Abstract

Mercury is a volatile heavy element with no known biological function. It is present in trace amounts (on average, ~80 ppb) but is not geochemically well-blended in the Earth's crust. As a result, it sometimes occurs in extremely high concentrations (up to a few %) in certain locations. It is found along tectonic plate faults in deposits of sulfide ores (cinnabar), and it has been extensively mobilized during the Anthropocene. Mercury is currently one of the most targeted global pollutants internationally, with methylmercury compounds being particularly neurotoxic. Over 5,000 tons of mercury are released into the atmosphere annually through primary emissions and secondary re-emissions. Much of the re-emitted mercury, resulting from exchanges with surface reservoirs, is considered to be related to (legacy) human activities, as are the direct releases. Understanding the dynamics of the global Hg cycle is critical to assessing the impact of emission reductions under the UN Minamata Convention, which became legally binding in 2017. This review of atmospheric mercury focuses on the fundamental advances in field, laboratory, and theoretical studies, including six stable Hg isotope analytical methods, that have contributed fairly recently to a more mature understanding of the complexity of the atmospheric Hg cycle and its interactions with the Earth's surface ecosystem.

1 Introduction

Mercury (Hg) is a potent neurotoxin that via methylmercury (MMHg⁺) food exposure poses global health impact (e.g. IQ decrement and heart attack) (Zhang et al., 2021b). The atmosphere plays a pivotal role in the Hg biogeochemical cycle, functioning as the most important transient reservoir, a conduit for transport and transformation, and a site of rich redox chemistry. In part due to concerns about global Hg transport, the multilateral UN-Environment Convention on Hg was negotiated and entered into force in 2017 with a mandate to reduce intentional use and emissions of Hg (UNEP, 2018). Research on the Hg biogeochemical cycling gained momentum after an outbreak of mass MMHg⁺ poisoning severely affected the population of Minamata Bay, Japan, in the 1950s and 1960s through the consumption of contaminated seafood, and it became clear that MMHg⁺ was present at chronically high levels in predatory fish in many lakes, particularly those in the boreal forest belt, through long-range transport and biomagnification (Lindqvist et al., 1991). The earliest known series of measurements on airborne elemental Hg, possibly the first systematic study of its kind, was conducted in Pacific North America during the second half of the 1960s (Williston, 1968). It was recognized as early as the 1970s that Hg circulates globally through the atmosphere (Nriagu, 1979). Somewhat later, Slemr et al. (1985) published an influential paper whose results on the distribution, speciation and budget of atmospheric Hg reproduce fairly well the qualitative features of the atmospheric Hg cycle, such as atomic vapor (Hg⁰) dominating the atmospheric pool and showing an interhemispheric difference with higher concentrations in the northern hemisphere, and being relatively well mixed vertically through the troposphere with an extensive residence time (concept as “global pollutant”).

The knowledge of the physical and chemical processes that govern the dynamics of Hg in the atmosphere has developed gradually. Over time, through technological leaps (stable isotope sampling in natural probes, refined methods in the theoretical and experimental field, etc.), its full complexity began to be appreciated. In earlier research, there was a prevailing view that water phase oxidation by ozone could be the primary mechanism initiating the removal of tropospheric Hg⁰ (Pleijel and Munthe, 1995; Seigneur et al., 1994). However,

newer data indicated that gaseous oxidized mercury (GOM) could also be present in the atmosphere (Xiao et al., 1997; Lindberg and Stratton, 1998), in addition to the particulate form (PBM). Specifically, the observation that Hg^0 was periodically depleted in the planetary mixing layer during the polar spring (Schroeder et al., 1998) prompted a reassessment of Hg chemistry in favor of homogeneous gas-phase chemistry (Hynes et al., 2009). The two-step gas-phase oxidation of Hg^0 initiated by Br atoms has emerged as the most important global channel for tropospheric conversion to Hg^{II} (Donohoue et al., 2006; Holmes et al., 2010). It used to be thought that gas-phase O_3 was an oxidizing agent for Hg^0 to Hg^{II} . However, it has now been found to effectively oxidize intermediate Hg^{I} species (Gómez Martín et al., 2022). This suggests that OH- and less certain I-initiated oxidation of Hg^0 , which produces more unstable intermediates than Br and Cl, may also be important for Hg turnover in parts of the troposphere and beyond (Dibble et al., 2020; Lee et al., 2024). A novel finding is that major $\text{Hg}^{\text{I,III}}$ species, which are expected to be formed in the atmosphere upon oxidation of Hg^0 , are themselves photolabile and undergo gas-phase reduction (Francés-Monerris et al., 2020; Saiz-Lopez et al., 2019). The complexity of rapid redox Hg chemistry involving multiple gas phase oxidation states (0, +1 and +2) is further compounded by the impact of multi-phase interactions, including reactive uptake and homogeneous and heterogeneous processes in condensed phase media, on the dynamics of atmospheric Hg. An indicator of the maturation of our understanding of atmospheric Hg chemistry is the inclusion of its bromine chemistry in critically evaluated data sets for use in atmospheric studies (Burkholder et al., 2019). Over the past two decades, measurements of Hg stable isotope ratios in natural samples have emerged as a valuable tool for gaining insights into the atmospheric Hg cycle. One notable outcome of isotope analysis is the recognition that Hg^0 dry deposition exerts a more pronounced influence on a global scale than was previously understood, with wet and dry deposition of the atmospheric Hg^{II} fraction being of lesser importance.

Hg in the atmosphere has been the subject of reviews over the past 45 years (Hynes et al., 2009; Lindqvist and Rodhe, 1985; Schroeder and Munthe, 1998; Jackson, 1997; Lin et al., 2011; Lin and Pehkonen, 1999; Bash et al., 2007; Ariya et al., 2015; Ariya et al., 2009; Ariya et al., 2008; Si and Ariya, 2018; Subir et al., 2011, 2012; Lin et al., 2006; Lin et al., 2007; Zhang et al., 2009; Gaffney and Marley, 2014; Gustin et al., 2015; Mao et al., 2016; Lyman et al., 2020a; Ariya and Peterson, 2005; Sprovieri et al., 2010; Schroeder et al., 1991). This review is based on the perspective of atmospheric scientists, with synthesis and a fairly comprehensive account of the results of fundamental research, including field, laboratory, and theoretical studies, that have contributed to a reductionist understanding down to a molecular level of the complexity of the atmospheric Hg cycle and its interactions with the Earth's surface ecosystem. This work does not address several topics related to Hg in the atmosphere. These include anthropogenic and natural emission inventories, corresponding top-down constraints and inverse modeling from atmospheric observations, account of long-term air data series and their temporal and spatial trends, observations of PBM and its particle size distributions, wet deposition, future scenarios for the effects of regulatory measures (Minamata Convention) and the ongoing climate change and many more topics. Our goal is to provide a comprehensive review of the atmospheric chemistry of both inorganic and organic Hg in the lower and upper atmosphere, coupled with tabulations of updated, critically evaluated kinetic, thermochemical, photochemical, and isotopic fractionation data. Where appropriate, we introduce the topic with basic concepts and fundamental aspects of Hg chemistry, including that of condensed phases. In atmospheric Hg isotope chemistry, our approach is comprehensive, encompassing a range of activities from field observations of air and of Hg^0 gas exchange with natural surfaces to laboratory studies of processes that may be of value to the atmosphere. We also highlight areas of persistent uncertainty or lack of consensus, such as measurement methods for atmospheric Hg speciation, partitioning of Hg^{II} in atmospheric water between inorganic and organic ligands, and several other areas.

2 Physical chemistry of elemental mercury

Hg is the only metal that is a liquid at standard temperature and pressure (freezing point of -38.8°C and boiling point of 356.7°C), and its vapor is monatomic. Under these conditions, the mixing ratio of neurotoxic Hg vapor in equilibrium with metallic liquid is already at the hazardous level of about 1.7 ppm (Huber et al., 2006). Liquid Hg possesses properties which have given it a wide range of applications in the past despite its known toxicity, including exceptional surface tension (nearly seven times of water at 25°C), high specific gravity, high electrical conductivity (reference substance for the measure of the SI-unit Ω), low compressibility, and a constant volume of expansion in the liquid state. Hg forms solid alloys (amalgams) with most metals except iron. This property enables its applications in gold panning (HgAu), dental fillings (HgAg), or as an electrode material in the chlor-alkali industry (NaHg). Its electronic configuration with filled f and d orbitals and a high density of 6s electrons near the nucleus ($[\text{Xe}]4f^{14}5d^{10}6s^2$),

contracts the orbital as the electron approaches a significant fraction of the speed of light. This shrinking cascade effect makes Hg less reactive than Zn and Cd in the same group (Pyykkö, 1988). It also follows that oxidation states 0 and +2 (mercuric ion, d^{10} metal ion) are the most stable for Hg. Nevertheless, Hg differs from other metals in its propensity to readily form a polycation in the aqueous phase, the mercurous ion, Hg_2^{2+} , which is, however, only meta-stable in the gaseous phase (Strömberg and Wahlgren, 1990). The solubility of Hg^0 in water is limited to $0.3 \mu M$ (Sanemasa, 1975) and the gas-water equilibrium is governed by Henry's law. The Henry's law constant for Hg^0 is $0.11 M atm^{-1}$ at $25^\circ C$ (Andersson et al., 2008) while the parameter is more than seven orders of magnitude higher for the $HgCl_2$ molecule at the same temperature (Sommar et al., 2000).

3 The atmospheric environment

95 3.1 Atmospheric measurements of mercury species

Hg is the only trace gas with the exception of the noble gases (Burnard, 2013) that is widely present as a free atom (Hg^0) in the atmosphere, making this pollutant exceptional in terms of low detection limits by optical measurement techniques. This makes it possible to measure Hg vapor emissions in real time, for example from mining, chlor-alkali production and geothermal activities, as has been done in Europe for decades using Light Detection and Ranging (LIDAR) in the differential absorption mode by mobile laser systems (Svanberg, 2002). If the optical path length in the measuring cell of an instrument is sufficiently long (i.e. using multi-path techniques such as cavity ring-down), then the conditions exist for continuous measurement of Hg^0 in ambient filtered air (at sub-ppt level, $\sim 5 \times 10^6$ atoms cm^{-3} in the northern hemisphere) using atomic absorption spectroscopy (AAS) with Zeeman background correction (Osterwalder et al., 2020). The application of Zeeman AAS in Hg stable isotope analysis has also been described (Lu et al., 2019). As an alternative to Zeeman splitting of the $Hg(6^3P)$ level for sensitive selective detection of Hg^0 (Sholupov et al., 2004), sequential two photon laser-induced fluorescence schemes have been used (Bauer et al., 2002; Bauer et al., 2014; Hynes et al., 2017). For initial excitation of the $Hg(6^1S_0) \rightarrow Hg(6^3P_1)$ transition at 253.7 nm, a light beam from a Hg discharge lamp or the frequency-doubled output of a dye laser pumped by the third harmonic of an Nd:YAG laser is used. As shown in **Fig 1a**, further excitation involves the sequential excitation of different atomic transitions by two laser systems, both starting from the $Hg(6^3P_1)$ state, followed by the detection of the emission of blue- ($Hg(6^1P_1) \rightarrow Hg(6^1S_0)$) at 184.9 nm or redshifted (e.g. at 578.9 nm) fluorescence. Detection of Hg^0 with such a sophisticated apparatus is an exception to the usual measurements, which are typically made by cold vapor atomic fluorescence spectroscopy (CV-AFS) after preconcentration sampling on gold (Ambrose, 2017). The smaller non- Hg^0 portions of atmospheric Hg are challenging to speciate due to their low concentrations. Instead, they are fractionated operationally based on their oxidation state (Hg^0 versus GOM) or phase state (GOM versus PBM). Since gold does not selectively trap Hg^0 but also captures other Hg species (Dumarey et al., 1985; Gačnik et al., 2024), GOM and PBM must be individually collected upstream of the sample air to accurately measure the triad Hg^0 – GOM – PBM. The KCl-coated annular denuder has been utilized for fractionating ambient GOM by gas-phase diffusion for over two decades. Nonetheless, upon the development of techniques to regularly assess its accuracy in measuring ambient air, the method was found to be biased in a non-systematic manner towards lower values (Jaffe et al., 2014; Lyman et al., 2010; McClure et al., 2014). The automated

Figure 1: Left (a). Energy level diagram of Hg atom. The wave-shaped arrows represent resonant radiation. Right (b): Actinic fluxes as a function of altitude. The wavelengths of the $Hg(6^1S_0) \rightarrow Hg(6^3P_1)$ and $\rightarrow Hg(6^1P_1)$ transitions at 253.7 and 184.9 nm, respectively, are given.

