Abstract. Urban areas, characterized by dense populations and many socio-economic activities, increasingly suffer from floods, droughts, and heat stress due to land use and climate change. Traditionally, the urban thermal environment and water resources management have been studied separately, using urban land surface models (ULSMs) and urban hydrological models (UHMs). However, as our understanding deepens and the urgency to address future climate disasters grows, it becomes clear that hydroclimatological disasters—such as floods, droughts, severe urban thermal environments, and more frequent heat waves—are actually not isolated events but compound events. This underscores the close interaction between the water cycle and the energy balance. Consequently, the existing separation between ULSMs and UHMs creates significant obstacles in better understanding urban hydrological and meteorological processes, which is crucial for addressing the high risks posed by climate change. Defining the future direction of process-based models for hydro-meteorological predictions and assessments is essential for better managing climate disasters and evaluating response measures in densely populated urban areas. Our review focuses on three critical aspects of urban hydro-meteorological simulation: similarities, differences, and gaps among different models; existing gaps in physical process implementations; and efforts, challenges, and potential for model coupling and integration. We find that ULSMs inadequately represent water surfaces and hydraulic systems, while UHMs lack explicit surface energy balance solutions and detailed building representations. Coupled models show potential for simulating urban hydro-meteorological environments, but face challenges at regional and neighborhood scales. Our review highlights the need for interdisciplinary communication between the urban climatology and the urban water management communities to enhance urban hydro-meteorological simulation models.

60 1 Introduction

Cities are characterised by dense populations and intense socio-economic activity, leading to intensive landscape modifications. Meteorology is notably intricate and heterogeneous in urban areas, and the hydrological processes differ significantly from those found in the natural environment, being characterised by small-scale heterogeneity. As a result, numerical simulations are often used in research to understand the impact of meteorological and hydrological processes on urban areas and enhance

65 urban resilience in the face of future climate change. Process-based simulations can be used to predict urban climate dynamics and hydrological conditions, as well as assess the effects of urban expansion and the effectiveness of mitigation and response measures. Over the past decades, significant developments have been made in numerical meteorological and hydrological models tailored explicitly for urban environments (Fletcher et al., 2013; Lipson et al., 2024). A systematic literature review will be provided later in this paper to cover the developments and advancements of these models.

70 To adequately simulate urban climate dynamics, land surfaces parameterisation schemes for urban land surface have been the main development in recent years, which may also include the urban land-atmosphere exchange. In this study, the urban meteorological simulation tools are referred to as *urban land surface models* (ULSMs). The ULSMs have been intensely applied to simulate urban thermal conditions in the past decades. The cornerstone of ULSMs is resolving the urban surface energy balance, meaning that in literature, these have also been referred to as *urban surface energy balance models*. The

75 main modelling philosophy is the same as that of the natural land surfaces models: the surface's effects on heat, moisture, and momentum fluxes need to be accounted for in the land-surface schemes used by numerical models. Existing models can exhibit varying levels of sophistication, depending on their underlying assumptions regarding surface features and exchange processes. To compare the capacity of the existing ULSMs, Grimmond et al. (2010) conducted the International Urban Energy Balance Models Comparison Project (PILPS-Urban). In this project, they summarised and compared thirty-three ULSMs. 80 One of the conclusions drawn was that models have a good overall capability to model net all-wave radiation and a limited capability to model latent heat flux. Over a decade later, Urban-PLUMBER (Protocol for the Analysis of Land Surface Models Benchmarking Evaluation Project) was conducted (Lipson et al., 2024), summarising the most recent developments of the ULSMs based on 30 selected representative examples. It compared the capability of the models, including building complexity, hydrological complexity, and behavioral complexity. The study concluded that over the past decade, advancements in urban 85 land surface models have led to a more accurate representation of urban morphology with good input data, coupled with focussed efforts on vegetation and hydrological processes.

Hydrological models have a long development history and have become increasingly important tools for managing water resources. Regarding the hydrological processes in urban areas, there is no standard definition for the urban water cycle, although previously, many texts agreed on dividing the system into two main networks of pathways: a modified natural set of pathways 90 and supply-sewerage pathways (Lerner, 2002; Dwarakish and Ganasri, 2015). This division, however, has become less strict in recent years as the increased inclusion of urban greening and blue-green infrastructure in the urban environment (Fletcher et al., 2024) has led to urban irrigation using drinking water (e.g., Guo et al. (2021)), hence linking the modified natural and supply-sewerage components. Thus, *urban hydrological models* (UHMs) must consider natural hydrological processes under artificial modifications and hydraulic processes (Urich and Rauch, 2014). The hydrological modelling of urban areas is highly 95 challenging as urban areas are strongly heterogeneous and exhibit very specific hydrological processes (Ichiba et al., 2018). Salvadore et al. (2015) reviewed 43 hydrological models applied to urbanized areas, noting that the main differentiation can be found in spatial and temporal scales of models and various functions as opposed to modelling schemes or approaches. One of the notable conclusions drawn by Salvadore et al. (2015) was that although all the included models consider precipitation and evaporation analysis, a few consider energy balance variables.

100 Historically, the urban thermal and hydrological environments have been treated as distinct fields and were studied independently. As the understanding deepens and the need to address future climate disasters becomes more urgent, hydrological disasters—such as floods, droughts, severe urban thermal environments, and more frequent heat waves—are no longer seen as isolated events, but compound events (Wehner, 2023; Zscheischler et al., 2020). Research indicates that heat waves following floods have caused more severe damage, as observed in Japan, where the 2018 floods were followed by a heat wave with temperatures exceeding 39°C (Wang et al., 2019), and South Asia, where Pakistan faced compound damage to infrastructure and 105 agriculture (Lau and Kim, 2012). Research also pointed out that summer floods in the central United States are often preceded by a heat stress event (Zhang and Villarini, 2020). Cities like Miami and New Orleans in the United States, as well as some South European cities, faced severe droughts exacerbated by the urban heat island effect, leading to extreme heat conditions and increased strain on water resources (Aboulnaga et al., 2024). To enhance urban safety and livability, various mitigation mea-

110 sures have been proposed and implemented. Among these, urban blue-green spaces are particularly effective, as they not only
mitigate the urban heat island effect but also reduce surface runoff, benefiting urban hydrological and the thermal environment
(Gunawardena et al., 2017; Li et al., 2019). The compound climate disasters and mitigation mechanisms highlight the crucial
role of the interaction between the water cycle and energy balance. For instance, urban water conservancy projects influence
the moisture content of surface and near-surface soils; integrating urban drainage facilities into landscapes with water features
115 may cool down urban temperature (Ferdowsi et al., 2024). Additionally, the interaction between the temperature of urban water
bodies and the near-surface, and urban thermal conditions influence the water body ecosystem and water quality (Chen et al.,
2023; Brans et al., 2018; Grey et al., 2023). These processes underscore the intricate link between urban meteorology and
hydrology (Oke, 1982; Fletcher et al., 2013).

Evidently, current process-based simulation tools, ULSMs and UHMs, have developed independently and are driven by
120 different considerations and applications. This has led to limited overlap and interaction between them. As a result, accurately
simulating both urban hydrological and near-surface meteorological conditions, hereafter called hydro-meteorological condi-
tions, simultaneously remains challenging. Recently, Jongen et al. (2024) evaluated the water balance in 19 ULSMs from the
Urban-PLUMBER project (Lipson et al., 2024), concluding that the water balance appears unclosed in 43% of the model runs.
The interactions between the urban water cycle and the energy budget may not be comprehensively captured by the existing
125 models. Consequently, assessing the risk of extreme events, particularly compound events, and devising diverse strategies to
address future climate change remains difficult. Until now, significant knowledge gaps in hydro-meteorological dynamics per-
sist within the intricate interplay of urban morphology, human activities, and the reciprocal effects of heat fluxes, radiation, and
hydrological processes (Grimmond et al., 2020). Previous literature reviews have conducted comparative analyses on one of
these two groups of models, but rarely have they compared the two groups of models. It is urgent to point out the future devel-
130 opment direction of physical models to meet the needs of hydro-meteorological prediction and assessment to better cope with
the occurrence of climate disasters, as well as the feasibility assessment of efficient response measures in densely populated
urban areas.

Triggered by the increasing demands of studying hydro-meteorology in urban areas, this study's main objective is to sum-
marise, assess, and formulate recommendations to effectively develop numerical simulation tools that can represent the key
135 urban hydro-meteorological processes. To achieve this goal, first, both ULSMs and UHMs are selected based on previous liter-
ature reviews, with extra attention focusing on the hydro-meteorological interface; second, we summarise the similarities and
differences between the selected ULSMs and UHMs, respectively; third, we assess models' ability to simulate the main urban
hydro-meteorological processes. Based on the results, we identify gaps between the ULSMs and UHMs and weaknesses and
advantages of the models, resulting in the identification of potential coupling opportunities between ULSMs and UHMs that
140 can offer insights for future model development in urban hydro-meteorology.

2 Selection of numerical simulation models

To bring the urban hydrological and meteorological fields together and assess the future of hydro-meteorological models, an inventory of the current state-of-the-art of meteorological and hydrological models was made. Both research-based and applied models were considered. The models considered are shown in Table 1 and Table 2, which lists the long and short names of the included models with the main literature on model development. The listed literature encompasses not only the initial development of the model but also subsequent enhancements by various researchers. However, it excludes studies where the model was applied. The latest version of the model does not ensure the inclusion of all developed physical processes. We consider all added physical processes as part of the model's existing simulation capabilities.

Depending on the complexity of the model (Lipson et al., 2024), the ULSMs can be divided into:

- (1) Bulk Models: These models treat the urban area as effectively a kind of bare soil, albeit with modifications. Bulk models parameterise heat capacities, thermal conductivities, surface albedo, roughness length, and moisture availability. The bulk models can be separated by how many urban facets are considered. The model is called the one-tile if it only has one urban facet, treating the urban area as a whole. There are also two-tile models with two urban facets: the roof and the ground.
- (2) Urban Canopy Models (UCMs): UCMs average the characteristics of buildings and assume an infinitely long street canyon. The urban canyon is the area beneath the rooftop and is flanked by buildings on both sides. Consequently, canopy models primarily operate in two dimensions (2D). The models have at least three urban facets: wall(s), roof, and ground. Depending on the vertical resolution the model resolves in the urban canyon, the model can be either single-layer or multilayer. The single-layer models treat the urban canyon as a homogeneous area. Atmospheric conditions do not change following the height change below the building height. However, the multilayer models solve the vertical profiles of the atmospheric conditions.
- (3) Building-Resolving Models: These models normally employ computational fluid dynamics (CFD) to accurately simulate thermal and airflow conditions with 3D information of the buildings and heterogeneous urban landscape. Thus, all the urban facets are represented and resolved in the models

Referring to the previous review works, several ULSMs were included in this study for the later analysis of included physical processes. The current study includes ten ULSMs, including a two-tile bulk model, seven urban canopy models, and two building-resolving models. Five out of ten ULSMs have been coupled with mesoscale land surface schemes. Here, we only consider the Weather Research and Forecast model (WRF) as the mesoscale model example. Not every ULSM is included in the summary of our analysis. We only selected some representative, widely used, and newly developed models based on our focus. Since we aim to focus on the interface of hydro-meteorology in the urban environment, the representation of vegetation, water surface, and the urban water balance in the ULSMs were given extra attention during the selection of the models and model versions. Studies that use CFD models to investigate the microscale urban climate, energy balance processes and the wind environment have been intensively addressed, but seldom focusing on the water balance processes (Lipson et al., 2024).

For example, PALM has recently been intensively developed with different modules to suit the urban layout (PALM-4U), but it has not yet been widely evaluated and applied (Resler et al., 2017; Gehrke et al., 2021). The development of the ENVI-met is not well documented since it is a commercial software package. Neither PALM nor ENVI-met is included in the current review (Maronga et al., 2020; Tsoka et al., 2018). It is also worth mentioning that the current review does not assess the performance of the individual models; for this, readers are referred to Lipson et al. (2024) and Jongen et al. (2024).

