained with ERA5 and  $T_{g-insitu}$  at 5 cm depth.

**Figure C1.** Yearly metrics obtained at Inigok from 2012 to 2020:  $T_{g, \text{MEM}_G}$  (in orange),  $T_{g, \text{MEM}_G + \text{WI}}$  (in blue) and  $T_{g-ERA5}$  (in red).  $R$ , bias and ubRMSD are plotted as bar plots, with error bars accounting for their 5% and 95% confidence intervals. On the far right, we show the global metrics obtained for the whole timeseries.

Appendix D: Summarizing performances

**Table D1.** Biases in °C for all sites (lines) and all  $H_r$  (columns). The last column gathers scores from ERA5. The sub-table on top corresponds to the model MEM<sub>G</sub> and the one bellow to the model MEM<sub>G</sub>. The smallest bias obtained with MEM<sub>G</sub> or MEM<sub>G+WI</sub> per site (i.e. line) is in bold.

|                 | Bias in °C       |            |             |            |       |             |             |             |             |       |            |       |

*Author contributions.* JO carried out this study by analyzing data, performing the inversions, and organizing and writing the paper. ARoyer, AM and ARoy proposed the initial idea. MS and MH provided expertise in microwave emission model and contributed to the writing of the manuscript. All the authors were involved in the analysis of the results and contributed to the writing of the paper.

445 *Competing interests.* The authors declare no conflict of interest.

*Acknowledgements.* This work was funded by the CNES (Centre National d'Etudes Spatiales) through J.O. PhD funding (contract no. JC.2020.OO39O41) and the Science TOSCA (Terre Océan Surfaces Continentales et Atmosphère) program. The authors acknowledge the support of the Natural Sciences and Engineering Research Council of Canada (NSERC). This study has been partially supported through the grant EUR TESS N°ANR-18-EURE-0018 in the framework of the Programme des Investissements d'Avenir. A contribution to this work  
450 was made at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.