120 KCl denuder method, with its variable efficiency, can thus lead to serious underestimation of GOM, while the refluxing mist chamber method, which is an alternative, carries the risk of artifact formation of Hg^{II} by co-sampling GOM with PBM (Gustin et al., 2021). However, the KCl-covered denuder does not have full penetration of PBMs $< 2.5 \mu\text{m}$, but aerosols of a hundred nm or less are increasingly trapped by the salt surface (Ghoshdastidar et al., 2019). When compared, refluxing mist chambers yielded ambient GOM concentrations that were 3 to 4 times higher on average than those obtained with KCl-coated annular denuders (Landis et al., 2002).

125 A decade later, the capture and retention efficiency of the KCl denuder method for GOM was evaluated, which was close to 95% in synthetic Hg^0 -free air, but dropped drastically to between 20 and 54% when exposed to ambient air, where ozone and humidity in particular were found to cause severe reductive losses as Hg^0 (McClure et al., 2014). In fact, ozone gas can heterogeneously reduce particle-bound Hg^{II} halides, as recent experiments have shown (Ai et al., 2023). In high-humidity marine applications, KCl denuder technology operates at very low efficiency; for example, He and Mason (2021) reported average losses of 80% during oceanographic

130 expeditions in the Pacific. By determining total airborne mercury (TAM) (Steffen et al., 2002; Slemr et al., 2018) and Hg^0 in air, a measure of reactive mercury (RM) is obtained as the sum of GOM + PBM by subtracting Hg^0 from TAM. In turn, Hg^0 is obtained by passing an air stream through a filter and a cation exchange membrane (CEM) in series, while TAM is measured as Hg^0 after a pyrolysis unit held at 800°C converts all Hg in the sample air to elemental vapor (Lyman et al., 2020b). CEM has the ability to quantitatively capture and retain Hg^{II} over long storage periods, but has no affinity for Hg^0 (Miller et al., 2019). However, by

135 subtracting two quantities that are usually close to each other, the precision of the RM determination is low. Hynes et al. (2017) used two-photon laser-induced fluorescence as an online detection method for RM (by switching between ambient and pyrolyzed air as the source for the Hg^0 analyte) and concluded that the variability in ambient Hg^0 severely limits the sensitivity of dual-channel difference RM measurement. For the separation of the semi-volatile GOM fraction from PBM in ambient air, the use of various membranes has been implemented, but has recognized limitations (Dunham-Cheatham et al., 2023; Gustin et al., 2023). The

140 realization of NIST-traceable GOM calibration systems has recently progressed (Gacnik et al., 2022). Several studies have been carried out with the aim of experimentally deciphering the molecular identities (speciation) of the GOM pool in ambient air. Most are based on a pre-concentration process of GOM on a substrate, which is then thermo-desorbed in a gas stream following a programmed temperature ramp and detected as Hg^0 after pyrolysis (Gustin et al., 2015), alternatively focused on a capillary column and analyzed by different types (chemical ionization CI; electron impact ionization) of mass spectrometry (MS) (Deeds et al., 2015; Jones et al., 2016). In the former case, standards are used in the form of a number of commercially available Hg chemicals (such as HgBr_2 , HgCl_2 , HgO , $\text{Hg}(\text{NO}_3)_2$, and HgSO_4) that are assumed to be a representative surrogate for GOM (Huang et al., 2017; Sexauer Gustin et al., 2016). As inferred by Khalizov et al. (2020), this speciation is indirect, as it has not been confirmed that the GOM molecule adsorbed on the substrate can be desorbed in the same chemical form as it was in air.

On the contrary, studies show that aerosol reactions lead to the re-speciation of mercuric halides on surfaces (Mao et al., 2021; Mao

150 and Khalizov, 2021). These authors also report that their ion-drift (ID) CI-MS system, which is sensitive enough for detection in laboratory studies, can achieve an LOD at 1 amu resolution of $(0.8 - 2.0) \times 10^5 \text{ molecules cm}^{-3}$ towards ambient GOM by switching to multi-stage atmospheric pressure ID-CI-MS. The feasibility of using proton transfer reaction mass spectroscopy (PTR-MS) to study the reaction products (GOM) of Br-initiated Hg^0 oxidation has been evaluated by Dibble et al. (2014), but is not recommended with respect to its inapplicability to multi-stage atmospheric pressure systems (Khalizov et al., 2020). In summary, direct

155 measurements of ambient GOM have not yet been achieved. No straight-forward method exists for chemically characterizing the GOM fraction, which is semi-volatile and may contain species that are photolytically unstable. Since an almost exclusive part of the previous GOM measurements are considered unreliable (Lyman et al., 2020a; Slemr et al., 2016) and the emerging RM data (Lyman et al., 2020b; Slemr et al., 2018; Swartzendruber et al., 2009; Gratz et al., 2015; Lyman and Jaffe, 2012) are still too sparse and spatially limited, it is not possible to draw far-reaching conclusions on atmospheric Hg^{II} . Sampling methods for organic Hg

160 (dimethylmercury (He et al., 2022) and monomethylated Hg^{II} species (Lee et al., 2003)) in ambient air, as opposed to inorganic Hg species, are more unambiguous. The speciation of Hg in atmospheric waters are discussed in **Section 4.6**. Hg measurement data in air and precipitation, ground-based or aircraft (Slemr et al., 2018; Slemr et al., 2016) observations that fall outside the scope of this

review, including those reported from continental- (Cole et al., 2014; Cole et al., 2013; Schmolke et al., 1999; Wängberg et al., 2001; Gay et al., 2013; Fu et al., 2015) to hemispherical-scale (Bencardino et al., 2024; Szponar et al., 2020; Slemr et al., 2020; Sprovieri et al., 2017; Sprovieri et al., 2016) monitoring networks, some of which have been in operation since before the turn of 2000 (Custódio et al., 2020), have been reviewed elsewhere (Mao et al., 2016; Lyman et al., 2020a; Howard et al., 2017; Angot et al., 2016; Kim et al., 2012; Zhang et al., 2017). In the case of the isotopic characterization of atmospheric Hg, however, we feel justified in compiling, analyzing, and discussing the considerable body of recent observations (**Section 8.2**).

3.2 Stability of atmospheric Hg⁰

Atomic vapor (Hg⁰) dominates the atmospheric Hg pool, shows an interhemispheric difference with higher concentrations in the northern hemisphere (Bencardino et al., 2024), and is relatively well mixed vertically through the troposphere (Weigelt et al., 2016). When crossing the intertropical convergence zone, Hg⁰ is subject to convective uplift that allows entry to the stratosphere. In the upper troposphere of the Pacific Ocean, there is evidence of augmented interhemispheric Hg exchange (Koenig et al., 2022). It is well accepted that the tropospheric Hg pool is close to 4000 Mg (Saiz-Lopez et al., 2025) and that direct anthropogenic emissions to the troposphere, excluding biomass burning, are around 2200 Mg yr⁻¹ worldwide (Sonke et al., 2023; Horowitz et al., 2017), while estimates of e.g. oceanic re-emissions (Zhang et al., 2023b; Zhang et al., 2019b; Soerensen et al., 2010) and vegetation uptake (Zhou and Obrist, 2021; Obrist et al., 2021; Jiskra et al., 2018; Yuan et al., 2023a) of Hg⁰ vary widely. Based on a synthesis of RM measurements at various heights in the atmosphere, it has been estimated that the atmospheric burden of Hg^{II} up to 20 km is approximately 360 Mg (Saiz-Lopez et al., 2020). This value significantly deviates from the values predicted by global models (~100 Mg, Shah et al., 2021; Zhang and Zhang, 2022; ~500 Mg, Saiz-Lopez et al. 2025) for the troposphere proper, values that are associated with significant uncertainties. Hg^I species are intermediates in the Hg⁰/Hg^{II} redox cycle, but their tropospheric mass is negligible (Shah et al., 2021). With scientific progress and new data, it has become clear that the magnitude of bidirectional mass fluxes through gas exchange (emission-deposition) and chemical transformation (reduction-oxidation) is much larger than previously thought. For transferring Hg⁰ from the oceans into the atmosphere, the mass transfer rate is usually parameterized using wind speed dependencies that have been tested for CO₂ emissions. However, recent evidence (Osterwalder et al., 2021) suggests that Hg⁰, which is less soluble than CO₂, behaves rather similarly to O₂ and N₂, where the impact of bubble-mediated transfer is greater. As a result, ocean emissions have an increased role in the global Hg budget, accounting for approximately 60% of total Hg emissions to the atmosphere due to a wind speed dependence with a cubic power exponent instead of quadratic in model simulations (Zhang et al., 2023b). The greater gross emissions from seawater are balanced by the deposition of Hg⁰, which is of comparable magnitude to that of Hg^{II} deposition (Jiskra et al., 2021) - and much higher than previously assumed (Soerensen et al., 2010). This also applies to the magnitude of Hg⁰ dry and wet deposition (throughfall; Wang et al., 2020b) to vegetation (forests). A comprehensive overview of the understanding of the gas exchange of Hg⁰ between the atmosphere and the Earth's surface has been presented elsewhere (Sommar et al., 2020).

Hg⁰ is estimated to have a global tropospheric lifetime of 3.8 - 7 mo. and a chemical lifetime against oxidation (to Hg^{I,II}) of 2.7 - 4.5 mo. (Shah et al., 2021; Horowitz et al., 2017; Zhang et al., 2023b; Shah et al., 2016; Saiz-Lopez et al., 2025), the differences between the two values being largely due to significant redox cycling in the gas phase and aerosols before deposition. Atmospheric Hg deposition persists for terrestrial ecosystems overall with a predominance of Hg⁰ compared to Hg^{II} (Zhou and Obrist, 2021; Wang et al., 2020b; Feinberg et al., 2022), while the situation appears opposite for cryospheric and marine systems. The total atmospheric Hg deposition is estimated to be 4800 - 6700 Mg yr⁻¹ Hg^{II} (Sonke et al., 2023; Zhang et al., 2019b; Feinberg et al., 2022) and 3600 - 6750 Mg yr⁻¹ Hg⁰ (Shah et al., 2021; Sonke et al., 2023; Zhang et al., 2023b). Hg in the stratosphere is estimated to account for about 20% of the total atmospheric Hg mass, with an exchange with the troposphere in the range of 176-300 Mg yr⁻¹ (Shah et al., 2021; Lyman and Jaffe, 2012), where Hg is mainly removed from the stratosphere as Hg^{II} on aerosols (Murphy et al., 2006) or, to a lesser extent, as the most photostable gas-phase mercurial species (Saiz-Lopez et al., 2022 & 2025). Based on correlations between Hg⁰ and N₂O in the stratosphere within 4 km above the thermal tropopause, Slemr et al. (2018) provided a lifetime estimate of 74 ± 27 yr., while Lyman and Jaffe (2012) inferred a relatively short lifetime for Hg⁰ in intercepted descending air with stratospheric origin. Saiz-Lopez

et al. (2022) estimate the lifetime of Hg^0 in the lower stratosphere against surface deposition of 3 – 9 years and Saiz-Lopez et al. (2025) a mean atmospheric (troposphere + stratosphere) lifetime of 8.2 mo. Hg^0 in the planetary boundary layer can be consumed at a surprisingly high rate, leading to low concentration levels bordering on complete depletion. Thus, chemical oxidation by reactive bromine species in a catalytic cycle (“bromine explosion”, Toyota et al., 2014; Gao et al., 2022) can explain atomic Hg depletion events (AMDEs) during the polar spring after sunrise (Schroeder et al., 1998; Sommar et al., 2007; Nerentorp Mastromonaco et al., 2016) and those observed over the Dead Sea (Obrist et al., 2011) (Fig. 2). Br-controlled oxidation via the intermediate $\text{Hg}^{\text{I}}\text{Br}$ is also

Figure 2. The chemistry behind bromine explosion events and related surface layer ozone and mercury depletion events.

critical for tropospheric oxidation of Hg^0 , as described later in the section on gas-phase oxidation. Upon entry into the stratosphere, thermal oxidation with Br^\bullet remains important for conversion to Hg^{II} , but with increasing altitude in the lower stratosphere, Cl

chemistry becomes the most important role, with OH-directed chemistry in second place at a slow net oxidation rate.