Hydrological models are typically categorised by their spatial resolution into lumped, semi-distributed or distributed models (Khakbaz et al., 2012). However, this review focuses on the processes modelled rather than their spatio-temporal resolution. For this reason, the UHMs included in the current review were separated into:

- (1) Hydraulic models: in a narrow sense, the urban hydrological models refer to the type of models whose main function is to quantify the inflow into stormwater drainage (and sewers) derived from rainfall-runoff processes. This is often coupled with a hydraulic model to simulate the routing inside the drainage conduits. A wide range of commercial and open-source software packages are available for this purpose. One good example is the Storm Water Management Model (SWMM) (Gironás et al., 2010). The description of typical natural hydrological processes is simplified for this group of models (Salvadore et al., 2015).
- (2) Hydraulic-hydrological models: this group of models with the main focus on the general hydrological simulations, usually used for evaluating the impact of urbanisation, have limited treatment of artificial pathways (sewers, stormwater systems, water supply).

The selection of UHMs also focuses on how they contribute to the interface of climatology and hydrology simulations. As mentioned by a previous review study (Salvadore et al., 2015), most UHMs do not include the surface energy balance and climatological process interactions. Only the weather conditions during the simulation period, such as precipitation and temperature, are general input for the models. The hydraulic models selected in the current study are mainly based on SWMM. There exist other simulation tools used for urban water management, such as MIKE URBAN, developed and managed by the Danish Hydraulic Institute (DHI, 2024), InfoWorks ICM, owned by AutoDesk (Wu et al., 2021) and the Delft3D model (Hasan Tanim and Goharian, 2021). However, many of them are not open source and focus specifically on wastewater treat-

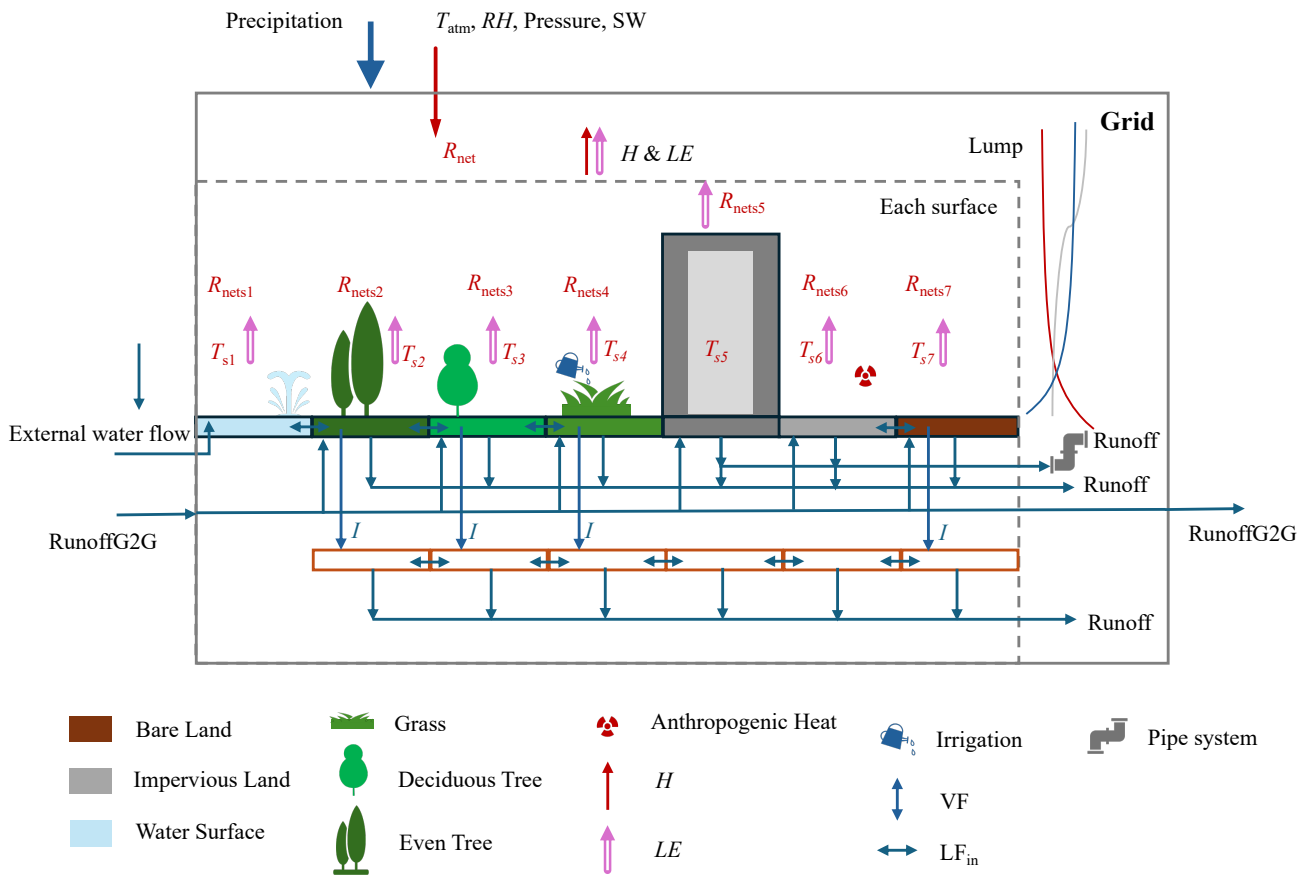

Figure 1. Schematic structures of SUEWS and the included elements and main processes calculated in the model are represented. Redrawn after the Figure 1 in Järvi et al. (2014). H is the sensible heat flux, LE is the latent heat flux, VF presents the vertical flow and LF_{in} presents the lateral flow within grid cell. The meaning of the abbreviations in the figure can be found in the List of Symbols and Acronyms.

ment, sewer system design, and coastal urban floods. Most of the hydro-meteorological interfaces in the models share major components similar to SWMM. Thus, our selection can be considered representative of the majority of urban hydraulic models. Three hydraulic-hydrological models that mainly consider the general urban hydrological simulations are selected in the current study for later analysis. Each model has a different spatial and process complexity level, which will be analysed later.

3 Urban land surface models (ULSMs)

3.1 Bulk models

The only bulk model selected, the Surface Urban Energy and Water Balance Scheme (SUEWS), is a two-tile model, which was first released by Järvi et al. (2011). The two-tile model resolves two urban surface facets (roof and street canyon) with different thermal and radiative properties. The two-tile model only resolves two surface energy balances. The primary objective of SUEWS is to be capable of simulating energy and water fluxes and getting the output at an hourly level temporal resolution (therefore requiring relatively low computational complexity) using minimal input data, which can be obtained from standard meteorological stations or an urban mesoscale model. The model is derived from the model developed by Grimmond et al. (1986), who initially introduced a water balance model for urban areas, considering actual evaporation rates at the neighborhood or local scale (ranging from 100 meters to 1 kilometer). Additionally, Grimmond et al. (1991) employed an evaporation-interception approach to calculate hourly fluxes. Järvi et al. (2014) further developed the model for cold climates, including snow-related processes. Wang et al. (2016) added an irrigation scheme to the model. Diagnosis of air temperature, humidity, and wind speed within the roughness sub-layer was updated by Theeuwes et al. (2019); Tang et al. (2021).

Figure 1 shows the schematic SUEWS and the included physical processes. The model takes the precipitation, first layer atmosphere air temperature and pressure, and shortwave radiation as inputs. Seven land use types are included in SUEWS, with a single soil layer. The surface temperature (T_s) and net radiation (R_{net}) are solved separately for each land use type and the building roof, but sensible heat (H) and latent heat (LE) fluxes are solved for the whole grid with the lumped (gridded average) result. There is no interaction between roof and land surface tiles. The model has the ability to compute the grid-average vertical profile of the near-surface air temperature, humidity, and wind. The hydrological cycle is included to some extent, with infiltration (I) and lateral water flow among different types of land surface (LF_{in}). Although grid-to-grid runoff (RunoffG2G) is included as an external fixed term in the water balance, the dynamic interaction between grids is not included.

3.2 Urban canopy models

UCMs are ULSMs that resolve the energy balance for the roof, wall, and ground surface separately. The current assessment includes seven ULSMs belonging to the canopy scheme, making it the most abundant ULSM type assessed in this review. Masson (2000) developed a single-layer urban canopy model called the Town Energy Budget (TEB) scheme. The single-layer urban canopy model developed by Kusaka et al. (2001) (SLUCM) is very similar to TEB. The only differences are that the SLUCM in this version (Kusaka et al., 2001) includes the canyon orientation and diurnal change of solar azimuth angle, and the surface consists of several canyons with different orientations. A multi-layer UCM was developed by Martilli et al. (2002) and is named the Building effect parameterisation (BEP). The primary objectives of UCMs are to focus on energy and momentum exchange between an urban surface and the atmosphere. Thus, UCMs are generally good at reproducing surface temperatures and sensible heat budgets. However, they are inevitably inadequate in capturing the dynamics of the urban water budget and the latent heat due to the lack of realistic urban hydrological processes incorporated.

Motivated by various research requirements, including investigations into the cooling influence of vegetation in urban street
235 canyons and the effects of urban water circulation on the thermal environment, UCMs have progressively incorporated consid-
erations related to urban vegetation and hydrological processes (Grimmond et al., 2010). Lee and Park (2008) first introduced
the Vegetated Urban Canopy Model (VUCM), which comprehensively accounts for the impact of vegetation on wind speed,
radiative energy partitioning, soil processes, and vegetation energy budgets within an urban canyon. Wang et al. (2013) pro-
posed a surface exchange scheme coupling the transport of energy and water in urban canopies for the SLUCM. Sun et al.
240 (2013) incorporated green roof-related processes based on the version of Wang et al. (2013) SLUCM. The parametrisation
scheme for urban trees also gradually included the shading effect and evaporation in the stand-alone SLUCM (Ryu et al., 2016;
Wang et al., 2016, 2021). Urban trees have also been included in BEP but do not include the hydrological module (Krayen-
hoff et al., 2014, 2020). Lemonsu et al. (2007) introduced both the rainfall interception capacities of built-up surfaces and
integrated water infiltration through artificial surfaces into the TEB, and later, the vegetation scheme was also implemented
245 for direct interaction between the urban landscape with vegetation and built-up area (Lemonsu et al., 2012; Redon et al.,
2017, 2020). A complete hydrological scheme for urban areas was developed by integrating the subsoil under built-up surfaces
and hydrological soil–surface interactions into the vegetation version of TEB (Stavropoulos-Laffaille et al., 2018, 2021).

Recently, newly developed models have focussed more on assessing the impact of blue and/or green spaces on urban mi-
croclimate. Broadbent et al. (2019) presented a new model called The Air-temperature Response to Green/Blue Infrastructure
250 Evaluation Tool (TARGET). As mentioned by the developers, TARGET is a simple simulation tool that calculates surface tem-
perature and street-level (below roof height) air temperature in urban areas. It has been claimed that it is designed to make quick
and accurate assessments of cooling impacts on green-blue spaces with minimal input data requirements. To further assess the
impact of vegetation on urban climate and hydrology, Meili et al. (2020) presented an urban eco-hydrological model, Urban
Tethys-Chloris (UT&C). The development of UT&C combines components of the eco-hydrological model Tethys-Chloris
255 (T&C) and SLUCM, thus including more detailed hydroclimatic processes. Moradi et al. (2021) developed a model called
the Vertical City Weather Generator (VCWG), and the inclusion of hydrological processes is based on UT&C (Moradi et al.,
2022).