With the maximum concentration of the O_3 layer (~25 km) as the dividing line, there is a strong dichotomy between the Hg chemistry in the upper and lower stratosphere. The former is UVC driven (Sun et al., 2022) (The UV-window > 30 km provides a substantial photon flux at $\lambda = 253.7$ nm, Fig. 1b), involving optically excited Hg^0 states with a strong electrophilic character. The electronic excitation of Hg^0 from the ground state (singlet, $^1\text{S}_0$) at 253.7 nm is spin-forbidden (leading to a triplet state, $^3\text{P}_1$ with a radiative lifetime of ~125 ns, Fig. 1a). The metastable dark $\text{Hg}(^3\text{P}_0)$ state cannot be produced directly from $\text{Hg}(^1\text{S}_0)$ by light absorption, but by spin-orbit relaxation of $\text{Hg}(^3\text{P}_1)$ atoms involving energy transfer to surrounding (air) molecules. In N_2 , the equilibrium constant between the $^3\text{P}_0$ and $^3\text{P}_1$ states at room temperature (297 K) is 1.87×10^3 (Callear and Shiundu, 1987), but in the presence of O_2 their distribution changes profoundly. Although O_2 is a slightly less effective quencher for $\text{Hg}(^3\text{P}_0)$ than for $\text{Hg}(^3\text{P}_1)$ (Callear, 1987), their effective lifetimes in air at atmospheric pressure differ by only one order of magnitude (~1.1 ns and ~0.2 ns, respectively, Saiz-Lopez et al., 2022). In addition to physical quenching to the ground state, both $\text{Hg}(^3\text{P}_0)$ and $\text{Hg}(^3\text{P}_1)$ may undergo chemical oxidation to mercury oxide(s) (Callear et al., 1959), although metastable atoms are expected to be less reactive. It is the chemical conversion of excited Hg atoms by O_2 that releases Hg^{II} , which can further react to more stable species, giving Hg^0 in the upper stratosphere a tiny lifetime against oxidation compared to transfer to the lower atmosphere (Saiz-Lopez et al., 2022). In the uppermost stratosphere, there appears to be access to deeper UVC (Fig. 1b) that at 184.9 nm allows a spin-allowed electronic transition from $\text{Hg}(^1\text{S}_0)$ to $\text{Hg}(^1\text{P}_1)$ with a light absorption cross-section of nearly two orders of magnitude greater than for the $\text{Hg}(^1\text{S}_0) \rightarrow \text{Hg}(^3\text{P}_1)$ transition (Morton, 2000). Like $\text{Hg}(^3\text{P}_1)$, the more energetic $\text{Hg}(^1\text{P}_1)$ reacts with O_2 at a rate approaching the collision frequency, but the HgO product formed in the latter case is so vibrationally hot that it promptly decays into Hg and O atoms. As a result, the chemistry of $\text{Hg}(^1\text{P}_1)$ is expected to play a minor role in the turnover of Hg in the upper stratosphere. The calculated lifetime of Hg^0 in the mid to upper stratosphere is altitude-dependent in the range of a fraction of up to a few hundred hours (Saiz-Lopez et al., 2022) and is most comparable to that of Hg^0 during AMDEs, but the underlying governing physicochemical processes are completely different.

4 Kinetics, thermodynamics and general chemistry

4.1 Fundamental kinetics and thermodynamical principles

A chemical process can be decomposed into a sequence of one or more single-step processes as elementary reactions. Elementary processes involve a transition between two atomic or molecular states separated by a potential energy barrier. The barrier represents the activation energy and determines the rate at which it occurs. The rate of a reaction is determined by the interaction between kinetics, a rate process, and thermodynamics that describes the energetics of the process. Processes that release heat as products and increase the entropy of the system favor the reaction. The balance between enthalpy (ΔH) and entropy (ΔS) is given by the Gibbs free energy equation, where T is the absolute temperature in Kelvin: $\Delta G = \Delta H - T\Delta S$. If the Gibbs free energy is negative, the reaction is spontaneous from a thermodynamic perspective. The index is used to distinguish the enthalpy of reaction (ΔH_R) from, say, the enthalpy of formation of a substance (ΔH_f). We can calculate the equilibrium constant, K , using $\ln K = -\Delta G_R/RT$ and determine the ratio of the forward and reverse rate coefficients from $K = k_f/k_r$. Examples of important types of reaction are as follows:

Reaction order	Type	Unit
Unimolecular step	Thermal dissociation	s^{-1}
Bimolecular step	Recombination	$cm^3 molecule^{-1} s^{-1}$, $L mol^{-1} s^{-1}$
Termolecular step	Recombination assisted by a third body ($M = N_2/O_2$)	$cm^6 molecule^{-2} s^{-1}$, $L^2 mol^{-2} s^{-1}$

Termolecular reactions are pressure (M) dependent at low pressures with an effective rate coefficient (k) of third order, but becomes pressure independent at high pressures. The transition from third to second order behavior is known as the fall-off region. For most atmospheric reactions, we can expect that rate coefficient is at the low pressure-limit. However, there are exceptions which are listed in **Table 1**. While *two-body* collisions are common in the gas phase, *three-body* collisions are much less probable and *four-body* collisions can be ignored because of their low probability. An *overall* reaction includes two or more *elementary* reactions. The temperature dependence of rate coefficients can be fit over a relatively narrow temperature range by the empirical *Arrhenius equation*: $k(T) = A \exp(-E_a/RT)$, where E_a is the activation energy and R the gas constant. The pre-exponential factor A , a constant in the original Arrhenius equation, is weakly temperature dependent for most reactions (varying as the square root of T according to collision theory). For a wider temperature range, the modified expression $k(T) = (T/300)^n \exp(-E_a/RT)$ provides a better fit to the experimental data. If the activation energy is high enough, there is a large endothermic barrier that prevents even a reaction with a strongly negative ΔG^0 from occurring at measurable rates. In select cases, the experimental data show a negative activation energy, suggesting that the reaction proceeds by the addition of reactants to form an intermediate species with excess energy that must be dissipated before decomposing into the final products. The rate constant for termolecular reactions between small molecules in the atmosphere can usually be well approximated by a combination of three parameters k_0 ($cm^6 molecule^{-2} s^{-1}$), k_∞ ($cm^3 molecule^{-1} s^{-1}$) and F_C . The first two correspond to the low- and high-pressure limits, and F_C is a form factor describing the transition region.

$$k = \frac{k_0 k_\infty [M]}{k_\infty + k_0 [M]} F_C \left(1 + [\log(k_0 [M]/k_\infty)]^2 \right)^{-1} \quad (1)$$

The temperature dependence of k is expressed by parameterizing k_0 and k_∞ as a function of temperature with the following expression:

$$k_0^T = k_0^{300} (T/300)^{-n} \text{ and } k_\infty^T = k_\infty^{300} (T/300)^{-m} \quad (2)$$

4.2 Surface kinetics

Atmospheric aerosols possess a high surface-to-volume ratio, which enables most of their constituents being concentrated at the surface. Furthermore, the influence of surface chemistry is enhanced with decreasing particle size. Gas-to-particle reactions, among other heterogeneous reactions, begin with adsorption, which links molecules from the gas phase to the surface of a solid or liquid. This process can be physical, with low adsorption energy (*physisorption*, van der Waals forces), chemical (*chemisorption*), when chemical bonding occurs as molecules approach the surface and overcome the activation energy barrier, and become reactive when the adsorbent reacts with sites on the surface. It is crucial to recognize that gases and solutes adsorbed at an interface frequently exhibit physicochemical

properties that diverge from their bulk properties, including reactivity and spectral shifts. Surface reaction kinetics are often expressed by the uptake probability (γ), which represents the fraction of gas collisions with a substrate surface that yield uptake or reaction. The net uptake of gas γ_{net} is quantified in terms of conductances (Γ), which are normalized to the rate of gas surface collisions:

$$\gamma_{\text{net}}^{-1} = \Gamma_{\text{g}}^{-1} + \alpha^{-1} + (\Gamma_{\text{rxn}} + \Gamma_{\text{sol}})^{-1} \quad (3)$$

where Γ_{g} , Γ_{rxn} , and Γ_{sol} represent the processes of gas-phase diffusion to the surface, solubility, and reaction in the bulk liquid phase, respectively, and α represents the (reversible) mass accommodation (“sticking”) across the gas-particle interface. In addition to α , these processes are related to the diffusion constants in gas (D_{g}) and liquid (D_{l}) phases, Henry’s law coefficient (k_{H}), and the rate constant of the (first order) reaction in the condensed phase bulk (Finlayson-Pitts and Pitts, 2000). For solids, bulk diffusion is generally too slow to allow bulk solubilities or bulk kinetics to control uptake. To justify the use of the formulation of additive kinetic conductances (Eq. 3) to solve the continuity equation and thus to be sufficient in laboratory studies to measure the net loss of a gas over a condensed phase of known volume and surface area, it is preferable to conduct experiments at low pressure. These experiments are typically performed in a tube reactor (radius r) with fast laminar flow conditions (FF). To vary the reaction time, a moving injector is employed to change the exposed surface length in this technique. The net flux of the gas X into the condensed phase (J_{x}) can in this case be expressed as Eq. 4:

$$J_{\text{x}} = \frac{2 \cdot k_{\text{obs}}}{r} \left([X]_{\text{g},\infty} - \frac{[X]_{\text{surf}}}{H} \right) \quad (4)$$

where k_{obs} is the experimentally observed first-order rate coefficient and the indices g,∞ and surf represent the gas bulk and surface, respectively. In turn, k_{obs} relates approximately to γ_{net} by Eq. 5:

$$k_{\text{obs}} = r^{-1} \left(\frac{r}{3.66 \cdot D_{\text{g}}} + \frac{2\gamma_{\text{net}}}{\bar{v}_{\text{x}}} \right)^{-1} \quad (5)$$

where D_{g} is the diffusivity of the gas and \bar{v}_{x} its mean thermal velocity. The value of γ_{net} changes as the surface is covered by molecules and depends on the concentrations of the reactants and the reaction time. The initial phase is denoted by γ_{net}^0 , while the steady state phase is denoted by $\gamma_{\text{net}}^{\infty}$. The calculated γ_{net} can be employed to estimate the lifetime of the gas X (τ_{x}) with respect to reactive uptake on particles. The following formula has been applied to the uptake on aerosols with a polydisperse distribution (Mao et al., 2021; Sander, 1999; Schwartz, 1986):

$$\tau_{\text{x}} = \left[\sum 4\pi r^2 \left(\frac{\Delta N}{\Delta \log r} \right) \Delta \log r \left(\frac{r}{D_{\text{g}}} + \frac{4}{\gamma_{\text{net}} \cdot \bar{v}_{\text{x}}} \right) \right]^{-1} \quad (6)$$

The uptake of the only Hg^{II} species studied so far, HgCl_2 , follows a Hinselwood-Langmuir mechanism (Pankow, 2007), where $\text{HgCl}_2(\text{g})$ must first be adsorbed to a site (\parallel) on the surface and can then react as a surface complex with a reactive center (e.g., anions) R on the surface, forming a product which is released from \parallel , which becomes vacant again:

where K in the above equation is referred to as the Langmuir constant. Deposition velocities and partitioning coefficients are an older empirical framework for parameterizing heterogeneous atmospheric processes. A coefficient for absorptive partitioning of compound X onto existing aerosol, K_{gp} , was proposed as Pankow (2007):

$$K_{\text{gp}} = \frac{[X]_{\text{p}}/\text{PM}}{[X]_{\text{g}}} \quad (8)$$

where the index gp is the gas-particle partitioning, $[X]_{\text{p}}$ and $[X]_{\text{g}}$ are the mass concentrations of compound X in the gas phase and particle phase, respectively, in a unit volume of air, and PM is the total mass concentration of particles.

4.3 Aqueous redox equilibria

The Gibbs free energy change (ΔG) presented previously is related to the electrode potential (E) by the formula:

$$\Delta G = -nFE \quad (9)$$

where n is the number of moles of electrons transferred in the reaction and F is the Faraday constant (96485 C mol^{-1}). The standard

potentials for the mercury-mercurous-mercuric free cation couples are:

These positive potential indicates that the reduction of $\text{Hg}^{2+}/\text{Hg}_2^{2+}$ to Hg^0 is favored under standard conditions. It is also evident that Hg^0 can be oxidized to $\text{Hg}_2^{2+}(\text{aq})$ rather than $\text{Hg}^{2+}(\text{aq})$ only by agents with potential from -0.79 to -0.85 V . None of the common
 305 oxidizing agents meet this narrow potential range. Therefore, in excess of oxidizing agent, Hg^0 is completely oxidized to $\text{Hg}^{2+}(\text{aq})$. Only when the excess of Hg^0 exceeds 50% does the oxidation leads to $\text{Hg}_2^{2+}(\text{aq})$. Ligation and hydrolysis have a major impact on standard potentials, including those listed in **Rxn 1 – 3**. For example, $\text{Hg}(\text{OH})_2 + 2 \text{e}^- \rightleftharpoons \text{Hg}^0 + 2 \text{HO}^-$, analogous to **Rxn 3**, has an E^0 value of 0.206 V .

4.4 Chemical properties of aqueous Hg^{II}

310 The Hg^{2+} aqua ion, $[\text{Hg}(\text{H}_2\text{O})_6]^{2+}$, exists only in distinctly acidic aqueous solutions containing a weakly coordinating anion (e.g., ClO_4^-). It undergoes hydrolysis readily at $\text{pH} > 1$ ($\log K([\text{Hg}(\text{OH})]^+ = 10.3$, Powell et al., 2005). Depending on its size and stable electron configuration, $\text{Hg}^{2+}(\text{aq})$ can be easily polarized by ligands and, therefore, has the potential to form strong covalent bonds. This property allows $\text{Hg}^{2+}(\text{aq})$ to interact with organic C to readily form $\text{Hg}-\text{C}$ bonds through mercury-hydrogen substitution (*mercuration*), addition (*oxy-* and *amino-mercuration*, etc.), and decarboxylation reactions. An example is aniline, which form
 315 covalent complex with Hg^{2+} readily in aqueous solution at room temperature:

The formation of organomercurials by mercuration in aqueous solution is generally slow due to the reduced electrophilicity of Hg^{2+} caused by the metal center's hydrolysis. However, the presence of a polar solvent has little influence on other processes of organomercurial formation, such as decarboxylation. Therefore, abiotic Hg methylation can occur in aqueous solution with the assistance of, e.g., light carboxylic acids (Deacon et al., 1986). In the case of keto-enolic organic compounds such as acetylacetone
 320 ($\text{R} = \text{H}$) and malonate ($\text{R} = \text{OH}$), the mercuric ion can, in principle, adopt a C-bond, an O-bond or a chelate structure:

Highly toxic CH_3Hg^+ (MMHg^+) species are by far the most abundant organic Hg in the environment and are formed from inorganic Hg^{II} mainly by the action of Fe^{III} and SO_4^{2-} reducing bacteria. Besides monomethylation, permethylation can also occur anaerobically (Sommar et al., 1999). $(\text{CH}_3)_2\text{Hg}$ (DMHg) is detected mainly in deep sea waters, but via upwelling waters (Conaway et al., 2009), it may reach the mixed layer, where gas exchange with the atmosphere can occur. DMHg has also been detected in landfill (Lindberg
 325 et al., 2005; Feldmann et al., 1994) and sewage gas (Sommar et al., 1999), flood plains (Wallschläger et al., 1995) and rice paddies (Wang et al., 2019c). The binding affinity of Hg^{2+} to ligands is often qualitatively rationalized by Lewis' acid-base theory with the message that mercurials (type B metal) prefer soft ligands such as heavier halides and hydrochalcogenides (e.g. I^- and SH^- , respectively) to hard ones (e.g. OH^- and F^-). In fact, Hg^{2+} is the softest of all metal ions acting as Lewis's acids. The preference for low coordination numbers (≤ 4 , typically linear two-coordination) in Hg^{II} complexes is related to the fact that relativistic effects come
 330 into play for the heaviest elements (Tossell and Vaughan, 1981). The interaction between $\text{Hg}^{2+}(\text{aq})$ and inorganic ligands and low molecular weight organics are given as stability constants. The tables show that Hg^{2+} also binds strongly to nitrogenous bases. The interaction with inorganic ones, such as ammonia, is extensive and complex (Breitinger and Brodersen, 1970). For organic nitrogen

ligands, there is a parallel between the basicity of the ligand and the stability of the Hg-ligand complex (e.g. guanidine). Heterocyclic nitrogen compounds, such as histidine, also form strong complexes with the mercuric ion. The hard-soft acid-base principle applies only to highly polar solvents, such as in aqueous solution, a result of solvation (hydrolysis) effects (Riccardi et al., 2013). In the gaseous phase, an inverse relationship prevails (Riccardi et al., 2013) and can be illustrated by the fact that gaseous $\text{Hg}(\text{OH})_2$ is a stable molecule, whereas in aqueous solution, Hg^{2+} and 2OH^- can form the intermediate molecule $\text{Hg}(\text{OH})_2$ (Yang et al., 2020b), which eliminates H_2O and precipitates solid HgO . Therefore, solid $\text{Hg}(\text{OH})_2$ is not known (Wang and Andrews, 2005). Furthermore, in the aqueous phase, the univalent state (mercurous species) is represented by the metal-metal bound ion $\text{Hg}_2^{2+}(\text{aq})$ that is ordinarily stable. Like $\text{Hg}^{2+}(\text{aq})$, $\text{Hg}_2^{2+}(\text{aq})$ is a soft Lewis acid.

Hg-ligand complexation is ubiquitous in the environment. This process involves a significant energy shift due to solvation effects, which result in a reduction in the number of solvating water molecules and an increase in the interaction between ligands/anions in the complexes and water. As opposed to the dimer cation, the discrete $\text{Hg}^{\bullet+}$ cation is paramagnetic and was detected for the first time using electron spin resonance (Symons and Yandell, 1971). The free $\text{Hg}^{\bullet+}$ is a highly potent reducing agent with a one-electron reduction potential, $E^0(\text{Hg}^{2+}/\text{Hg}^{\bullet+})$, estimated to be well below -2.0 V (Gårdfeldt and Jonsson, 2003). However, hydrolyzed or ligated forms are less reactive (Gårdfeldt and Jonsson, 2003; Kozin and Hansen, 2013). The dissociation $\text{Hg}_2^{2+}(\text{aq}) \rightleftharpoons 2 \text{Hg}^{\bullet+}(\text{aq})$ is considerably less significant than the disproportionation $\text{Hg}_2^{2+}(\text{aq}) \rightleftharpoons \text{Hg}^0(\text{aq}) + \text{Hg}^{2+}(\text{aq})$, with a conservative upper bound for the ratio $[\text{Hg}^{\bullet+}]/[\text{Hg}_2^{2+}]$ of 10^{-7} (Moser and Voigt, 1957). Free cation acidity decreases in the order of Hg^{2+} (pK 3.4), Hg_2^{2+} (pK 4.9) and $\text{Hg}^{\bullet+}$ (pK 5.1). $\text{Hg}_2^{2+}(\text{aq}) \rightleftharpoons \text{Hg}^0(\text{aq}) + \text{Hg}^{2+}(\text{aq})$ has an equilibrium constant of $5.5 \times 10^{-9} \text{ M}$ (Moser and Voigt, 1957), which indicates that a solution of initially only Hg_2^{2+} in pure water will contain only a single percent Hg^{2+} in the absence of ligands that form complexes with Hg^{2+} . However, in the presence of ligands that form complexes with Hg^{2+} , disproportionation is rapid and Hg_2^{2+} is consumed. The same applies when $\text{Hg}^0(\text{aq})$ is removed from the solution, e.g., by a gas stream. Hg_2^{2+} can be a major speciation component in heavily polluted waters (Fang et al., 2024), but is insignificant in the atmosphere.

4.5. Chemical equilibria data

For a general complex equilibrium with Hg^{2+} and the ligand L, $\text{Hg}^{2+} + q \text{L} + r \text{H}_2\text{O} \rightleftharpoons [\text{HgL}_q(\text{OH})_r]^{(2-r)+} + r \text{H}^+$, a stability constant β_{qr} is defined as $[\text{M}_p\text{L}_q(\text{OH})_r][\text{H}^+]^r / ([\text{M}]^p[\text{L}]^q)$. When the complex is not hydrolyzed β_{qr} is reduced to $\beta_q = [\text{ML}_q]/([\text{M}][\text{L}]^q)$. For the equilibrium obtained by adding a ligand (L) to a metal complex in a stepwise manner, K_q is used, which is related to β_q by $\prod_{i=1}^q K_i$. **Tables 1 and 2** present the equilibrium constants for Hg^{2+} associated with a range of inorganic and organic natural ligands, respectively, without purporting to be comprehensive. The reader's attention should also be drawn to the open-access AQUAMER database and web server dedicated to Hg, which provides direct speciation results by combining web-based interfaces to a speciation calculator, thermodynamic constants databases, and a computational chemistry toolbox for input to other software to estimate missing constants. (Lian et al., 2020).

4.6 The speciation of Hg^{II} in atmospheric waters

Hg^{II} speciation in atmospheric waters such as clouds and fog is governed by interaction with inorganic nucleophiles, low molecular weight organics (LMWO), and high molecular weight dissolved organic matter (DOM). Identified LMWOs typically make up a smaller mass fraction of the DOM in ambient cloud and fog droplets. Despite its limited abundance (0.5 - 3% in freshwater), sulfurized DOM exerts control over Hg cycling in terrestrial aquatic systems by forming predominantly strong HgL ($\log K \sim 21.9 - 23.6$) and HgL_2 ($\log K \sim 30.1 - 31.6$) complexes (Dong et al., 2011), where L represents functional groups with reduced sulfur. Although sulfur-containing DOM (with the elemental composition CHSO and CHNSO) is also relatively ubiquitous in atmospheric organic matter (AOM), it is mainly in hexavalent form, with reduced sulfur being a rare occurrence (Zhao et al., 2013; Bianco et al., 2018; Jiang et al., 2022). In contrast to sub-zero valence S, whose presence in AOM is thus not universal, conjugate bases of strong oxo acids that are common in AOM, such as organic nitrates and sulfates, form weak complexes with Hg^{II} , which is not relevant in this context. It is therefore questionable to apply speciation by geochemical equilibrium modeling to assess the interaction between

atmospheric DOM and Hg^{II} as in some studies (Li et al., 2018; Zhen et al., 2023). Bittrich et al. (2011) used pH, a confined set of
 375 inorganic ions (NH_4^+ , NO_3^- , SO_4^{2-} and Cl^-), and LMWO acids to speciate observations of dissolved Hg^{II} in a study of cloud and fog
 water. Strongly dependent on pH, at < 5 even moderate Cl^- levels can control speciation (HgCl_2), whereas in more alkaline waters
 (e.g. influenced by NH_3) speciation is controlled by $\text{Hg}(\text{OH})_2$, $\text{Hg}(\text{OH})\text{Cl}$ and to some extent by $[\text{Hg}(\text{NH}_3)_2]^{2+}$. A more realistic
 approach is to include DOM in the speciation. In this regard, Yang et al. employed Hg^{II} complexation with fulvic acids under
 conditions of binding to mainly O-donors (1:2 complexes with $\log K = 5.6$, Haitzer et al., 2002) as surrogates for AOM interaction.
 380 It was found to dominate in the Hg^{II} speciation of rainwater samples in rural and urban France (Yang et al., 2019). Studies of cloud
 water in eastern China show a remarkable change in acidity and other chemical composition in the post-2008 period, where Hg^{II} ,
 although the concentration is unchanged over time, in the former acidic environment is mainly bound by DOM (~79%) (Li et al.,
 2018) and in the later more neutral environment is more homogeneously distributed in addition to DOM among hydrolyzed and
 halide ($\text{X} = \text{Cl}, \text{Br}$) bound species ($\text{Hg}(\text{OH})_2$, HOHgX , and HgX_2 , Zhen et al., 2023). In conclusion, it is clear that as long as the
 385 complexation of Hg^{II} with AOM is less constrained, there is considerable uncertainty regarding the partitioning of aquatic Hg^{II}
 between stable and reduction-labile complexes in the photic atmosphere.

Table 1. Hg^{2+} – inorganic ligand complexes. Omitted in the table is, e.g., interactions with reduced sulfur (HS^- , R-S^-) that can be found in e.g. Sklylberg (2011).