Figure 2 presents the integration of all the UCMs that share a similar model structure but include different levels of physical
complexity. Figure 2 includes all the physical processes that can be simulated by UCMs according to development literature. It
260 is obvious that, unlike SUEWS, urban landscapes are included within urban canyons in UCMs. The UCMs take precipitation,
air temperature, and specific humidity of the first layer of the atmosphere, as well as downward shortwave and longwave
radiation, as inputs. Building roofs directly interact with the first layer of the atmosphere in terms of energy and humidity. The
other surfaces, including the surface water, vegetated land, bare land, building walls, and trees, directly interact with the urban
canyon air. The exchanges of energy, water, and momentum take place between the urban canyon and the first layer of the
265 atmosphere. The canyon-average air temperature, humidity, and wind can be solved, but the vertical profile of each simulation
grid can only be solved in some of the UCMs. The soil layer can be single or multiple. The representations of vegetation and
water surface are only included in some UCMs. The water balance, including infiltration, vegetation root uptake, urban pipe
system inflow, lateral water flow between different land surfaces, and groundwater flow, can also be included based on the

270 extent of development of each UCM. The canyon concept has been intensively adopted while developing simulation tools for the urban climate. Different UCMs have been developed by referring to each other but, meanwhile, vary due to the specific focus and developers' interests.

3.3 Building resolving models

3D-Models seldomly resolve the subsurface conditions and lack representation for the hydrological cycle, which is also why only two models are included in this study. The current analysis includes two building resolving models: the Vegetated Temperatures Of Urban Facets (VTUF-3D) model (Nice et al., 2018) and the Solene-Microclimat model (Musy et al., 2015).

275 VTUF-3D is the vegetated version of the Temperatures Of Urban Facets (VTUF-3D) model (Krayenhoff and Voogt, 2007). The TUF-3D model was integrated with a model called MAESPA, which is the combination of the MAESTRO and SPA (Soil-plant-atmosphere) models, enabling the inclusion of any vegetation type in any configuration within a modelling domain to consider vegetation's structural and physiological processes. VTUF-3D uses cube-shaped structures (as TUF-3D uses to represent buildings) to represent vegetation. The structure of this coupled model can be seen in Figure 1 in Nice et al. (2018). The purpose of developing the VTUF-3D is to estimate accurate latent energy fluxes and the soil-vegetation-atmosphere pathway critical for vegetation and water-sensitive urban design assessments within the urban canyon, which is also the major reason we include this model in our analysis. However, the water balance is missing in the TUF-3D model (Krayenhoff and Voogt, 2007). The water balance is included only for the vegetation as mentioned in Duursma and Medlyn (2012). The flowchart of the water balance component for vegetation can be found in Figure 2 in Duursma and Medlyn (2012).

285 The Solene-Microclimat model was first developed for outdoor comfort assessment and then built the connection between building energy and indoor thermal conditions (Musy et al., 2015, 2021). The model is based on a 3D-representation of urban geometry, and the simulated scenes are modeled by the meshing of the 3D-developed surface with rectangular or triangular elements. It is a coupled model with three main parts: radiation model, thermal model, and airflow model. The radiation-thermal model is called the Solene model. The Solene-Microclimat model is completed by coupling the CFD model to simulate the airflow. The coupling was first performed by Vinet using the N3S CFD code, which has been replaced by FLUENT and later by Code Saturne (Robitu et al., 2006). More details can be found in Musy et al. (2021). Trees are considered a surface in the radiative model (the tree crown envelope) and a volume in the CFD model. Green roofs and walls, as well as lawns, are included in the model. A thermal model developed by Robitu et al. (2004) considers the radiation absorbed, transmitted, and reflected at the water surface. The model can also simulate the behavior of watered surfaces. The Modelling of Actual Runoff Infiltration and Evapotranspiration (MARIE), based on a distributed hydrological model, was later coupled with the Solene-Microclimat urban climate model (Musy et al., 2021). One of the main reasons for including this model in the analysis is that it shows the potential capability of coupling hydrological and land surface models.

3.4 ULSMs summary and comparison

300 With three different types of model structures (bulk model, UCMs, and building resolved models), the selected models have a wide spatial resolution coverage. The top part of Table 3 summarises the simulation unit name and spatial and temporal

Table 3. Information of included models. The information is based on the literature listed in Table 1 and Table 2 and also on Salvadore et al. (2015).

Shortname	Type	Simulation Unit	Spatial Resolution	Temporal Resolution
SUEWS (WRF-SUEWS)	Bulk (2-Tile)	Grid cell	100 m - 5 km	hr

resolutions of the included ULSMs. The simulation domain is the combination of at least one simulation unit. The models solve each unit separately in most cases. The spatial resolution of the models indicates the general support of the simulation unit. Both bulk models and UCMs are 2D ULSMs. The standalone 2D ULSMs can be applied to a neighborhood scale, sometimes called district scale, with a simulation resolution of 100 m - 1 kilometer (Figure 3a and b), called standalone mode hereafter. The 2D-ULSMs can be coupled with regional and global climate models, with a simulation resolution of 1 to 5 kilometers (Figure 3c and d), called coupled mode. The 3D building resolved models are, in general, only applied at the neighborhood scale and have resolutions of the order of one meter (Figure 3e). The temporal resolution of the 2D ULSMs is above half an hour and can reach the minimum level for the 3D ULSMs.

Figure 3a shows the structure of the selected standalone 2D bulk model (SUEWS). The model can simulate the impervious land area and the other six landscapes, as mentioned in Figure 1. Figure 3b shows the structure of the UCMs. It can be seen that UCMs assume the whole study area is within the urban canyon. Both standalone model SUEWS and UCMs focus on the study area in one or several independent simulations. If the study area is separated by different landscapes (four squares used as an example here), the standalone mode will solve each square independently, which means: 1) the landscape and urban morphology are assumed to be homogenous within each square; 2) there is no interaction between squares. The atmospheric condition for each single square can differ for the standalone mode depending on the user setting and data availability, represented by the dashed blue lines in the top square of Figures 3a and b. It is worth mentioning that the 'square' here in Figure 3a and b

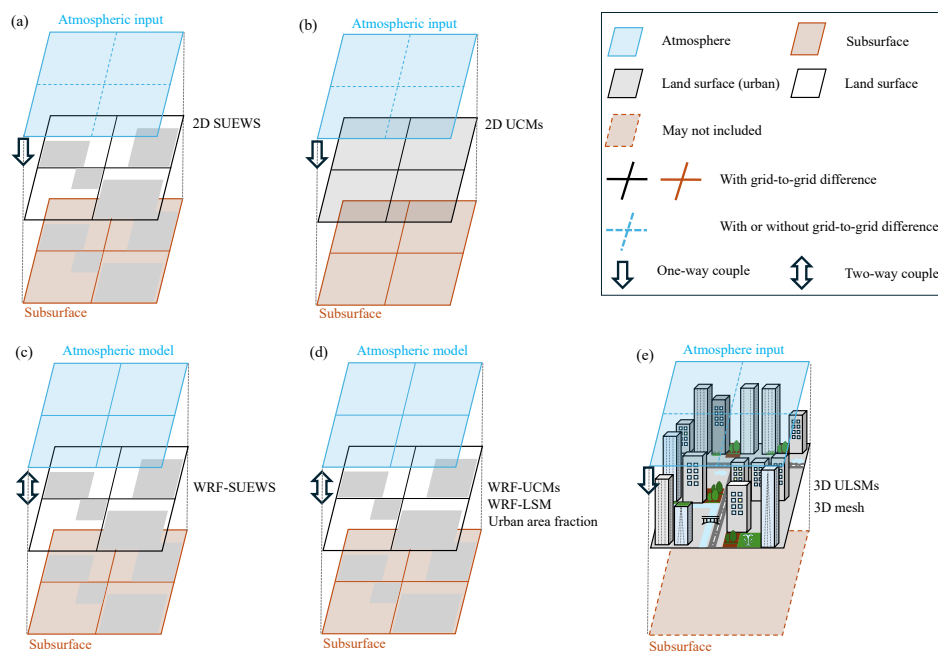

Figure 3. Conceptual figure of model structure and coupling condition for standalone ULSMs (a) and (b), coupled ULSMs (c) and (d), and building resolved ULSMs (e).

does not need to be a strict square. Once we assume a certain urban neighborhood shares the same morphology, an individual standalone mode simulation can be set up.

320 Figures 3c and d show the structures of the coupled mode in the regional or global climate models. The coupled mode would yield the results for the whole study area with one simulation instead of independently. Most of the regional or global climate models are grid-based. Thus, the squares shown in Figures 3c and d are strictly square shapes with the same size in the coupled mode simulation; hereafter, we call each square a grid in the coupled mode. SUEWS, as a bulk model, actually shares similarities with a complete land surface model with the impervious land included. Indeed, recently, WRF-SUEWS
 325 (Sun et al., 2023) has been developed as a land surface scheme (Figure 3c). The difference between the standalone and coupled versions of SUEWS is whether the atmospheric conditions are two-way and interact with the land surface. The coupled mode only uses UCMs to solve the impervious area in each grid. The fraction of the impervious land area in each grid cell is set manually depending on the urbanisation level or based on the land use data set. The land surface model solves the other landscapes that cover the rest of the grid, like grass or bare land. Interactions exist between the impervious land solved by
 330 UCMs and the other land use areas solved by the land surface model within a grid cell. However, the interactions are indirect through the exchange or mixing of air at the near-surface and upper atmosphere. For the coupled mode simulation, grid-to-grid differences in atmospheric conditions are necessary and solved by the atmospheric model. The grid-to-grid interactions are limited in coupled mode simulation. Since the land surface model solves all the other landscapes, the coupled mode 2D UCMs

do not need to include different landscapes, like trees, grassland, and bare land, but focus only on impervious land. However,
335 standalone UCMs with the canyon concept were developed with more and more integration of the processes that happen in the
urban canyon (Ryu et al., 2016; Wang, 2014; Lemonsu et al., 2012). Thus, the version of the models in standalone mode is
normally more advanced than the coupled mode (Krayenhoff et al., 2020; Meyer et al., 2020).

Building resolving models (Fig. 3e) solve the simulation area with the 3D mesh concept with resolutions down to 1 meter. 3D
models can be scaled up to mesoscale models, providing detailed three-dimensional meteorological variables. However, due
340 to their computational demands and substantial initial and boundary conditions, building resolving models are predominantly
applied at micro-scale levels (less than 100 meters) and less frequently in regional or global climate simulations. The upper
atmosphere condition and meteorological information are usually one way forcing the simulations.

The trend in developing 2D models is towards higher complexity than bulk models. Unlike bulk models, UCMs incorporate
the urban canopy concept, allowing for the analysis of more intricate influences within urban areas and street canyons, such as
345 the effects of street trees and urban green spaces. Consequently, UCM models are more widely utilised for studying regional
impacts at the urban block scale, and high-resolution CFD models are primarily used for detailed research in neighborhood
areas.

4 Urban hydrological models (UHMs)

4.1 Hydraulic models

350 In the context of stormwater drainage and sewer flow simulations, we have opted to utilise SWMM, one of the most widely
employed urban watershed hydrological models (Niazi et al., 2017) as the representative model containing overland hydrology
and subsurface hydraulics. Our choice of SWMM serves as an illustrative representation for this type of model and was
chosen due to its open-source nature and therefore interpretability of the model structure. The schematic figure inside the
model is shown in Figure 4. The atmospheric conditions, including air temperature and precipitation, are inputs to the model.
355 There are three types of subareas within each sub-catchment: pervious land and impervious land with and without depression
storage. Water can be transferred among the different subareas within a simulated unit though it is strictly zero-dimensional.
Evaporation and transpiration can be solved either through the inclusion of meteorological parameters or are normally taken
as input time series. The household wastewater, piped system (resolved in one-dimension), water treatment process, and low-
impact development, which includes green vegetation, are also included in SWMM (Fig. 4). The subsurface is represented by
360 a two-zone scheme: an unsaturated zone and a saturated zone. Building and urban morphology are not present in SWMM. The
spatial resolution of the hydraulic model is largely dependent on model requirements and data availability. Usually, individual
conduits are considered, with the surface characteristics lumped per manhole (e.g. Nedergaard Pedersen et al. (2021)), though
the entire network can also be lumped into a single hydrological model within the SWMM environment (e.g. Farina et al.
(2023)).

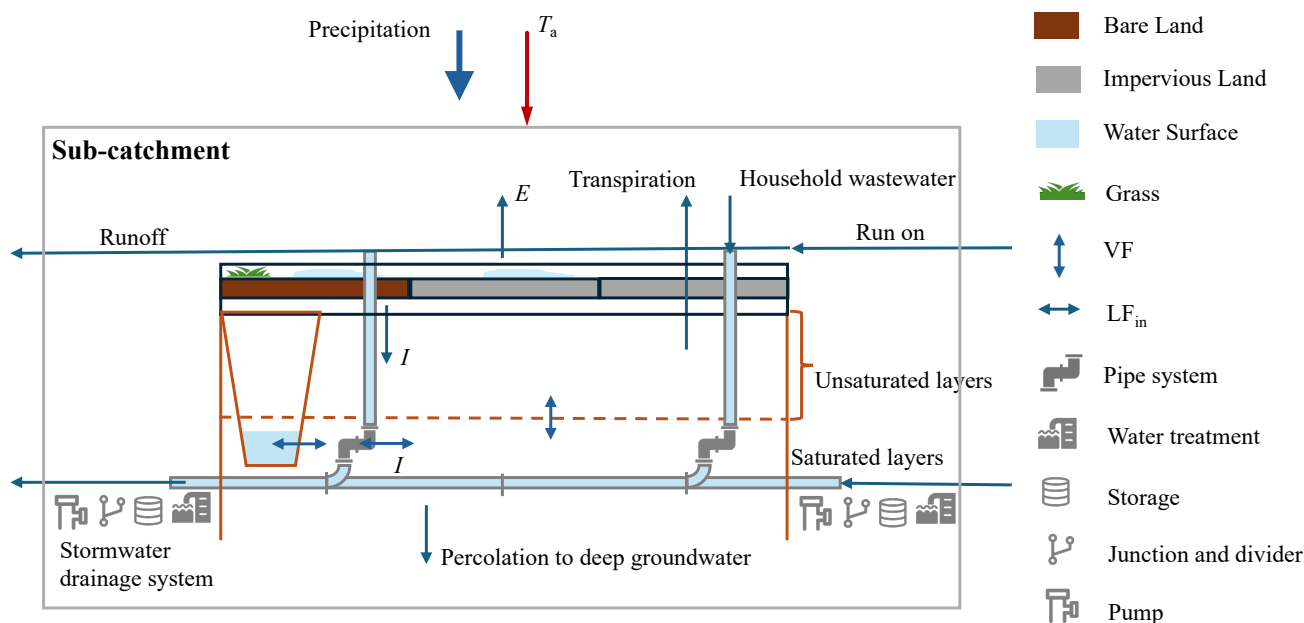

Figure 4. Schematic structure of SWMM and the included elements and main processes calculated in the model are represented (drawn by referring to Figure 3-1 and Chapter 3 in Rossman and Simon (2022)). The meaning of the abbreviations in the figure can be found in the List of Symbols and Acronyms.

365 4.2 Hydraulic-hydrological models

Rodriguez et al. (2008) developed a hydrological model, the Urban Runoff Branching Structure (URBS) model (see Figure 5 for the model structure). The atmospheric conditions, precipitation, and air temperature are the inputs. The geometry information of the urban catchment, including the houses, street sections, and vegetation; topography, street segments, storm sewers, and rivers are provided by a database (Urban Databank) (Rodriguez et al., 2003). URBS solves each simulation unit with three profiles for three land use types: natural soil, street, and house. The trees are represented ‘above’ the land surface with a depression storage function for precipitation water. The subsurface of each land use type is the same, namely a two-zone scheme. Pophillat et al. (2021) implemented the groundwater section, including interactions between surface hydrology, groundwater, and underground structures in URBS. URBS can be coupled with the Solene-Microclimat urban climate model, a 3D building resolved ULSM mentioned in the above Section 3.3 (Robineau et al., 2022). The procedure for the coupling between the microclimate and hydrological models can be found in Figure 3 in Robineau et al. (2022). Although the two models are operated independently and the data exchange is done manually, this coupling study shows the potential of simulating the urban hydro-meteorological interface (Robineau et al., 2022).

Figure 5. Schematic structure of URBS and the included elements and main processes calculated in the model are represented (redrawn after Figure 2 in Rodriguez et al. (2008)). The full name of the abbreviations in the figure can be found in the List of Symbols and Acronyms.

Another hydraulic-hydrological model is called Multi-Hydro (Ichiba et al., 2018). As the Multi-Hydro model is more like a coupled model with four modules (rainfall, surface, soil, and drainage), the schematic structure of Multi-Hydro is not shown here and can be found in Figure 1 in Ichiba et al. (2018). The four open-source software packages are integrated, each representing a portion of the water cycle in urban environments. As mentioned by Ichiba et al. (2018), seven parts are generally included: precipitation, interception and storage, infiltration, overland flow, sewer flow, infiltration into the subsurface zone, and sewer overflow.

The last included model, the water and energy transfer processes (WEP) model, is developed by Jia et al. (2001). Figure 6 displays the process included in WEP. WEP is the only hydrological model we selected that includes the energy balance. The precipitation and incoming radiation are the inputs for WEP. Three land use types are distinguished: water surface, pervious land (bare soil), and impervious land. Buildings and vegetation are included in WEP. Evaporation, together with latent heat flux, is solved. Root water uptake, infiltration, and water leakage are included. The unsaturated and saturated subsurface layers are represented in WEP. The model has four layers in the unsaturated zone. The saturated zone includes one unconfined aquifer, two confined aquifers, and in-between aquitard layers. However, it is worth mentioning that the pipe system is not included in WEP. This means that WEP cannot be used for urban drainage design and planning, the major objectives for SWMM. WEP is in that sense more similar to a hydrological model than a hydraulic model.

4.3 UHMs summary and comparison

The lower part of Table 3 lists the simulation unit and resolution information of the included UHMs. Most of the included models have a spatial resolution larger than 100 meters (Salvadore et al., 2015). Figure 7 shows the simulation structure of the included UHMs. All selected UHMs do not have two-way coupling with the atmosphere. The atmospheric inputs can come from weather stations, as well as regional weather simulations. Each UHM has a different simulation unit and unit linkage. In SWMM, each sub-catchment has an inlet node to the pipe system or channel. The simulation domain is subdivided into sub-catchments. Each sub-catchment is assumed to be an idealised rectangular area with uniform properties and a uniform slope and width (Figure 7a). URBS simulates the hydrological processes at the urban hydrological element (UHE) scale. An UHE encompasses a cadastral parcel and its corresponding adjacent street segments. It considers an urban catchment to be composed of a set of UHEs connected to the catchment outlet by means of a runoff branching structure (Figure 7b). WEP is a grid-based model. The grids are linked with a one-dimensional channel and then linked with the main river. The Multi-Hydro model is also grid-based, with the land use type assumed to be homogeneous within a grid. Thus, the model structure is similar to the one shown for WEP in Figure 7c.

Urban hydrological models continue to face significant trade-offs due to highly complex and heterogeneous systems in which natural and anthropogenic processes interact at various spatial and temporal scales. One of the shortcomings of hydraulic models like SWMM is that they tend to underrepresent land surface processes and land-atmosphere interactions. Although WEP can solve the near-surface atmospheric conditions, it lacks a hydraulic system, which indicates that WEP is geared towards larger study areas (Li et al., 2017). Overall, it can be concluded that UHMs are generally unable to solve near-surface meteorological conditions. Unlike ULSMs, current UHMs do not need detailed urban morphology as the input. On the other

Figure 6. Schematic structure of WEP and the included elements and main processes calculated in the model are represented (redrawn after Figure 1 in Jia et al. (2001)). The meaning of the abbreviations in the figure can be found in the List of Symbols and Acronyms.

hand, UHMs are better equipped to simulate the grid-to-grid interaction for the hydraulic-hydrological processes on the surface and the sub-surface than ULSMs.

5 Simulations of urban hydro-meteorological processes

415 In the context of modelling urban environments, physical processes are governed by energy and water balance equations, which are linked through the evaporation process. The various models analysed exhibit different levels of process complexity, based on their primary objectives. In this section, we analyse how the selected models implement the physical hydro-meteorological processes and explore an alternative approach for incorporating hydro-meteorological interactions within the urban environment. Our examination begins with an exploration of the energy balance across different surfaces within the urban setting,
 420 followed by a summary of how the models simulate meteorological conditions for urban areas, especially for the near-surface.

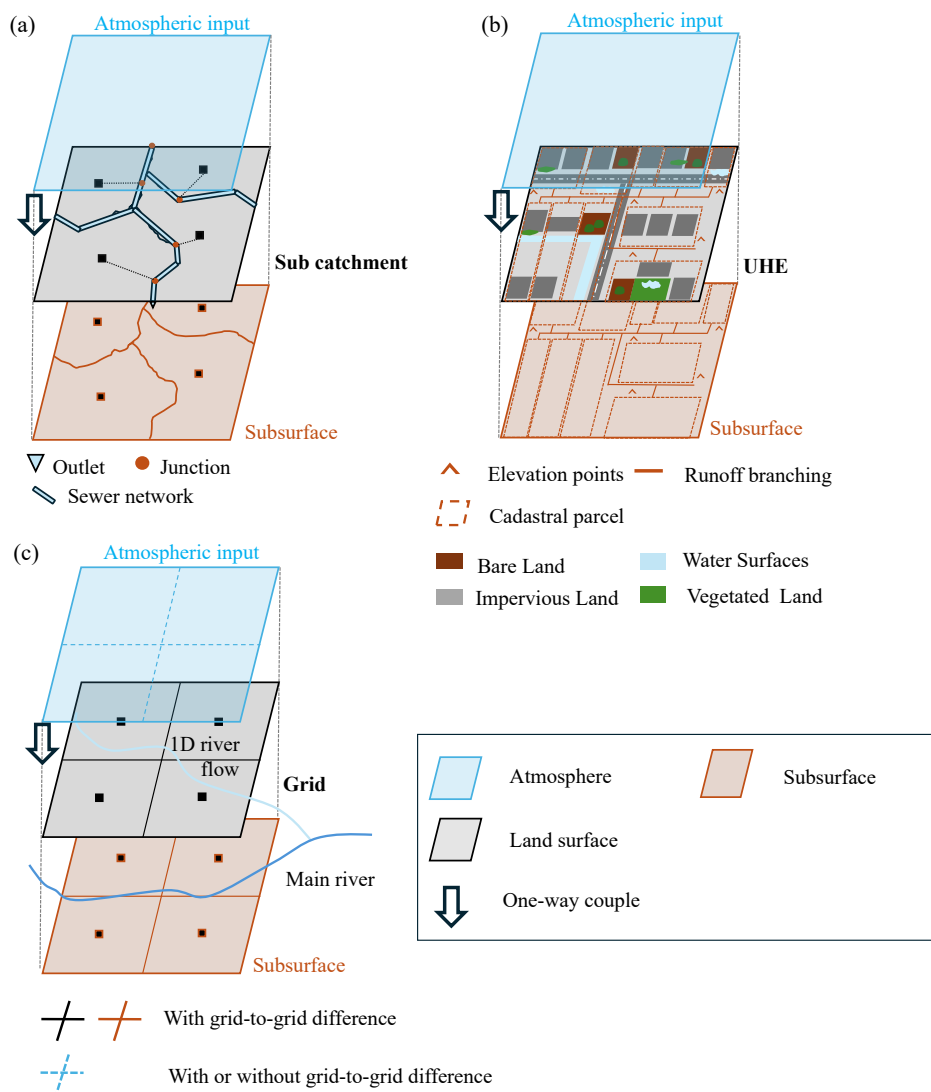

Figure 7. Conceptual figure of model structure and coupling condition for Urban Hydrological Models SWMM (a), URBS (b) and WEP (c).