390 4.7 Chemical reactions data

The subsequent two principal sections address the chemical redox reactions in the gaseous phase (**Section 5**) and in the aqueous phase (**Section 6**), respectively. **Table 3** summarizes the gas-phase reactions with the corresponding rate coefficients and reaction enthalpies. The reaction numbers are designated with the prefix G (G1, G2, etc.). The aqueous phase reaction numbers are designated with the prefix W and are listed in **Table 4** with the corresponding rate coefficients. It should also be noted that several chemical reactions appear in the text that are not labeled with G or W and are not assigned to **Tables 3** and **4**. This is particularly the case for heterogeneous (multi-phase) processes (**Section 7**), such as reactive uptake and reduction on surfaces, which consequently have no prefix and follow the sequential numbering throughout the document.

5 Gas-phase atmospheric Hg chemistry

5.1 Inorganic species

400 5.1.1 Initial reactions of ground state Hg^0

The homogeneous gas-phase oxidation of Hg^0 in the electronic ground state of atmospheric importance is limited to a few reactive species formed by the action of actinic light. In the atmosphere, multi-step reactions involving both Hg^{I} and Hg^{II} species are crucial for Hg transformations. Atmospheric oxidation of Hg^0 occurs largely in the gas phase, whereas the rates of aqueous phase reactions in deliquescent aerosols are relatively slower on a unit air volume basis and are inherently limited by the low water solubility of Hg^0 . Oxidation of Hg^0 vapor by closed-shell molecules, such as halogenation chemistry with reference to the gas phase, has been studied in the laboratory at various temperatures (Hall, 1992; Qu et al., 2009; Chi et al., 2009; Ariya et al., 2002; Sumner et al., 2005; Raofie and Ariya, 2004; Raofie et al., 2008; Wilcox, 2009) since Ogg et al. (1936). Direct oxidation by the free halogens (X_2) via the insertion reaction $\text{Hg} + \text{X}_2 \rightarrow \text{XHg}^{\text{II}}\text{X}$ is highly exothermic but very slow under atmospheric conditions due to large energy barriers (Auzmendi-Murua et al., 2014), whereas the abstraction $\text{Hg} + \text{X}_2 \rightarrow \bullet\text{Hg}^{\text{I}}\text{X} + \text{X}^\bullet$ proceeds at significant rates only at high temperatures (Niksa et al., 2001). Thus, free halogen chemistry is of great importance for the conversion of Hg in the flue gas from power generation systems (Wilcox, 2009), such as the coal-fired (CFPP) type but not in the atmosphere. The same applies to the $\text{Hg} + \text{NO}_2$ reaction, which is barrierless and whose pathway to $\text{Hg}^{\text{II}}(\text{ONO})_2$ shows a negative temperature dependence (Li et al., 2022c). However, reactions that are only important in combustion and flue gas cleaning systems are outside the scope of this review.

Hg + XO (X = O_2 , NO_2 and Br)

Although oxidation of Hg^0 vapor by common atmospheric oxidants O_3 (Sumner et al., 2005; Hall, 1995; Pal and Ariya, 2004b; Snider et al., 2008), BrO^\bullet (Raofie and Ariya, 2004; Spicer et al., 2002) and NO_3^\bullet (Sommar et al., 1997; Sumner et al., 2005) has been observed in the laboratory, the identity and phase of the product(s) are in doubt. Laboratory studies of gas-phase oxidation of ppb levels of Hg^0 (the atmospheric level is sub-ppt) have observed product particles in the accumulation mode, suggesting that gas-to-particle conversion takes place (Raofie and Ariya, 2004; Sun et al., 2016). These data attributed to the gas phase are almost certainly compromised by complex kinetics including reactions at the reactor wall (Hynes et al., 2009). In all cases, gas-phase oxidation pathways leading to HgO by O atom transfer are endothermic (**Rxn G5 – G7, Table 3**). Furthermore, experimentally measured pre-exponential factors for the $\text{Hg}-\text{O}_3$ reaction, $\sim 10^{-16} - 10^{-18} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Hall, 1995; Pal and Ariya, 2004b), are very much smaller than expected for a simple O atom transfer (Calvert and Lindberg, 2005). Alternative O_3 oxidation via a weakly bound ($\sim 16 \text{ kJ mol}^{-1}$) adduct HgO_3 lacks exothermic dissociation pathways (i.e., $\text{HgO} + \text{O}_2$, **Rxn G5a**) and is therefore unlikely to occur in the atmosphere but in laboratory experiments can conceivably diffuse to surfaces and be deposited as solid HgO possibly via oligomerization (Tossell, 2006). Recombination of Hg^0 with NO_3^\bullet results in the weakly bound $\bullet\text{Hg}^{\text{I}}\text{NO}_3$ ($\sim 27 \text{ kJ mol}^{-1}$), which dissociates in the lower troposphere before oxidation to Hg^{II} species of the type $\text{O}_2\text{NOHgO}^\bullet$ or O_2NOHgY can occur (Edirappulige et al., 2023a). Abstractions (e.g., $\text{Hg} + \text{BrO}^\bullet \rightarrow \text{HgO} + \text{Br}^\bullet$ or $\text{Hg} + \text{BrO}^\bullet \rightarrow \bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}$, **Rxn G7a & b**) are endothermic, whereas direct insertion reactions (e.g., $\text{Hg} + \text{BrO}^\bullet \rightarrow \text{BrHg}^{\text{II}}\text{O}^\bullet$, **Rxn G7c**) is exothermic (-84 kJ mol^{-1} , Shepler 2006) but affected by large barriers (170 kJ mol^{-1}) and therefore unlikely to proceed (Balabanov and Peterson, 2003). The remaining exit channels, namely the recombination of Hg and BrO^\bullet (**Rxn G7d**) leading to the formation of the geometric isomers of $\text{BrHg}^{\text{II}}\text{O}^\bullet$ ($\bullet\text{Hg}^{\text{I}}\text{BrO}$ and $\bullet\text{Hg}^{\text{I}}\text{OBr}$),

are also inconceivable as these adducts are thought to be very weakly bound (Shepler, 2006). Stable Hg^{I} species of this type have been reported in one laboratory suggesting that BrO^{\bullet} is important during AMDEs (Raofie and Ariya, 2004). However, other studies both in the field (Wang et al., 2019a) and in the form of models (Xie et al., 2008; Ahmed et al., 2023) show that the synchronous disappearance of Hg^0 and O_3 during AMDEs can best be described solely as the action of Br atoms, with an upper limit for $k_{\text{Hg}^0 + \text{BrO}}$ of $1 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, but that the reaction product $\text{Hg}^{\text{I}}\text{Br}$ (Fig. 2) rapidly adds BrO^{\bullet} , presumably mainly to $\text{BrHg}^{\text{II}}\text{OBr}$, which is 117 kJ mol^{-1} more stable than the isomer $\text{BrHg}^{\text{II}}\text{BrO}$ (Jiao and Dibble, 2017a). Despite its thermal stability, $\text{BrHg}^{\text{II}}\text{OBr}$ is rapidly photolyzed (Figs. 2 and 4), and therefore does not constitute a significant component of the Hg^{II} pool following an AMDE.

Table 3. Atmospheric gas-phase reactions. Except where otherwise noted in the reference column, the thermodynamic data have been compiled from the following sources of information: CRC Handbook of Chemistry and Physics (Lide, 2008), Hepler and Olofsson (1975), Chemical Kinetics and Photochemical Data for Use in Atmospheric Studies (Burkholder et al., 2019), Guzman and Bozzelli (2019), Saiz-Lopez et al. (2020; 2022), Balabanov and Peterson (2003; 2004), and Shepler (2006).

⁵ The basics of gas phase kinetics have been introduced in section 3.2. Unimolecular rate coefficients are in s^{-1} (photolysis frequencies refer to excitation energies at $\lambda > 290 \text{ nm}$ calculated according to $J = \int \phi(\lambda, \text{T}) \cdot \sigma(\lambda, \text{T}) \cdot F(\lambda) d\lambda$, where ϕ is the quantum yield (≤ 1), σ is the absorption cross section ($\text{cm}^2 \text{ molecule}^{-1}$), F is the photon flux (photons $\text{cm}^2 \text{ s}^{-1}$), λ is the wavelength and T is absolute temperature), bimolecular reaction rate coefficients are in $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (expressed as a rate constant or as a coefficient with an Arrhenius or other type of temperature dependence) and three-body reactions according to Eq. 1, i.e. $k = \frac{k_0[\text{M}]}{1 + k_0[\text{M}]/k_{\infty}}$ (where $[\text{M}]$ is the number density of air molecules, k_0 ($\text{cm}^3 \text{ molecule}^{-2} \text{ s}^{-1}$) is the low-pressure limiting rate coefficient, k_{∞} ($\text{cm}^3 \text{ molecule}^{-2} \text{ s}^{-1}$) is the high-pressure limiting rate coefficient. The temperature dependence of k_0 and k_{∞} is expressed with Eq. 2.

⁶ Refers to the calculated enthalpy (0 K) or to the experimental ditto (298 K).

⁷ Equilibrium coefficient (unit: $\text{cm}^3 \text{ molecule}^{-1}$)

Hg + X• (X = Br, Cl, OH and I)

Besides bromine atoms (Br•), hydroxyl radicals (HO•) and, to lesser extent, chlorine (Cl•) and possibly iodine (I•) atoms have been
445 proposed to globally initiate the gas-phase oxidation of Hg⁰ in the ground state in the atmosphere:

The reaction rate for X = Cl (**Rxn G2**, Donohoue et al., 2005; Taylor et al., 2005) and Br (**Rxn G1**, Donohoue et al., 2006) has been determined by pulsed laser photolysis-laser induced fluorescence (PLP-LIF) for a range of pressures and temperatures. The reaction is apparently termolecular, i.e. it shows a linear dependence on pressure (M), a slightly negative temperature dependence and a
450 significant difference in deactivation efficiency with N₂ and He as third bodies (Donohoue et al., 2005). There are also several experimental static studies of the halogen atom reactions carried out at 1-atm pressure, which, with the exception of the studies by Horne et al. (1968) and Greig et al. (1970), have used the relative rate (RR) technique at room temperature (Ariya et al., 2002; Spicer et al., 2002; Sun et al., 2016; Guérette, 2011). The Hg + X• rate expression determined absolutely by Donohoue et al. over 0.26 – 0.79 atm and 243 – 293 K by the preferred PLP-LIF technique gives a rate coefficient of 5.4×10^{-13} (Donohoue et al., 2005) and 3.6
455 $\times 10^{-13}$ (Donohoue et al., 2006) cm³ molecule⁻¹ s⁻¹ at 298 K and 1-atm pressure in air for the Cl•- and Br•- reactions, respectively. Although the rate constant of the chlorine atom reaction is at STP 50% greater than that of the bromine atom reaction, the significance of the former is small in the remote troposphere, taking into account the low concentration of chlorine atoms. It should also be added that a significant increase in the apparent recombination rate coefficient of Hg + Cl• was observed in the presence of air. This result has been rationalized on the basis that secondarily formed ClO_x species may also react rapidly with Hg⁰ (Donohoue, 2008). A
460 plausible candidate is Hg + ClO₂ → •Hg^ICl + O₂ (**Rxn G8**), which is exothermic (ΔH_R = -80 kJ mol⁻¹), but the channel has not been investigated further. Byun et al. (2010) studied the Hg + ClO_x gas phase system experimentally at 130 °C. Their results in favor of a

¹⁴ Estimated value from CH₃O + NO

¹⁵ Estimated value from CH₃O + NO₂

¹⁶ refers to *singlet* Hg(OH)₂, but is 10 kJ mol⁻¹ endothermic for formation of spin-conserving *triplet* Hg(OH)₂

¹⁷ Assuming Δ_fH⁰(CH₃HgCl) = Δ_fH⁰(CH₃HgOH)

rapid reaction between $\text{Hg} + \text{ClO}^\bullet \rightarrow \text{products}$ at $1.1 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ are surprising, but they also report $\text{Hg} + \text{Cl}^\bullet \rightarrow$ products at $1.2 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and $\text{Hg} + \text{Cl}_2 \rightarrow \text{products}$ at $4.3 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, which may indicate that the results are strongly affected by surface reactions. Computational studies (Shepler et al., 2007; Goodsite et al., 2004; Goodsite et al., 2012) gave a slightly larger rate constant ($\sim 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) for the $\text{Hg} + \text{Br}^\bullet$ reaction than the absolute PLP-LIF determination at STP. On the other hand, the experimental RR studies generally give rate constants that exceed the limit obtained from theoretical calculations, suggesting complex kinetics including reactions at the reactor wall.