Furthermore, we provide an overview of the hydrological processes affecting both surface and subsurface components. We separate the urban surfaces into impervious land, bare soil land, building facets (BudF), urban vegetation (VegL), and water surfaces (WatS). By summarising and comparing these aspects, we can identify gaps between the existing ULSMs and UHMs.

5.1 Surface energy balance

425 We systematically consider several key components from the energy balance equation: shortwave and longwave radiation (SW and LW), sensible and latent heat flux (H and LE), and anthropogenic heat release (AH). Table 4 displays the selected models' capability of simulating the surface energy balance. Note that Table 4 only includes the stand-alone versions of ULSMs. It can be seen that the surface energy balance constitutes a pivotal aspect of ULSMs. During the course of ULSM development, on the basis of simulating the energy balance of impermeable urban surfaces, the models added parameterisations of more complex
430 and diverse urban surfaces, such as urban vegetation and bare soil land. The conductive and turbulent heat flux calculation is based on temperature differences between the surfaces in the urban environment, air near the surface, and the upper atmosphere. It also depends on the aerodynamic resistance to the transport of heat, which is assumed to be equal to that of water vapor; thus, it is applied for calculating both sensible heat flux and latent heat flux. The latent heat calculation will be discussed in relation to evaporation and transpiration in Section 5.3.3. However, most ULSMs do not include the energy balance process
435 for the water surface (Table 4). Three exceptions are the SUEWS, TARGET, and Solene-Microclimat models.

SUEWS simulates the water surface energy balance and the other land surfaces based on the net all-wave radiation parameterization scheme (NARP) and Local-Scale Urban Meteorological Parameterization Scheme (LUMPS) (Grimmond and Oke, 2002; Offerle et al., 2003). Unlike models based on the urban canyon concept, SUEWS calculates net radiation based on the input data: incoming shortwave radiation with relative humidity and air temperature or incoming long-wave radiation and cloud
440 cover can be used if available (Loridan et al., 2011). It is worth mentioning that SUEWS computes net radiation separately for individual surface types within a grid while solving the sensible, latent, and storage heat flux for the entire grid (Fig. 1). The sensible and latent heat fluxes are determined using the parameterised scheme proposed by Berggren et al. (2012), while the storage heat flux is solved using the objective hysteresis model developed by Grimmond et al. (1991).

As the name suggests, the main function of TARGET (The Air-temperature Response to Green/blue-infrastructure Evaluation Tool) is to evaluate the impact of blue and green spaces on air temperature. Thus, including urban vegetation and water
445 surfaces in the energy balance is particularly important (Bera et al., 2022). The LUMP model serves as the foundational component for the TARGET model (Grimmond and Oke, 2002). However, TARGET is specifically designed around the concept of urban canyons (Fig. 2). Within these canyons, various surface types are considered. Tree height is the same as roof height, and the areas beneath trees represent ground-level surfaces. The tree canopy is incorporated into the urban canyon representation
450 to account for the shading effects of trees. Additionally, sky view factors play a role in the net radiation calculations. Notably, the OHM-force-restore method employed in LUMP for solving surface temperature and storage heat flux across different surfaces is unreliable for reproducing water surface temperatures (Broadbent et al., 2019). TARGET employs a simple water body model for addressing the energy balance of the water surface within the urban canyon. This model draws inspiration from the pan evaporation model (Molina Martínez et al., 2006) and closely resembles the lake model proposed by Jacobs et al. (1998).

Table 4. Selected model capabilities on simulating the surface energy balance process over different surfaces. ‘Y’ represents that the process is included, and ‘N’ for the opposite. Different are identified, namely impervious land (Impl), building facet (BudF), vegetated land (VegL), bare soil (BsoL) and water surface (WatS).

Models	Surface energy balance																
	Shortwave and longwave radiation				Sensible heat flux				Latent heat flux				AH

455 The Solene-Microclimat model utilises a 3D representation of urban geometry. Within this model, simulated scenes are
created by meshing the 3D-developed surface with rectangular or triangular elements (Musy et al., 2015). The size of the
simulated scene determines the area covered by these elements. The thermal-radiation model addresses the energy balance
for each facet. Unlike traditional urban canopy models that rely solely on sky view factors, the Solene-Microclimat model
employs a radiosity method to compute multiple reflections. This method involves two critical aspects: 1) geometric form
460 factors between all facets of the built surface and the sky vault are calculated using the contour integral technique; 2) radiative
properties (reflection, transmission, and absorption) are considered for all surfaces within the scene. The thermal-radiation
model is coupled with a CFD (Computational Fluid Dynamics) model, allowing for the exchange of sensible heat fluxes that
impact the energy balance, moisture mass transfer, near-surface air velocity, and air temperature. The Solene-Microclimat
model also accounts for both trees and water surfaces (Musy et al., 2015, 2021). Trees are treated as surfaces in the radiative
465 model (specifically, the tree crown envelope) and as volumes in the CFD model, considering factors such as shading, solar
radiation absorption, and aerodynamic resistance. The latent heat flux from vegetation is regulated by an evaporation rate,
given the absence of a hydrological model. Additionally, the energy balance of water pond surfaces is based on a thermal
model developed by Inard et al. (2004), which considers radiation absorption, transmission, and reflection at the water surface.
Furthermore, the model includes the simulation of the water surface, as discussed by Musy et al. (2021).

470 Regarding UHMs, energy balance simulations diverge significantly from ULSMs. In SWMM, energy balance processes are
notably absent. However, efforts have been made to integrate energy balance processes with hydrology in the water and energy
transfer processes (WEP) model. Land use is initially divided into three groups in WEP: a water body group, a soil–vegetation
group, and an impervious area group (Figure 6). The energy balance is solved for each type of surface. Short-wave radiation is
based on observation or deduced from sunshine duration, and long-wave radiation is calculated according to temperatures. The
475 interaction of radiation between soil and vegetation is considered by using the fraction of transmitted short-wave radiation of
vegetation, whereas the interaction between the urban cover and the urban canopy is considered by using the sky view factor of
urban cover. Latent and sensible fluxes are computed using the aerodynamic method, and surface temperature is solved using
the force–restore method (Jia et al., 2001).

Conclusions can be drawn from the comparison and analysis of the surface energy balance among the selected models:
480 Despite differing resolutions, both the bulk model SUEWS and the building-specific Solene-microclimate model account for
the surface energy balance across diverse landscapes. The majority of urban canopy models (UCMs) lack the capability to
simulate water surfaces within urban canyons. Urban Land Surface Models (ULSMs) emphasise radiation and sensible heat
processes, such as the obstruction and reflection of radiation by trees, while neglecting latent heat flux. Among the chosen
hydraulic and hydraulic-hydrological models, only the WEP hydrological model is equipped to address the surface energy
485 balance.

5.2 Urban canopy meteorology condition

All the models in the current study include atmospheric conditions but with different levels of complexity; the summary is
displayed in Table 5. In the context of most UHMs, meteorological variables serve as forcings. They are shown as the ‘N’

Table 5. Selected model capabilities concerning the near-surface hydro-meteorological processes. ‘P’ stands for ‘profile’, which indicates the model resolves vertical profiles; ‘L’ stands for ‘Lumped’, representing canyon average conditions; ‘N’ indicates models that do not resolve the urban canyon.

Models	Urban canopy hydro-meteorology condition		
	Near-surface air temperature	Near-surface humidity	Near-surface wind
SUEWS	P	P	P
VUCM	L	L	P
SLUMC	L	L	P
TEB	L	L	P
UT&C	L	L	P
VCWG	P	P	P
BEP	P	P	P
TARGET	L	L	P
VTUF-3D	L	L	P
Solene-Microclimat model	P	P	P
SWMM	N	N	N
Multi-Hydro model	N	N	N
URBS	N	N	N
WEP	L	L	P

in Table 5, representing that the model does not resolve the near-surface urban meteorology condition. Take the Storm Water
 490 Management Model (SWMM) as an example: it relies on precipitation, air temperature, and wind speed data. Precipitation
 data can come from multiple sources, such as nearby rain gauges or radar observations. When simulating snow melt or using
 the Hargreaves method to compute potential evaporation, SWMM also requires air temperature data. Wind speed, on the other
 hand, primarily affects the snowmelting process. However, due to the absence of an energy balance process, many hydrological
 models struggle to represent meteorological conditions within urban canyons accurately. The meteorological forcings for the
 495 hydrological models represent only the average conditions of the entire area considered.

In fact, the regional scale meteorological conditions are also part of the boundary conditions of the ULSMs. For the ULSMs
 within regional climate models, like WRF-SUEWS, WRF-SLUMC, and WRF-BEP, regional scale meteorological conditions
 are two-way coupled with ULSMs. Stand-alone ULSMs, in general, need the first-level air temperature, humidity, wind speed,
 and precipitation as the input, together with radiation. ULSMs resolve the urban canopy atmospheric conditions with different
 500 complexities: canyon average (Table 5: ‘L’) and canyon profile (Table 5: ‘P’).

Six of ten included ULSMs solve the average canyon temperature and humidity. It is worth mentioning that the hydrological
 model WEP, which includes the energy balance, can also solve the canyon average meteorological conditions. The solution is

based on the energy balance and is directly linked with turbulent heat fluxes among surfaces, canyons, and the upper atmosphere (Jia et al., 2001). Masson (2000) and Wang et al. (2013) documented in detail the scheme used to calculate the canyon mean
505 temperature, humidity, and wind for single-layer UCMs. In the VTUF-3D model, although resolving radiative exchanges in 3D, the convection has been simplified into a 1D equation instead of more computationally intensive methods such as large eddy simulations (LES) or Reynolds-averaged Navier-Stokes (RANS) (Krayenhoff and Voogt, 2007). The convection scheme is also based on what is mentioned in Masson (2000), which is one-dimensional. For the regional climate models that are two-way coupled with USLMs, 2-meter air temperature, humidity, and 10-meter wind can be obtained for a single grid on
510 average (Chen et al., 2011). Some recent studies applied a revised scheme based on sensible heat flux from urban canopy from the ULSM in the regional climate model to specifically focus on 2-meter air temperature over urban areas (Chen et al., 2021; Theeuwes et al., 2014). In all selected ULSMs, the wind speed profile is assumed to be logarithmic above the urban canopy, exponential within the urban canyon, and logarithmic again close to the ground surface (Masson, 2000).

The remaining four ULSMs are SUEWS, BEP, VCWG and the Solene-Microclimat model, which can resolve the vertical
515 profile of air temperature, humidity, and wind within urban canyons. It is well known that the Monin-Obukhov Similarity Theory (MOST) provides the dimensionless mean flow and mean temperature in the surface layer under non-neutral conditions, which can be applied primarily to flat and horizontally homogeneous terrain (Högström, 1996). However, MOST fails to be applied in a layer extending from the ground to several canopy heights, the roughness sublayer (RSL), which can be two to five times the mean canopy height (Fazu and Schwerdtfeger, 1989; Moriwaki and Kanda, 2006). Several corrections for
520 MOST have been proposed to resolve the conditions within the roughness sublayer, including those of Harman and Finnigan (2007) and De Ridder (2010). Theeuwes et al. (2019) evaluated these two correction approaches that parametrise wind speed and temperature vertical profiles within the urban roughness sublayer. In the 2020a version of SUEWS, a diagnostic RSL scheme based on Harman and Finnigan (2007, 2008) for calculating the wind, temperature, and humidity profiles has been implemented. Researchers have attempted to quantify the interaction between urban elements and the atmosphere in relation
525 to dynamic and thermal effects. This approach is grounded in the multi-layer model (referred to as BEP) (Martilli et al., 2002).

In contrast to Monin-Obukhov Similarity Theory (MOST), which relies on gradient relationships, multilayer models consider the aerodynamic and thermal impacts of urban elements as either sources or sinks for potential temperature, momentum, specific humidity, and turbulent kinetic energy equations. In both BEP and VCWG, a one-dimensional vertical diffusion model that is based on the diffusion coefficient is applied to solve the vertical momentum, heat, and moisture fluxes (Santiago and Mar-
530 tilli, 2010; Martilli et al., 2002; Moradi et al., 2021). The major difference between BEP (multi-layer urban canopy model) and VCWG is that BEP solves the energy balance for each layer of the urban canopy, whereas the radiation model in VCWG adopts the scheme of SLUCM. Until recently, the vertical diffusion model was in the developmental phase, with ongoing sensitivity tests aimed at enhancing the parameterised scheme. These tests were based on computational fluid dynamics (CFD) studies conducted by Nazarian et al. (2020) and Simón-Moral et al. (2017). Unlike the other three models, the Solene-Microclimat
535 model is a CFD model. Thus, 3D conditions can be obtained over the 3D simulation domain.

It can be concluded that similar to their capacity for resolving the surface energy balance, Urban Land Surface Models (ULSMs) prioritise assessing near-surface urban hydro-meteorological conditions compared to Urban Heat Models (UHMs).

All the selected ULSMs can resolve the vertical wind profile based on the similarity theory and can solve the 2D average (lumped) air temperature and humidity. For the bulk model, SUEWS, vertical profiles of atmospheric variables are included, but only for the grid average; the multi-layer urban canopy models (BEP and VCWG) and building resolving models can resolve the vertical profile within the urban roughness sub-layer (urban canyon).

5.3 Surface water balance

Table 6 presents the capability of the included models to simulate the urban surface water balance, in which surface runoff, depression storage (water stored on the land surface depending on surface characteristics), infiltration, evaporation, snow-related processes, and irrigation are included. The complexity of the surface water balance-related processes is different per model. Overall, the VUCM, BEP, TARGET, VTUF-3D, and Solene-Microclimat models do not have a good capacity for simulating the water balance over heterogeneous urban landscapes. Runoff only occurs when interception water of each surface type exceeds the maximum reservoir capacity. Interception storage is determined by the difference between the incoming source, which includes precipitation, and the sink, which includes evaporation and infiltration. Different models include various source and sink terms. For example, irrigation is included in SUEWS, SLUCM, TEB, VCWG and UT&C, but leakage from impervious roofs is considered an extra sink term in UT&C and VCWG, and the snow melting process is also only included in SUEWS and TEB (Järvi et al., 2014; Colas et al., 2024). The sub-sections below compare the other processes.

5.3.1 Runoff

Many of the ULSMs assume that runoff travels directly to the sewer system and does not affect the water balance in the urban canyon; these models include VUCM, SLUCM, TEB, UT&C, and VCWG (Lee and Park, 2008; Wang et al., 2013; Stavropoulos-Laffaille et al., 2018; Meili et al., 2020; Moradi et al., 2022). Based on this assumption, there is no limit for surface runoff to enter the sewer system. It is worth mentioning that in UT&C and VCWG, a fraction of the surface runoff is maintained in the system for depression storage (ponding) and exchanges between the various surfaces in the urban environment before the water reaches the sewer system, which is a source term for the next simulation time step (Meili et al., 2020; Moradi et al., 2022). For example, the models can account for runoff from impervious areas that is redirected to infiltrate over bare land areas. The rest of the surface runoff follows the assumption that it disappears in the water balance. In contrast, a limit to pipe inflow is considered for runoff in SUEWS. If the pipe capacity is exceeded, flooding above ground occurs as the water is added to above-ground runoff. The total runoff is the sum of the runoff to the pipe system and the above-ground runoff in SUEWS (Järvi et al., 2011).

The reservoir concept solves runoff in UHMs. In WEP, surface water runoff is estimated as precipitation minus evaporation (Jia et al., 2001). In impervious areas, surface runoff can be obtained from a water balance analysis including depression storage, precipitation, and evaporation on land surfaces. It is assumed that there is no infiltration in impervious areas. The infiltration is included for bare land in WEP. WEP is a grid-based model, which means it solves the energy and water balance for each grid cell. The subgrid heterogeneity of land use is considered by using the mosaic method. The main structure of WEP is similar to most of the ULSMs, but WEP simulates the 1D river flow horizontally. River flow routing is conducted

Table 6. Selected model capabilities regarding simulation of the surface water balance process over different surfaces. ‘Y’ represents that the process is included; ‘Y-av’ represents indifference among the land use types, and ‘N’ represents the exclusion of the process. Different surfaces are considered, namely impervious land (ImpL), building facet (BudF), vegetated land (VegL), bare soil (BsoL) and water surface (WatS).

Models	Surface water balance																							
	Runoff				Depression storage				Infiltration				Evaporation				Snow melting removing		Irrigation					
	ImpL	BudF	BsoL	VegL	ImpL	BsoL	ImpL	BsoL	ImpL	BsoL	ImpL	BudF	VegL	BsoL	WatS	Y-av	Y	Y-av	Y	Y-av	Y	Y-av	Y	Y

for every tributary and a main channel by using the kinematic wave method. Overland flow is simplified as lateral inflow to rivers. In URBS, the surface is represented by an interception reservoir (Rutter et al., 1971), whose capacity depends on the land use type: natural soil, streets, or roofs. The non-intercepted rainwater is separated into three components: evaporation, infiltration into the vadose zone, and surface runoff. Surface runoff occurs only when the surface storage exceeds its capacity.

575 The URBS model solves the water balance at the urban hydrological element (UHE) level (Berthier et al., 2004; Rodriguez et al., 2003). The representation of the UHE is also 2D, which is similar to the representation in the SUEWS. However, URBS considers the spatial discretisation based on UHE connected to the drainage network. Thus, the horizontal spatial distribution can be solved. In SWMM, the reservoir concept for generating runoff is more complex, called the nonlinear reservoir model (Rossman and Huber, 2016). The most obvious difference in the nonlinear reservoir, as indicated by its name, is that the runoff

580 volume is not linearly linked to the water depth above the depression storage depth. Further, it is also related to the surface roughness coefficient, the apparent or average slope of the sub-catchment, and the area across the sub-catchment's width through which the runoff flows. Each sub-catchment separates the land into categories: pervious land area and impervious land with and without depression storage. SWMM supports the overland flow within one sub-catchment among the pervious and impervious areas, as well as overland flow among sub-catchments. The overland flow can be solved by the Multi-Hydro model

585 by equations ensuring the conservation of mass (continuity) and momentum. This flow depends on the surface properties as well as the elevation and is computed using the diffusive wave approximation of Saint-Venant equations (Ichiba et al., 2018).

Surface runoff is one of the most essential items in the water balance. Based on the comparison, it can be concluded that most of the selected models that can solve the water balance would address the runoff amount based on the reservoir concept. However, in the ULSMs, most of the runoff cannot participate in the water balance at the next time step, which is highly related

590 to whether the model includes the sewer system capacity and run-on portion. Overland flow cannot be solved by all selected ULSMs but can be solved by some of the UHMs (SWMM and Multi-Hydro model).

5.3.2 Depression storage and infiltration

Depression storage and infiltration describe the process of the water held by the land surface and transferred downward through the surface. In ULSMs, depression storage and infiltration over impervious and bare soil land are included. Among the im-

595 pervious land, the infiltration part is defined as a constant value that must be calibrated or ignored. TEB sets the infiltration rate over impervious roads, referring to Ramier et al. (2011). However, the infiltration over impervious land is not accounted for in VUCM, SLUCM, UT&C, and VCWG. Several methods in these models simulate infiltration and depression storage on bare land. The 1D Richards equation is applied in some of the selected models, including SLUCM, UT&C, and VCWG (Wang et al., 2013; Meili et al., 2020; Moradi et al., 2022). The Richards equation is a differential equation that relates soil moisture

600 content to hydraulic conductivity and capillary pressure. It accounts for both vertical flow driven by the hydraulic gradient and capillary rise. In TEB and SUEWS, the Green and Ampt model is adopted (Järvi et al., 2011; Stavropoulos-Laffaille et al., 2018). The Green-Ampt model is a simplified physical model based on the Richards equation. It assumes that infiltration occurs instantaneously at the soil surface (Kale and Sahoo, 2011). One more option in SUEWS for infiltration simulation is the

Horton method. The Horton method is an empirical model. It assumes that infiltration occurs constantly until the soil becomes saturated, after which it decreases exponentially (Horton, 1941).
605

For the UHMs, the Richards equation and Green-Ampt model are also adopted by the distributed WEP, URBS, and Multi-Hydro models. In SWMM, there are four options for infiltration, including the Green-Ampt model, Horton's method and its modified version, and the Curve Number Method (Rossman and Huber, 2016). One major difference between the Curve Number Method and the Green-Ampt model is that the curve number model assumes an initial abstraction before the surface runoff, while the Green-Ampt model assumes surface runoff only when the precipitation rate is greater than the infiltration rate.
610 There is no universal conclusion on the best method. Previous studies have conducted a comparison analysis among different infiltration methods for various cases (Parnas et al., 2021; Mallari et al., 2015).

Generally, if the model includes the water balance, it considers the depression storage and infiltration process. Based on the above summary, depression storage over impervious land areas can be solved relatively easily, but the infiltration process over impervious land is seldom considered.
615

5.3.3 Evaporation and transpiration

The simulation of evaporation and transpiration is closely tied to the latent heat flux, which is a critical link between the energy and the water balance. The evaporation and transpiration process can be expressed by both latent heat flux in the energy balance (in terms of watts per square meter) and the evapotranspiration (ET) in water balance (in terms of water depth per unit of time).
620 The approach for quantifying moisture and latent heat flux relies on the Penman and Penman-Monteith equations, which finds application in ULSMs and UHMs (De Bruin and Holtslag, 1982; Beven, 1979). Although based on the same methodology, the complexity of different models introduces variations in how they account for evaporation and transpiration processes in the heterogeneous urban environment. Table 6 focuses on evaporation and transpiration in terms of the water balance. Whether the models include the latent heat flux can be found in Table 4.

In ULSMs, the energy balance can be considered independent of the water balance. In BEP, the water balance is not included, and the latent heat flux is also disregarded. In the other ULSMs, evaporation and transpiration over impervious land is much simpler to parameterize than that over vegetated or bare land. The method to simulate the latent heat flux (LH) from impervious land is well documented by Masson (2000) and Wang et al. (2013). When the actual depth of water on the impervious land is available, the LH and ET are solved depending on specific humidity, saturated specific humidity at a given surface temperature, and aerodynamic resistance. The depth of the water would be updated based on the water balance equation. Regarding bare land, a reduction factor as a function of soil water content is further considered and updated based on the water balance over bare land in each simulation step.
630

The evaporation from vegetation can be complicated, not in the least because there are differences between short and tall vegetation. In SLUCM and TEB, vegetation's stomatal resistance is further considered when calculating evaporation over vegetated land. The stomatal resistance of vegetation can be obtained by a parametrisation scheme based on a meteorological approach, relating the stomatal resistance to meteorological variables, including solar radiation, soil-water availability, vapor pressure deficit, and air temperature. However, this method is only suitable for short vegetation on the ground and does not
635

consider the effect of the sun's direction. Evaporation and transpiration are simulated in much detail in UT&C (Meili et al., 2020). Except for the ponding water on the impervious land and soil evaporation from bare soil land that SLUCM and TEB take
640 into account, evaporation from intercepted water on vegetation canopy, transpiration from sunlit and shaded ground vegetation
canopy, and tree canopy are also considered in UT&C. VCWG adopts most parts of the hydrological module of UT&C. Regarding the TARGET model, the latent heat flux originates solely from the water surface and not from other surfaces within
the urban environment (Krayenhoff and Voegt, 2007). The VTUF-3D model combines TUF-3D for simulating impervious land
and MAESPA for simulating vegetated land. The water balance, including evaporation and latent heat flux, is only considered
645 for vegetated land.