The reaction with $\text{X} = \text{OH}$ (**Rxn G3**) was studied with PLP-LIF using an excess of Hg^0 over $^\bullet\text{OH}$ (generated from photolysis of HNO_3 at 266 nm) without evidence for a reaction, giving an upper rate limit of ($< 1.2 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Bauer et al., 2003). The rate constant of $\text{Hg} + ^\bullet\text{OH} \rightarrow \text{products}$ determined by Sommar et al. (2001) relative to cyclohexane + $^\bullet\text{OH} \rightarrow \text{products}$ of $8.7 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ falls below this limit at 295 K and 1 atm air, as does the temperature-resolved RR study of Pal and Ariya (2004a) extrapolated to 295 K ($\sim 1 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$). External re-analysis of the Pal and Ariya (Calvert and Lindberg, 2005) and Sommar et al. (Dibble et al., 2020) data using kinetic modeling has shown that the fate of $^\bullet\text{Hg}^\text{I}\text{OH}$ under their experimental conditions is exclusively reaction with NO_2 ($^\bullet\text{Hg}^\text{I}\text{OH} + \text{NO}_2 \rightarrow \text{HOHg}^\text{II}\text{ONO}$, **Rxn G59**) rather than dissociation. The time resolution in the PLP-LIF study also allowed a lower bound estimate of the equilibrium constant $K_{\text{HgOH}} = [^\bullet\text{HgOH}]/([\text{Hg}][\text{HO}^\bullet])$ of $5 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1}$ (Bauer et al., 2003). This equilibrium constant has also been modeled by computational studies. A recent one using high-level quantum chemical calculations (Dibble et al., 2020), performed at 200 – 320 K yields a K_{HgOH} of $\sim 7 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1}$ at 298 K corresponding to a k_{13} of $9.5 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 1 atm. In contrast, Saiz-Lopez et al. (2022) arrive at a K_{HgOH} more than an order of magnitude smaller ($\sim 5 \times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1}$) at the corresponding temperature.

The kinetics of the reaction between Hg^0 and iodine atoms (by photolysis of $\text{CH}_2\text{I}_2/\text{CF}_3\text{I}$) was studied in an early work by monitoring $^\bullet\text{Hg}^\text{I}$ by absorption spectroscopy at 403 – 438 K (Greig et al., 1971), and in a later study by following the Hg^0 loss by MS at 296 K (Raofie et al., 2008). In the first study, sufficiently high $^\bullet\text{Hg}^\text{I}$ densities could not be generated to gauge a reaction, for which the rate constant is lower than that of the competing $\text{I}^\bullet + \text{I}^\bullet \xrightarrow{\text{M}} \text{I}_2$ reaction of $\sim 1 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. The latter study lacks conclusive results on $\text{Hg} + \text{I}^\bullet \xrightarrow{\text{M}} ^\bullet\text{Hg}^\text{I}$ reaction but provides a limit on the rate constant for the reaction of Hg with molecular iodine vapor ($\leq 1.3 \times 10^{-19} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$), a reaction that lacks any atmospheric significance. A rate coefficient of $4.0 \times 10^{-13} (\text{T}/298)^{-2.38} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ was calculated for $\text{Hg} + \text{I}^\bullet \xrightarrow{\text{M}} ^\bullet\text{Hg}^\text{I}$ reaction at 1 atm N_2 and T between 180 and 400 K using Rice-Ramsperger-Kassel-Markus (RRKM) theory, based on a calculated binding energy (46 kJ mol^{-1}) and molecular properties of $^\bullet\text{HgI}(\Sigma)$ (Goodsite et al., 2004).

5.1.2 Stability of $^\bullet\text{Hg}^\text{I}\text{X}$

The first step (termolecular reactions **G1 – G3**), which is exothermic, produces Hg^I radical intermediates ($^\bullet\text{Hg}^\text{I}\text{X}$), which can revert to Hg^0 both thermally and photolytically:

Photo- and thermal dissociation

The first excited electronic state of $^\bullet\text{Hg}^\text{I}\text{X}$ (designated $\text{A}^2\Pi$ for halogenated radicals) is exclusively repulsive, resulting in dissociation with visible light for wavelengths exceeding $\sim 460 \text{ nm}$, where the absorption maxima are predicted at ~ 480 , ~ 575 , ~ 650 , and $\sim 690 \text{ nm}$ for $^\bullet\text{Hg}^\text{I}\text{OH}$, $^\bullet\text{Hg}^\text{I}\text{Cl}$, $^\bullet\text{Hg}^\text{I}\text{Br}$, and $^\bullet\text{Hg}^\text{I}\text{I}$, respectively (Saiz-Lopez et al., 2019; **Fig. 3**). While the bond strengths of $\text{Hg}-\text{Cl}$ and $\text{Hg}-\text{Br}$ are well-defined in relative terms ($89.5 - 98.0 \text{ kJ mol}^{-1}$, Tellinghuisen et al., 1982; Shepler et al., 2005; Saiz-Lopez et al., 2022; Cremer et al., 2008 and $60.2 - 68.1 \text{ kJ mol}^{-1}$, Goodsite et al., 2004; Shepler et al., 2005; Cremer et al., 2008; Tellinghuisen and Ashmore, 1983, respectively), there is significant variation in the estimates of the bond strengths of $^\bullet\text{Hg}^\text{I}\text{I}$ and $^\bullet\text{Hg}^\text{I}\text{OH}$, ranging from ~ 33 to 46 kJ mol^{-1} (Goodsite et al., 2004; Shepler et al., 2005; Cremer et al., 2008; Jordan et al., 1993; Salter et al., 1986) and ~ 23 to 55 kJ mol^{-1} (Dibble et al., 2020; Tossell, 2003; Goodsite et al., 2012; Guzman and Bozzelli, 2019; Cremer et al., 2008), respectively. Therefore, the stability of $^\bullet\text{Hg}^\text{I}\text{OH}$ and $^\bullet\text{Hg}^\text{I}\text{I}$ is uncertain, and it is debatable whether their thermal lifetimes in the atmosphere are long enough for these radicals to be further oxidized to mercuric species to any significant degree. The question has been raised recently since it was experimentally established that $^\bullet\text{Hg}^\text{I}\text{Br}$ is kinetically oxidized by O_3 without a reaction barrier (**Rxn**

G22), which was also theoretically established to be true at least for $\bullet\text{Hg}^{\text{I}}\text{Cl}$ and $\bullet\text{Hg}^{\text{I}}\text{OH}$ (**Rxn G44 & G59**, respectively, **Section**
 505 **5.1.3**). A study using RRKM theory suggests that the recombination rate coefficients of Hg with I^{\bullet} and HO^{\bullet} are similar in the free
 troposphere, while the thermal dissociation of $\bullet\text{Hg}^{\text{I}}\text{I}$ gradually exceeds that of $\bullet\text{Hg}^{\text{I}}\text{OH}$ at lower temperatures (Goodsite et al., 2004).
 $\bullet\text{Hg}^{\text{I}}\text{I}$ is the $\bullet\text{Hg}^{\text{I}}\text{X}$ species with the shortest photolytic lifetime in the troposphere globally (~ 17 s), according to computational
 chemistry theory (Saiz-Lopez et al., 2019). Recently, Dibble et al. estimated the HO–Hg binding energy to be 46 kJ mol^{-1} using high-
 level quantum chemical calculations (Dibble et al., 2020). Compared to a global photolytic lifetime of just over one minute (Shah et
 510 al., 2021), the thermal lifetime of $\bullet\text{Hg}^{\text{I}}\text{OH}$ in the lower troposphere is significantly shorter (according to data from Dibble et al., 2020
 ~ 10 ms at the surface up to about ten seconds at the tropopause). For the lighter mercurous halides (i.e., excluding $\bullet\text{Hg}^{\text{I}}\text{I}$), the
 relationship is reversed with respect to the importance of photolytic versus thermal dissociation. The lifetime of the former channel
 is globally ~ 20 and ~ 40 s for $\bullet\text{Hg}^{\text{I}}\text{Br}$ and $\bullet\text{Hg}^{\text{I}}\text{Cl}$, respectively, while the thermal decay is slower for $\bullet\text{Hg}^{\text{I}}\text{Br}$ above the planetary
 boundary layer and $\bullet\text{Hg}^{\text{I}}\text{Cl}$ is much less thermally unstable.

Figure 3. Computed absorption spectra of the atmospherically important mercurous chloride, bromide, and hydroxyl radicals. Wavelengths accessible in the troposphere are to the right of the colored area. Data from Saiz-Lopez et al. (2019).

5.1.3 Bimolecular reactions of $\bullet\text{Hg}^{\text{I}}\text{X}$

In addition to thermal and photolytic decomposition, the fate of $\bullet\text{Hg}^{\text{I}}\text{X}$ in the atmosphere is controlled by further oxidation to
 520 thermally stable mercuric species molecules. Experimental studies of specific bimolecular reaction kinetics of $\bullet\text{Hg}^{\text{I}}\text{X}$ are limited to
 $\text{X} = \text{Br}$ and Cl (**Rxn G15 & G39**). Taylor et al. (2005) studied the reaction of $\bullet\text{Hg}^{\text{I}}\text{Cl}$ with Cl_2 , HCl and Cl^{\bullet} at temperatures
 characteristic of post-combustion conditions. The observed reaction with free chlorine to form HgCl_2 was rapid ($1.2 \times 10^{-11} \text{ cm}^3$
 $\text{molecule}^{-1} \text{ s}^{-1}$) and temperature independent. Jiao and Dibble (2017b) determined the rate constant and product yield for the reactions
 of $\bullet\text{Hg}^{\text{I}}\text{Br}$ with abundant atmospheric NO_2 (**Rxn G20**) and HOO^{\bullet} (**Rxn G21**) radicals using computational chemistry. Analogous to
 525 the experimental $\bullet\text{Hg}^{\text{I}}\text{Cl}$ study, these reactions were calculated to be rapid with the rate constant for oxidation by NO_2 being
 approximately twice that for oxidation by HOO^{\bullet} . This theoretical study indicated that the $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{NO}_2$ reaction occurs along two
 competing channels (**Rxn G20a, b**), one proceeding by oxidative addition resulting in $\text{BrHg}^{\text{II}}\text{ONO}$ and another operating by reductive
 displacement resulting in $\text{Hg}^0 + \text{BrNO}_2$. The dichotomy occurs depending on the fact that $\bullet\text{Hg}^{\text{I}}\text{Br}$ ($^2\Sigma^+$) possesses a delocalized
 electron that spreads more equivalent spin density over the molecule ($\bullet\text{Hg}^{\text{I}}\text{Br} \leftrightarrow \text{Hg}^{\text{I}}\text{Br}^{\bullet}$), whereas the spin density of HgOH ($^1\text{A}'$)
 530 radical is most localized on the Hg atom. Reaction with another radical center occurs for $\bullet\text{Hg}^{\text{I}}\text{OH}$ when the reactant is oriented
 towards Hg, leading to addition, while for HgBr reductive displacement is also possible when the collision involves the Br atom
 (Castro Pelaez et al., 2022). The existence of a branching ratio was also confirmed by an experimental study of $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{NO}_2$ reaction
 by Wu et al. (2020) using PLP-LIF, who found that the computed rate coefficients for both reduction and oxidation were greatly
 overestimated. This study deduced that the importance of the reductive channel increases slowly with altitude from ground level to
 535 the tropopause but is only $\sim 10\%$ as fast as the oxidation reaction. Wu et al. (2022) have also experimentally studied the interaction
 between NO and $\bullet\text{Hg}^{\text{I}}\text{Br}$, leading to $\text{Hg}^0 + \text{BrNO}$. $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_2 \rightarrow \text{BrHg}^{\text{II}}\text{OO}^{\bullet}$ (**Rxn G19**) is slightly exothermic while that leading
 to $\text{Hg}^0 + \text{BrOO}^{\bullet}$ is less feasible due to endothermicity. $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_2$ reaction is thus described by $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_2 \rightleftharpoons \text{BrHg}^{\text{II}}\text{OO}^{\bullet}$ with
 an equilibrium constant that decreases dramatically with temperature (Wu et al., 2022). To the extent that $\text{BrHg}^{\text{II}}\text{OO}^{\bullet}$ can be attributed
 significance, it is a reservoir for $\bullet\text{Hg}^{\text{I}}\text{Br}$ at low temperatures, with an upper limit of $\sim 50\%$ stored at 220 K. Wu et al. (2022) argued