Widely adopted for estimating evaporation from meteorological data, the Penman-Monteith equation method demands
meticulous attention to input parameters. The model results are sensitive to aerodynamic and canopy resistance values. Further-
more, these parameters can vary significantly from site to site. In ULSMs adopting the urban canyon concept, the aerodynamic
resistances to the transport of heat and water vapor are assumed equal and, thus, applied for calculating both sensible heat
650 flux and latent heat flux. The estimation of aerodynamic resistances between canyon facets and air can be formulated based
on in situ measurements (Masson, 2000; Cole and Sturrock, 1977). The total resistance would also differ for different urban
canyon surfaces. The level of complexity depends on the model. For instance, in UT&C, stomatal, leaf, and soil resistance are
included. But in SLUCM, the resistance over impervious and bare land is set the same. It is worth mentioning that, unlike the
UCMs, SUEWS calculates the turbulent heat flux according to a lumped concept. Thus, a modified Penman-Monteith equation
655 is presented (Järvi et al., 2011). Instead of the stomatal resistance that is considered for the vegetated land area in UCMs,
SUEWS calculates the lumped latent heat based on surface resistance, which is also estimated based on measured values.

It is clear that, although at different levels of complexity, many ULSMs include the linkage between the thermal environment
and water availability through the evaporation and transpiration process with a two-way coupling. However, in most UHMs,
the temperature used for calculating the evaporation and transpiration process is only input data, as mentioned in Section 5.2.
660 The Multi-Hydro model ignores the water loss from the evaporation and transpiration process in the water balance. In SWMM,
several options can yield the ET rate:

- (1) Set as a single constant value that does not have temporal variation. The value can also be set based on the simulation
month, and the user can also set daily temporal information.
- (2) Read from an external climate file.
- 665 (3) Compute the daily values from the daily temperatures in an external climate file.

The calculation in SWMM adopts the Hargreaves method (Hargreaves and Samani, 1985), which is based on daily max-
min temperatures contained in a climate file and the study area's latitude. The latitude sets the radiation water equivalent of
incoming extraterrestrial radiation. This method is suitable for the case without detailed information on the latent heat flux
being included.

670 WEP and URBS share a similar approach to the ULSMs based on the Penman-Monteith equation. In WEP, evaporation
over water surfaces is accounted for considering the psychrometric constant. ET from vegetation in WEP is a combination

of interception evaporation, transpiration from low vegetation, and from high vegetation (Jia et al., 2001). Since the energy balance is calculated by WEP, the latent heat flux (LH) is calculated based on net radiation and ground heat flux and linked with the ET. WEP is also the only UHM that is included that considers differences in evaporation and transpiration processes for different land uses. However, for URBS, meteorological conditions and potential evaporation are inputs for the model. The evaporation flux is assumed to be proportional to the Penman–Monteith potential evapotranspiration and water storage (Rodriguez et al., 2008).

Evaporation, as one of the sink terms in the water balance, is considered by most of the ULSMs that have the ability to solve the water balance but can be ignored by some UHMs due to the small amount of water lost through the process. Most of the ULSMs focus less on evaporation over the water surface. Furthermore, ULSMs solve the evaporation over the different landscapes separately within a simulation unit, but UHMs usually solve the process over the simulation unit as a whole.

5.4 Urban subsurface

ULSMs and UHMs resolve several hydro-meteorological processes beneath the ground surface. Water stored in the soil layers below the surface can be transported upward through transpiration. Five of the selected models, SUEWS, VUCM, BEP, TARGET, and VTUF-3D, do not include this process. The two sub-sections below discuss the moisture conditions in soil layers in the subsurface and the processes related to the (man-made) pipe system.

5.4.1 Moisture transfer in and between soil layers

For most of the included ULSMs, a multi-layer soil hydrology model is included. Exceptions are SUEWS and TARGET. SUEWS includes a bucket soil model, while TARGET does not include a hydrology module at all (also mentioned in Section 5.3). In VUCM, the moisture flux between the soil layers is calculated based on the hydraulic conductivity of the soil, soil moisture content, and the depth of the soil layer (Clapp and Hornberger, 1978). The moisture flux at the bottom is set to zero. It is worth mentioning that surface runoff is not parameterised over the vegetated land in VUCM. Instead, when the water content on the surface of vegetation exceeds the maximum amount that vegetation can hold, the excess amount is first brought to thermal equilibrium with the vegetation temperature by heat transfer and then shed from the vegetation to the soil surface. In SLUCM, infiltration and runoff are both considered to be over the bare land and vegetated land. Soil moisture in the first layer is solved by the surface water balance, and the soil layers below are solved by the water exchange among the nearest two layers. Soil-water diffusivity and hydraulic conductivity for computing the infiltration into the soil layer are determined using a method based on Clapp and Hornberger (1978). The moisture flux at the bottom is assumed to be zero, meaning no deep drainage. In both VUCM and SLUCM, no soil layers beneath impervious areas exist, in contrast to TEB and UT&C. The parameterisations of the vadose soil moisture dynamics are more complete in TEB and UT&C compared to the other models, with both vertical and lateral moisture fluxes considered. Vertical moisture fluxes are simulated by the 1D-Richards equation, which is similar to those in VUCM and SLUCM. The lateral moisture flux in the upper soil layers is computed solely between the garden and building compartments in TEB and is similar in UT&C in that the horizontal water transfer is absent at the top two layers of soil. It is worth mentioning that, although SUEWS uses a single-layer soil scheme, lateral flow is considered.

Table 7. Selected model capabilities regarding simulation of the urban subsurface conditions. The complexity of resolving soil moisture can be single (SL) or multi-layer (ML), and the water transfer among the soil layer(s) can be vertical (Vf) or/and lateral within/between the grid(s) (Lfin/Lfbt). The presentation of the pipe system can be only the inflow with or without limitation (Inflow - limited/Inflow - infinite), or it can be with a detailed hydraulic system (Hydraulic). ImpL stands for impervious land and BsoL stands for bare soil land.

Models	Urban subsurface			
	Soil layers moisture		Transpiration	Pipe system
	ImpL	BsoL		
SUEWS	SL - Lfin		N	Inflow - limited
VUCM	N	ML - Vf	N	Inflow - infinite
SLUMC	N	ML - Vf	Y	Inflow - infinite
TEB	ML - Vf - Lfin		Y	Inflow - infinite
UT&C	ML - Vf - Lfin		Y	Inflow - infinite
VCWG	ML - Vf - Lfin		Y	Inflow - infinite
BEP	N	N	N	N
TARGET	N	N	N	N
VTUF-3D	N	N	N	N
Solene-Microclimat model	N	ML - Vf	Y	Hydraulic
SWMM	ML - Vf - Lfbt		Y	Hydraulic
Multi-Hydro model	ML - Vf		Y	Hydraulic
URBS	ML - Vf - Lfin		Y	Hydraulic
WEP	ML - Vf - Lfbt		Y	Inflow - infinite

705 The soil hydraulic conductivity and soil water potential in TEB and SUEWS are based on Clapp and Hornberger (1978) and van Genuchten (1980), respectively. In UT&C, the soil hydraulic properties can follow either the van Genuchten (1980) or the Saxton and Rawls (2006) parameterisation. Moreover, the transpiration sinks of high and low vegetation are included while calculating the soil layer moisture in SLUCM, UT&C, and TEB, depending on the root biomass fraction in each soil layer. In TEB, the infiltration to the pipe system from saturated soil moisture is further represented, which is adapted from URBS, one of the selected hydraulic-hydrological models (Rodriguez et al., 2008).

710 Because SWMM was originally developed to simulate combined sewer overflows in urban catchments, the fate of infiltrated water was considered insignificant. The subsurface soil layers are represented by a two-layer scheme: an unsaturated upper zone and a saturated lower zone, which is called a two-zone groundwater model. The scheme in URBS is similar to SWMM in that it has two zones. The vertical transfer between the unsaturated upper zone and the saturated lower zone is estimated to be similar to those in the ULSMs, but instead of the 1D-Richards equation, the Green–Ampt model is applied. The infiltration to artificial networks from saturated soil moisture that is included in TEB is also included in URBS. In SWMM, lateral outflows in and out of the conveyance system are further considered in the saturated zone. The top three layers in WEP are

called the subsurface in a narrow sense. The water balance among each subsurface is calculated differently. The continuity of water movement is considered when the application of the generalised Green–Ampt model is switched to that of the Richards model and vice versa (Jia et al., 2001). Subsurface runoff (lateral flow) is calculated according to land slope and soil hydraulic conductivity. The capillary rise can be a source term of the upper unsaturated soil layers in WEP and is parameterised by means of Boussinesq equations (Jia et al., 2001). The soil conductivity and saturated soil conductivity in urban hydrological models are all similar to what has been represented in most of the ULSMs, which can be calibrated and based on empirical models.

By comparing all the selected ULSMs and UHMs, we found that multi-layer soil moisture and vertical water transfer are commonly solved for bare soil land in the ULSMs capable of simulating the water balance and in UHMs. The lateral water transfer between the simulation units exists only in UHMs. The development of integrating hydrological processes in the subsurface in ULSMs would follow the methods used in UHMs.

5.4.2 Pipe system

Pipe inflow, also called sewer discharge, is usually equal to the total runoff and ‘disappears’ from the further water balance in most ULSMs, including VUCM, SLUCM, TEB, UT&C, and VCWG (Lee and Park, 2008; Wang et al., 2013; Stavropoulos-Laffaille et al., 2018; Meili et al., 2020; Moradi et al., 2022). In most cases, there is no limit to this discharge. Only in SUEWS, groundwater runoff can be distinguished from pipe inflow, and there is a limit to the amount of water that can enter the pipe system (Järvi et al., 2011). This is consistent with the conclusions mentioned in Section 5.3.1.

None of the included ULSMs follow the pipe system scheme. This would be called a hydraulic model and is the core of SWMM. The SWMM hydraulics model includes seven parts: junction nodes, outfall, dividers, storage units, conduits, pumps, and regulators (Rossman and Simon, 2022). Some hydraulics processes that are included in SWMM, such as external inflow of surface runoff, groundwater interflow, rainfall-dependent infiltration/inflow, and non-uniform flow routing through any configuration of open channels, pipes, and storage units, are closely coupled with hydrological processes like surface runoff, evaporation, and infiltration. The governing equation for the water movement through a conveyance network of pipes and channels is the St. Venant equation for unsteady free surface flow. In the distributed Multi-Hydro model, the hydraulic model is adopted from SWMM and is coupled two-way with the surface module and soil module. In hydraulic-hydrological models, the hydraulic part is usually not as complete as in a hydraulic model such as SWMM. The drainage module in the Multi-Hydro model is based on the 1D SWMM. In URBS, the hydraulic routing configuration has been modified to contain two modelling stages: routing of surface runoff on streets from UHEs up to the sewer inlets, as represented by the travel time routing procedure used in URBS, and hydraulic routing inside sewer networks, as represented by using the classical Muskingum–Cunge scheme, which offers an approximate solution to the diffusive wave equation (Rodriguez et al., 2003). WEP is the only UHM that considers the pipe inflow and assumes the inflow amount is infinite without considering pipe capacity, which is similar to ULSMs.

Based on the above summary, it is obvious that the pipe system in ULSMs is not well represented in the water balance calculation. The pipe system includes various levels of detail depending on the model focus of the UHMs.

6 Challenges and future developments

6.1 Land surface-atmosphere coupling

Besides accounting for complex physical processes in the models, coupling is an essential way to support studies on the interface of meteorology and hydrology. The coupling between the atmosphere and land surface has been intensively studied.

755 ULSMs are widely implemented in regional climate models, as mentioned in Section 3 and Figure 2. Coupling the atmospheric models with land surface models, including ULSMs, supports studies of land-atmosphere interactions, specifically the impact of urban land on this interaction. In general, the development of ULSMs initially focused on stand-alone models, which have subsequently been implemented in coupled versions with mesoscale climate models. Therefore, stand-alone versions are usually more advanced in physical complexity than models in the coupled version. This is the case for, e.g., SLUCM (Wang
760 et al., 2013) and WRF-SLUCM (Yang et al., 2015), as well as the SUEWS and WRF-SUEWS (Sun et al., 2023; Sun and Grimmond, 2019). However, the hydrological module of BEP was first implemented in a coupled version by Yu et al. (2022) (WRF-BEP) instead of as a stand-alone version. In the version of WRF-BEP, the depression over the impervious land, evaporation over the urban green surface, and the pipe system parameterisation based on Manning's formula are included (Yu et al., 2022).