that $\text{BrHg}^{\text{II}}\text{OO}^\bullet$ behaves like a peroxy radical ($\text{HOO}^\bullet/\text{ROO}^\bullet$) in reactions with atmospheric radicals. Recently, Saiz-Lopez et al. (2020) implied missing oxidation pathways to better reconcile their GEOS-Chem global atmospheric chemistry model simulations with field observations. Suggested by Shepler (2006) and later Lam (2019) as a potential pathway of Hg^{I} oxidation, the Saiz-Lopez group has carried out theoretical (Saiz-Lopez et al., 2020) and experimental (Gómez Martín et al., 2022) investigations of the system $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$. In addition, Castro Palaez et al. (2022) have carried out theoretical calculations for rate constants and product yields, including $^\bullet\text{Hg}^{\text{I}}\text{OH} + \text{O}_3$. $^\bullet\text{Hg}^{\text{I}}\text{X} + \text{O}_3 \rightarrow \text{XHg}^{\text{II}}\text{O}^\bullet + \text{O}_2$ (Rxn G22a, G43 and G59) is highly exothermic (172 kJ mol^{-1} for $\text{X} = \text{Br}$) and proceeds without a substantial activation barrier and is currently considered to be of great importance for the atmospheric oxidation of $^\bullet\text{Hg}^{\text{I}}\text{X}$, with $\text{XHg}^{\text{II}}\text{O}^\bullet$ as a key intermediate. Being a radical, $\text{XHg}^{\text{II}}\text{O}^\bullet$ is relatively thermally stable with a strong $\text{Hg}-\text{O}$ bond (333 and 294 kJ mol^{-1} for $\text{X} = \text{Cl}$ & Br , respectively, Balabanov and Peterson, 2003). Gómez Martín et al. (2022) determined the rate coefficient of the $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$ reaction at 295 K using a PLP-LIF system. To generate $^\bullet\text{Hg}^{\text{I}}\text{Br}$ (photolysis of HgBr_2 at 248 nm by a KrF excimer laser), it was inevitable that the introduced O_3 would be photolyzed to some extent before it could react with $^\bullet\text{Hg}^{\text{I}}\text{Br}$. This led to complications due to the following potential chemistry:

By performing experiments at different KrF laser energies and the ozone concentrations and by numerical modeling of the data, Gómez Martín et al. isolated $k(^\bullet\text{HgBr} + \text{O}_3)$, $k(^\bullet\text{HgBr} + \text{O})$ and $k(\text{BrHgO}^\bullet + \text{O})$ as 7.5 , 5.3 and 9.1 ($\text{all} \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$), respectively. They presented an upper limit for $\text{BrHg}^{\text{II}}\text{O}^\bullet + \text{O}_3$ ($k < 5 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$), which, however, was considered obsolete by theoretical calculations as sterically hindered. Instead of leading primarily to $\text{BrHg}^{\text{II}}\text{O}^\bullet$ as is the case for the $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$ reaction, $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}$ results in reductive elimination ($\text{Hg}^0 + \text{BrO}^\bullet$) for all collision geometries. Hg^0 is also produced in the rapid reaction between $\text{BrHg}^{\text{II}}\text{O}^\bullet + \text{O}$. In the lower atmosphere ($\leq 25 \text{ km}$), the content of free O atoms is low, and therefore, its role as an oxidant is minor (Calvert et al., 2015). The energetic $\text{O}(^1\text{D})$, formed primarily by photolysis of O_3 by UV light ($< 340 \text{ nm}$), is rapidly consumed through two competitive channels: deactivation to $\text{O}(^3\text{P})$ by collision with air molecules or reaction with the ubiquitous water vapor to form OH radicals. $\text{O}(^3\text{P})$, also formed by photolysis of NO_2 ($< 430 \text{ nm}$), reacts rapidly thermally with O_2 in the atmosphere to form ozone (Calvert et al., 2015). It is important to note that $k(^\bullet\text{HgBr} + \text{O}_3)$ is more than twice as fast as $k(^\bullet\text{HgBr} + \text{NO}_2)$ when the experimental results are extrapolated to the atmospheric surface layer (1 atm , 295 K). The combination of a high $k(^\bullet\text{HgBr} + \text{O}_3)$ and the abundance of ozone relative to other radicals such as NO_2 and HOO suggests that $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$ is of ultimate significance in the conversion of Hg^{I} to Hg^{II} in the atmosphere. The experimentally determined $k(^\bullet\text{HgBr} + \text{O}_3)$ is close to the upper limit of $1 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ estimated by Saiz-Lopez et al. (2020), which excludes steric effects. For an updated chemical mechanism in the global atmospheric model GEOS-Chem, Shah et al. (2021) used a conservative rate constant of $3 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for oxidation of $^\bullet\text{Hg}^{\text{I}}\text{X}$ with O_3 ($\text{X} = \text{Cl}$, Br and OH). By postulating $k(^\bullet\text{HgOH} + \text{O}_3) = k(^\bullet\text{HgBr} + \text{O}_3)$, simulations by Shah et al. (2021) showed that the OH -initiated pathway accounts for one-third of the global Hg^{II} production. In contrast, by not including $^\bullet\text{Hg}^{\text{I}}\text{OH} + \text{O}_3$ in their model, Dibble et al. (2020) found the OH -initiated channel to be largely irrelevant, with only some regional significance in areas with high levels of photochemical smog. More recently, however, they (Castro Palaez et al., 2022) compared $^\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$ and $^\bullet\text{Hg}^{\text{I}}\text{OH} + \text{O}_3$ systems by computational chemistry and found that the former has a slight tendency ($\leq 0.1\%$) to undergo reductive elimination ($\text{Hg} + \text{BrO}^\bullet + \text{O}_2$) rather than oxidation ($\text{BrHg}^{\text{II}}\text{O}^\bullet + \text{O}_2$) when the orientation of the terminal oxygen in ozone is towards the Br atom. There is no such tendency for $^\bullet\text{Hg}^{\text{I}}\text{OH} + \text{O}_3$. It was also found that $k(^\bullet\text{HgBr} + \text{O}_3)$ and $k(^\bullet\text{HgOH} + \text{O}_3)$ are likely to be similar with a computational value for the latter at 298 K in the range $(6.6 - 8.5) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. The positive covariation of O_3 and $^\bullet\text{OH}$, as opposed to $^\bullet\text{Br}$ and O_3 (O_3 titrates $^\bullet\text{Br}$, Fig. 2), suggests precedence for the OH -initiated Hg oxidation in air with secondary pollutants (Rutter et al., 2012). Field observations of speciated Hg in urban air speculate

radical-initiated $\text{Hg}^0 \rightarrow \text{Hg}^{\text{II}}$ gas-phase transformation, which is claimed to be completed by certain radicals (Peleg et al., 2015; Hong et al., 2016). An interesting case is urban Jerusalem with episodes of elevated daytime and nighttime gaseous Hg^{II} levels co-varying with O_3 (max $250 \mu\text{g m}^{-3}$) and NO_3 (430 ng m^{-3}), respectively (Peleg et al., 2015). To the east of the city lies the Dead Sea basin, where effective bromine-controlled oxidation of Hg^0 has been observed (Tas et al., 2012). Finally, in discussing the reactivity of $\text{Hg}^{\text{I}}\text{X}$, it can be concluded that it is low viz-à-viz volatile organic compounds in that the species neither abstracts H atoms (e.g. from CH_4) nor adds significantly to double bonds ($\text{C}=\text{C}$) (Dibble and Schwid, 2016).

5.1.4 Stability of $\text{Hg}^{\text{II}}\text{XY}$

Photoreduction and stoichiometric yields

Atmospheric Hg^{II} species are more stable than Hg^{I} species. Not all Hg^{II} molecules are stable, but the atmospheric pool contains mercuric species with different thermal and photolytic stability. Most of the atmospherically relevant gas-phase species have well-defined absorption bands in deep UV, in some cases extending into the UV-B and UV-A regions. Early theoretical studies (Strömberg et al., 1989; Strömberg et al., 1991), at a time when knowledge of the atmospheric chemistry of Hg was rudimentary, indicate that the photoreduction of HgCl_2 and $\text{Hg}(\text{CN})_2$ in actinic light at the Earth's surface is negligible, while that of $\text{Hg}(\text{OH})_2$ and $\text{Hg}(\text{SH})_2$ is extremely slow. The UV absorption spectra for mercuric halides become increasingly red-shifted as the halogen becomes heavier. HgCl_2 vapor absorbs only radiation below 240 nm (Fig. 8a), HgBr_2 absorbs mainly in the deep UV with a tiny tail ($< 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$, Fig. 8c) into UV-B, while HgI_2 has a significant absorption in the entire UV region (Maya, 1977; Sitkiewicz et al., 2019). However, binary compounds such as HgBr_2 or HgCl_2 do not completely dominate the atmospheric $\text{Hg}^{\text{II}}(\text{g})$ speciation. Mixed compounds such as $\text{BrHg}^{\text{II}}\text{Y}$ ($\text{Y} = \text{ONO}, \text{OOH}, \text{OH}, \text{OCl}, \text{OBr}$ etc.) and $\text{XHg}^{\text{II}}\text{O}^\bullet$ ($\text{X} = \text{Br}, \text{OH}$) are also predicted to be important. Saiz-Lopez et al. (2018) computed the absorption spectra of mixed compounds and found that abundant $\text{BrHg}^{\text{II}}\text{Y}$ molecules absorb in UV-B. The rapidly photolyzed Hg^{II} species identified include BrHgONO (Rxn G35), BrHgOOH (Rxn G36) and BrHgOBr (with lifetimes of a few min. to less than a second, Fig. 4a-c), with BrHgOH being comparatively long-lived (> 1 day, Fig. 4d) in terms of photodissociation. HgCl_2 and $\text{Hg}(\text{OH})_2$ were estimated to be photolytically stable in the troposphere by Shah et al. (2021) in their modeling study, while the photolysis frequency of HgBr_2 was calculated to be just over an order of magnitude lower than that of BrHgOH (1.2×10^{-6} and $1.3 \times 10^{-5} \text{ s}^{-1}$, respectively).

Figure 4. Computed absorption spectra of the atmospherically important (a) BrHgOBr , (b) BrHgOOH , (c) syn-BrHgONO and (d) BrHgOH . Wavelengths accessible in the troposphere are to the right of the colored area (Francés-Monerris et al., 2020).