765 Within urban land surface models (ULSMs), tension arises between stand-alone and coupled simulations of natural land surfaces, including water and vegetation. Ideally, land surface models should simulate natural lands, with ULSMs focusing solely on impervious urban areas in the coupled version. However, the land surface in the transition zone between urban and suburban regions exhibits strong heterogeneity. Interactions across different land surface types and building facets are inadequately accounted for. As stand-alone ULSMs increasingly incorporate natural land surfaces and interaction processes,
770 the question emerges: how should regional atmosphere-land models and ULSMs deal with the radiation, aerodynamic, and dynamic interactions between natural landscapes and human-influenced landscapes, especially water surfaces and built-up facets?

6.2 Integration of atmospheric and terrestrial hydrological processes

By leveraging the two-way coupling between land and atmospheric models, researchers can explore the effects of urbanisation
775 on atmospheric processes and hydrological processes, respectively. For instance, an emerging study area involves investigating urban-induced convective precipitation events (Wang et al., 2021; Yang et al., 2024). However, these studies ignored the interactions with the terrestrial-hydrological system. The atmospheric models have been coupled only one way with the urban hydraulic models. For example, recently Gu et al. (2022) coupled the WRF with SWMM to provide precipitation input for the hydraulic simulation.

780 There is another group of existing studies using hydrological models to investigate the impact of urbanisation on terrestrial-hydrological processes, such as runoff and infiltration (Oudin et al., 2018; Locatelli et al., 2017; Yoo et al., 2021). However, these investigations often overlook atmospheric interactions, concentrating solely on land surface and subsurface hydrologi-

cal processes. This alignment with the findings in the current analysis underscores the complexity of terrestrial-hydrological processes, which exhibit strong coupling with atmospheric dynamics.

785 Recent studies have employed physically realistic, coupled atmosphere-land surface-subsurface models (Wagner et al., 2016; Fersch et al., 2020; Kim et al., 2021). These coupling simulations make an effort to evaluate the intricate interplay between terrestrial and atmospheric processes, shedding light on their influences on hydro-meteorological phenomena. However, it is difficult to reach the neighborhood (100 meter - 1 kilometer) scale focusing on urban hydrothermal environments based on these approaches. Recently, by coupling the WRF-SLUCM and a land surface-subsurface model (ParFlow), Talebpour et al.
790 (2021) emphasised the critical need to account for terrestrial hydrology, particularly in urban areas where diverse development patterns introduce additional complexities to coupled atmosphere-groundwater interactions. The coupling between the WRF-SLUCM and ParFlow can overcome some of the limitations of representing the saturated soil layer and groundwater in the ULSMs found in the current study.

6.3 Enhancing models coupling and cross-disciplinary collaboration

795 As the importance of urban hydrological-meteorological interactions becomes increasingly prominent, the parallel development model of the two groups of models can no longer meet research needs. However, integrating physical processes on top of the existing model versions or coupling several models with different focuses has not fully addressed the interface of the urban environment's hydro-meteorological processes, including both thermal and hydro-hydraulic processes.

The coupling and integrations are mainly applied to the land surface and atmospheric models. Based on our findings, one
800 essential point that prevents the hydraulic and terrestrial-hydrological processes from being fully implemented with the thermal processes in the simulation is that overland flow, channel flow, and subsurface lateral flow of water have to include the interaction and connection between the simulation units, which is the grid cell in most of the ULSMs, notably Multi-Hydro and WEP, and the sub-catchment in SWMM, UHE in URBS. A notable example of this approach is WRF-Hydro, which is coupled with the land surface model, including the terrain routing modules, allowing to solve 2D overland flow with the linkage
805 among the simulation grids and soil moisture (Gochis et al., 2018). WRF-hydro also includes channel and reservoir routing modules and can be two-way coupled with the atmospheric model. WRF-hydro can be coupled with SMWW to take urban hydrology and drainage into account (Son et al., 2023). However, based on our knowledge, the development and application of the WRF-Hydro model, focusing on urban areas and the interface between the urban thermal and hydrological environment, are limited (Fersch et al., 2020).

810 With the support of more efficient computing systems, CFD models, which have mainly been used to analyse urban wind environments, are gradually becoming more widely used to simulate urban thermal environments. Although, based on our current summary, 3D ULSMs lack implementation of the hydrological cycle, they also show the potential of resolving the urban hydro-thermal environment by being integrated with distributed hydrological models (Robineau et al., 2022). However, 3D ULSMs and URBS hydrological models need high-resolution input data, including urban morphology, topography, and
815 sewer systems. This is the main reason for the limited application of URBS, which needs high-resolution urban data sets compared to models like SWMM. With the development of collection and measurement methods for urban morphology and

infrastructure data, high-resolution simulation of the urban microclimate and hydrological processes at the neighborhood scale may be achieved simultaneously with comprehensive meteorological and hydro-hydraulic interactions.

The hydro-meteorological process's spatial and temporal variations have been discussed extensively in the literature. Finding suitable resolutions for the simulations is still being debated. At the regional scale, WRF-Hydro shows the potential coupling between the land-surface model and the atmospheric model. This can provide the opportunity to study how urban influences on terrestrial-hydrological processes indirectly affect the urban thermal environment and further affect the atmospheric-hydrological process. Regional studies can provide a comprehensive view of the mutual influence of natural processes at the regional scale and the signals of urban agglomerations in these interactions. Therefore, quantifying various human activities in cities and converting human activities and natural processes of different spatiotemporal resolutions into data with unified spatiotemporal resolution and putting them into regional models are worthy of attention in future model coupling. At the neighborhood scale and microscale, CFD models show great advantages. Different from the process research on land-atmosphere coupling and the impact of urban agglomerations on natural processes at the regional scale, CFD models are more suitable for the research on mitigation measures for climate-hydrological processes and hazards at the community planning scale. Therefore, CFD models need to be further developed to embed physical processes or implemented with high spatial-temporal resolution hydraulic-hydrological models. The answer to how much of the heterogeneous landscape should be included and how much complexity of the physical processes should be included should also consider the data availability and computational resources.

In our discussion on model comparison and future numerical model development, we recognized the significant potential and challenges of interdisciplinary cooperation. Whether for regional-scale mechanism research or micro-scale applications, collaboration in atmospheric science, hydrology, and hydraulics is essential. Additionally, detailed terrain data, urban complex building information, and other model input data can advance research on urban hydrological and climate processes and related extremes. This need for collaboration extends to disciplines such as geology and civil engineering. Recently, the concept of urban geoscience has highlighted that communication and cooperation across different geoscience fields are crucial for cities to effectively address various climate and natural disasters (Bricker et al., 2024). Urban geoscience, defined as the application of geology and earth sciences to urban management, land use planning, and development, encompasses disciplines like engineering geology, hydrogeology, geological modelling, geochemistry, and environmental geology. It also emphasizes the interactions and linkages between urban environmental systems (subsurface, surface, and atmospheric) and human activities, aligning with our findings and recommendations from this review (Bricker et al., 2024; Pescatore et al., 2024).

7 Conclusions

In response to the growing significance of research on compound natural disasters, implementation of nature-based solutions in urban areas and their impact, we have reviewed key models for simulating urban meteorological and hydrological environments. These models are either widely used, rapidly developed, or highly specialised. By disassembling and comparing the structure of various models, the complexity of the physical processes considered, and the resolving methods, we have found

850 that simulation tools for urban thermal and hydrological environments have evolved in parallel over time. Although starting
from different objectives, the interface of urban hydro-meteorology is receiving increased attention due to the potential im-
855 plications of climate change and the imperative of climate adaptation. Recent trends in interdisciplinary research highlight
the growing importance and potential of collaborative efforts in atmospheric science, hydrology, and hydraulics for advancing
urban hydrological and climate studies. The current study calls attention to disciplinary barriers that may prevent the two com-
munities, urban climate and urban water management, from communicating well. The key findings are summarised below, and
the corresponding recommendations are followed respectively:

- (1) - Integrating various models with different foci is crucial for advancing research at the intersection of urban meteorology
and hydrology. There are both challenges and opportunities in simulating the urban hydro-meteorological environment
at regional and neighborhood scales.
860 - WRF-Hydro coupled with urban land surface models (ULSMs), and computational fluid dynamic (CFD) models cou-
pled with hydraulic-hydrological models show potential for regional and neighborhood scales in urban hydro-meteorological
studies.
- (2) - Urban land surface models (ULSMs) predominantly adopt grid-based frameworks. However, their grid-to-grid energy,
water, and momentum interactions are limited. In contrast, urban hydrological models (UHMs) establish direct links
865 between individual simulation units and features such as sewer systems, channels, and rivers. The topography of the
simulation domain significantly influences water transfer.
- Grid-to-grid linkages are key points for coupling the ULSMs and UHMs. Topography data and building information
data sets should be considered while integrating the urban hydro-hydrological processes and thermal environments.
- (3) - Both ULSMs and UHMs rely on atmospheric conditions as input. ULSMs excel at resolving near-surface conditions
870 over urban areas, capturing average values for each simulation unit. Some models even provide vertical profiles within the
urban canopy. Notably, ULSMs exhibit bidirectional integration capabilities with atmospheric models, whereas UHMs
lack this feature.
- Gaps are shown among the parameterizations of atmospheric and terrestrial hydrological processes and the urban
thermal environment. The evaluation of interaction among these is limited and needs effort.
- (4) - The surface water balance in ULSMs involves evaporation and latent heat flux, linking the water and energy balances.
875 In contrast, UHMs may overlook or aggregate evaporation. ULSMs commonly incorporate multi-subsurface soil layers
with vertical water transfer, primarily within the unsaturated zone. However, their representation of the saturated zone
remains limited. ULSMs are seen to incorporate more physical processes to solve the soil moisture budget in urban areas.
Compared to ULSMs, UHMs pay more attention to saturated soil layers and lateral runoff. Notably, most ULSMs lack a
880 comprehensive hydraulic system, with pipe capacities often set as unlimited for surface runoff.
- More attention should be paid to the subsurface, surface, and atmospheric processes and human activities. To achieve
this, it is necessary to break down disciplinary barriers and create a multidisciplinary cross-communication platform.

885 (5) - Regarding land use types, ULSMs address the surface energy balance for most categories except water surfaces. In canyon concept-based ULSMs, intense vegetation development plays a crucial role in hydro-meteorological processes. Unfortunately, ULSMs tend to represent water surfaces inadequately. Conversely, UHMs do not explicitly solve the surface energy balance and lack detailed representations of building and land use types.

- Water bodies are one of the most popular nature-based solutions for climate and hydrological disasters. Not only from the process aspect but also from the urban planning aspect, future research is recommended to investigate the role of urban water bodies in the urban thermal environment and their link to urban hydrological conditions.

890 (6) - Snow-related processes receive attention in only a subset of ULSMs. UHMs generally consider snow melt as one of the inputs for the surface runoff. Even fewer models included snow-related human activities.

895 - Urban climate studies have traditionally concentrated on heat-related processes, often overlooking snow-related phenomena. However, with the advent of climate change and a growing emphasis on hydro-meteorology, it is crucial to broaden this focus. Not only should heat be considered, but urban snow and its interaction with human activities must also be examined from both thermal and hydrological perspectives. This shift is essential as snow processes and their impacts on urban environments become increasingly significant, especially in cold regions.

Author contributions. XC, AD, MCG, and RU conceptualized the review approach and designed the methodology; XC, JAvdW and MCG collected and categorized the literature; XC analyzed the data; XC visualized the results; XC wrote the paper draft; XC, JAvdW, AD, MCG, and RU reviewed and edited the paper; MCG and RU supervised the research activities; RU acquired funding and managed the project.