The photodissociation mechanism (quantum and product yield) of $\text{BrHg}^{\text{II}}\text{Y}$ has been studied using computer-assisted theoretical calculations, with the result that photodynamics leads to different channels in which the Hg-containing products can exhibit +II, +I and 0 oxidation states (Francés-Monerris et al., 2020; Lam et al., 2019b). Photolysis of $\text{BrHg}^{\text{II}}\text{ONO}$, forms NO_2 and $\text{BrHg}^{\text{II}}\text{O}^\bullet$ in 90% of cases, while the remainder reverts to $\text{Hg}^{\text{I}}\text{Br}$ and NO_2 (Francés-Monerris et al., 2020). Consistently, a large dominance of the photoproducts $\text{BrHg}^{\text{II}}\text{O}^\bullet + \text{NO}$ was predicted by calculations of Lam et al. (2019b), in contrast to an early work by Saiz-López et al. (2018) that favors $\text{Hg}^{\text{I}}\text{Br}$ and Hg^0 formation. During the photolysis of $\text{BrHg}^{\text{II}}\text{OOH}$, the Hg-Br, Hg-O and O-O bonds can be broken,

resulting in three main exit channels:

Thus, the photodissociation of $\text{BrHg}^{\text{II}}\text{OOH}$ produces Hg^0 , $\bullet\text{Hg}^{\text{I}}\text{Br}$ and $\text{BrHg}^{\text{II}}\text{O}\bullet$ to varying degrees (Francés-Monerris et al., 2020). In the case of $\text{BrHg}^{\text{II}}\text{OH}$, the photolytic formation of $\text{BrHg}^{\text{II}}\text{O}\bullet$ is negligible, while in half of the cases (49%), reduction to elemental Hg occurs, and in the other half, $\bullet\text{Hg}^{\text{I}}\text{Br}$ or $\bullet\text{Hg}^{\text{I}}\text{OH}$ is formed, with the former being predominant (~70%) (Francés-Monerris et al., 2020). Photolysis of $\text{BrHg}^{\text{II}}\text{ONO}$ and $\text{BrHg}^{\text{II}}\text{OOH}$ thus results in significant yields of $\text{BrHg}^{\text{II}}\text{O}\bullet$, the radical form of Hg^{II} described above as the major product of the rapid reaction between $\bullet\text{Hg}^{\text{I}}\text{Br}$ and O_3 . In this series of reported compositional chemical results, it should be noted that the only $\text{YHg}^{\text{II}}\text{O}\bullet$ species that has been experimentally characterized is the fluorine analog that is formed along with $\text{FOHg}^{\text{II}}\text{F}$ when excited Hg atoms react with OF_2 (Andrews et al., 2012). Although $\text{FHg}^{\text{II}}\text{O}\bullet$ has no atmospheric significance, its experimentally determined properties are important as a benchmark for other homologs in the series. $\text{YHg}^{\text{II}}\text{O}\bullet$ has two strong bonds (the dissociation energy for $\text{YHg}-\text{O}$ is ~250 kJ mol⁻¹) and is thermally stable in gas phase. However, $\text{YHg}^{\text{II}}\text{O}\bullet$ is photolabile in UV-VIS (cf. Fig. 5) and decompose photolytically along two channels. The calculated branching ratio for both $\text{Y} = \text{Cl}$ and Br is in favor of the formation of HgO (67% and 56%, respectively, Saiz-Lopez et al., 2022) over a splitting into atoms, as shown below:

For $\text{HOHg}^{\text{II}}\text{O}\bullet$, there are no stoichiometric calculations for the photoproducts. The main product generated, HgO with a ³Π ground state, as a monomer in the gas phase (Sun et al., 2022), possesses a weak Hg-O bond of disputed magnitude (15–30 kJ mol⁻¹, Tossell, 2006; Balabanov and Peterson, 2003; Cremer et al., 2008; Filatov and Cremer, 2004; Shepler and Peterson, 2003; Peterson et al., 2007), which is only ≤ 10% as strong as in $\text{YHg}^{\text{II}}\text{O}\bullet$. HgO can be reduced to Hg^0 by reaction with O_2 and by thermal- and photodissociation:

The $\text{HgO} + \text{O}_2$ reaction is exothermic but is subject to a barrier which, using transition state theory, gives a rate coefficient of $3.4 \times 10^{-13} \exp(-1993/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Saiz-Lopez et al., 2022). The enthalpy of thermal decay of HgO is weakly endothermic and therefore favored by high temperature with a dependence of $8.4 \times 10^{-11} \exp(-3150/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ calculated by RRKM theory (Saiz-Lopez et al., 2022). In addition, HgO is more photolabile than $\bullet\text{Hg}^{\text{I}}\text{OH}$, with a calculated global annual mean $J(\text{HgO})$ of 0.54 s⁻¹ for the troposphere (Saiz-Lopez et al., 2018, absorption spectrum in Fig. 5a). Taken together, this information indicates that gas-phase HgO is highly unstable in the troposphere, but that the thermal lifetime is extended at cryogenic conditions ($T < 250 \text{ K}$) in the

Figure 5. Computed absorption spectra of (a) HgO (low lying ³Π and ¹Σ states) and (b) ClHgO radical (Saiz-Lopez et al., 2018; Saiz-Lopez et al., 2022). Wavelengths accessible in the troposphere are to the right of the colored area.

stratosphere where HgO has more abundant sources than that controlled by Hg^{II} radical species photolysis (see below). Analogous to the photolysis of Hg^I compounds, the quantum yield for the photo-dissociation of Hg^{II} compounds is assumed to be at unity.

645 **Thermochemistry of YHg^{II}O•**

Experimental data on the kinetics and mechanisms of the atmospheric chemistry of YHg^{II}O• are marginal (the reaction BrHg^{II}O• + O₃ to •Hg^IBr and O₂ has been described above, Gómez Martín et al., 2022). The computational calculations focus on BrHg^{II}O•. Dibble and colleagues (Lam et al., 2019b; Khiri et al., 2020; Lam et al., 2019a) have concluded that the bimolecular reaction with CH₄ is of primary importance for the disappearance of BrHg^{II}O•: BrHg^{II}O• + CH₄ → BrHg^{II}OH + •CH₃ (Rxn G26). Unlike •Hg^IX, BrHg^{II}O• readily abstracts hydrogen atoms from saturated hydrocarbons, overcoming a modest energy barrier with a rate expression of $4.1 \times 10^{-12} \times \exp(-856/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for BrHg^{II}O• + CH₄. Computational modeling suggests that BrHg^{II}O• mimics the OH radical in terms of reaction selectivity. In addition to that BrHg^{II}O• abstracts H from aliphatic hydrocarbons, it adds to unsaturated bonds of olefins (such as the biogenic isoprene), NO (Rxn G29) and NO₂ (Rxn G30) and interacts with CO (Rxn G27). The addition of NO produces BrHg^{II}ONO is susceptible to photolytic decomposition to predominantly BrHg^{II}O•, while the addition of NO₂ promptly produces peroxy nitrates of BrHg^{II}OONO type which are likely to be isomerized to BrHg^{II}ONO₂. Whether bromomercuric nitrate is photolabile in the troposphere is not yet known. Another source of BrHg^{II}OH is the reaction of BrHg^{II}O• with aldehydes (e.g. HCHO, Rxn G28). The pathway for the BrHg^{II}O• + HCHO reaction bifurcates into two processes leading to different products (Khiri et al., 2020). The dominant reaction is H-abstraction leading to BrHg^{II}OH and a formyl radical. The alternative route involves the addition of the oxygen atom in BrHg^{II}O• to the carbon center in HCHO to form a methoxy radical, which eliminates a hydrogen atom unimolecularly or in the presence of O₂ to form a formate salt (BrHg^{II}OCHO). Secondary chemistry initiated by O₂ after the addition of BrHg^{II}O• to a carbon double bond (such as in ethene) also involves alkoxy radicals formed after titration of the primarily formed peroxy radical by NO. The atmospheric fate of these mercuric alkoxy and alkyl peroxy radicals (with one Hg–O bond) is similar to the general characteristics of organic oxidation in the atmosphere described in detail elsewhere (Finlayson-Pitts and Pitts, 2000). However, apart from the CH₄ reaction, the interaction between BrHg^{II}O• and VOCs is considered limited in the atmosphere.

665 By analogy with •OH + CO, the reaction between BrHg^{II}O• and CO is not a simple bimolecular reaction. However, the intermediate BrHgOCO is much less stable than HOCO with respect to the release of CO₂. The very weakly bound BrHgOCO promptly dissociates in •Hg^IBr + CO₂ (Khiri et al., 2020). The above reaction is highly exothermic (> 280 kJ mol⁻¹), and therefore, the product •Hg^IBr can be chemically activated to the extent that it increasingly decomposes in atoms. The importance of this Hg reduction channel has been identified as difficult to constrain theoretically, as the shape of the potential energy surface is unfavorable for the application of standard kinetic simulation methods. Nevertheless, by using an inverse Laplace transformation method, Khiri et al. (2020) calculated the range for the rate coefficient at two temperatures: $(9.4 - 52) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 298 K and $(3.8 - 29) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 220 K. These data are the basis for the current inclusion of the reaction YBr^{II}O• + CO → •Hg^IY + CO₂ in chemical models (Shah et al., 2021; Saiz-Lopez et al., 2022) with the averaged expression of $6.0 \times 10^{-11} \times \exp(-550/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. With this numerical characterization, the YHg^{II}O• + CO reaction becomes profoundly important when implemented in simulations, as it largely counteracts the effect of the •Hg^IX + O₃ reaction, thereby extending the predicted lifetime of Hg⁰ in the troposphere. However, other candidates have emerged that, like CH₄, may react with HOHg^{II}O• to directly form very stable Hg(OH)₂ molecule, namely water vapor. The reaction HOHg^{II}O• + H₂O → Hg(OH)₂ + •OH (Rxn G60) is nearly thermoneutral due to the stability of Hg(OH)₂ ($\Delta H_f = -226 \text{ kJ mol}^{-1}$, Wang and Andrews, 2005) and Saiz-Lopes et al. (2022) give the temperature dependent rate constant expression of $5.3 \times 10^{-12} \times \exp(-2894/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ without further details. Since both the calculated HOHg^{II}O• + H₂O rate coefficient and the H₂O(g) mixing ratio vary considerably across the troposphere, the HOHg^{II}O• loss due to this channel may largely exceed or fall below the more monotonic rate of hydrogen abstraction by HOHg^{II}O• from CH₄, depending on the circumstances. The fate of HOHg^{II}O• is thus influenced by several exit channels (Edirappulige et al., 2023b), none of which have been investigated experimentally and especially the uncertainty of the CO and H₂O reaction makes it difficult to determine the importance of the OH-initiated oxidation to the atmospheric Hg^{II} pool.

685 Gas to nucleation

Oxidized Hg species have properties that make them suitable for nucleation processes, such as being ionic solids at equilibrium under atmospheric conditions, which makes them improbable to evaporate from nucleating clusters (Ariya et al., 2015). They can condense, either homogeneously or onto pre-existing nuclei of subcritical or critical size. A particle formation event associated with polar spring partial AMDE has been observed in the East Antarctic pack ice, where 3 nm particle formation lags the phase of gaseous Hg^0 loss in the air mass (Humphries et al., 2015). Observations over a decade in the Canadian High Arctic region clearly show that PBM transmitted by KCl-coated denuders dominate Hg^{II} fractionation over GOM during the early period of AMDEs, where the highest frequencies of depleted Hg^0 occur between -45 and -40 °C, while during the late period of higher temperatures and lower particulate concentrations (AMDEs then occur most frequently between -25 and -20 °C) the Hg^{II} fractionation has shifted to a clear dominance of GOM (Steffen et al., 2014). The KCl-denuder technique used cannot selectively separate nano- to submicron-sized mercuric halide clusters completely from GOM (Ghoshdastidar and Ariya, 2019), which, along with the other nonsystematic bias of the method previously mentioned, makes the separation into Hg^{II} fractions tentative. The measurement methodology deficiencies make it highly uncertain to establish empirical gas-particle partitioning schemes (Amos et al., 2012; Rutter and Schauer, 2007b, a). This complicates the assumption and verification of model parameterization, which relies on accurate atmospheric concentration measurements. For example, assuming that the release of Hg^{II} from aerosols into the gas phase is entirely in the form of the tropospherically stable HgCl_2 molecule (Shah et al., 2021). Coupling an oxidized Hg vapor source or a reactor where oxidized Hg is formed by gas phase oxidation of Hg^0 to particle characterization instruments (such as scanning mobility or optical particle sizers) provides conclusive evidence that mercuric halide molecules readily form clusters that undergo particle growth (Ghoshdastidar and Ariya, 2019). In experimental studies of the vapor-phase oxidation of the volatile Hg forms Hg^0 and $(\text{CH}_3)_2\text{Hg}$, aerosol-phase products have been detected (Raofie et al., 2008; Raofie and Ariya, 2004; Sun et al., 2016; Niki et al., 1983a; Niki et al., 1983b). For example, using a scanning mobility particle sizer, Sun et al. (2016) found that well below saturation pressure of HgX_2 , reaction products from X (Cl and Br)-initiated Hg^0 vapor oxidation began to generate particles that grew from the Aitken nuclei range (few tens of nm) into the accumulation range (> 100 nm) over the course of a few hours (**Fig. 6**). **Fig. 7** summarizes the main elements of Hg gas phase chemistry in troposphere.

Figure 6. Particle growth of reaction products (yield of $\text{HgX}_2 > \text{Hg}_2\text{X}_2$) from the halogen atom ($\text{X} = \text{Cl}, \text{Br}$). Induced oxidation of Hg^0 vapor studied after the same degree of Hg^0 conversion ($\sim 75\%$, $5-8$ ppb) but at different reaction times a and b (~ 45 min, $\text{Hg}^0 + \text{Br}$ and ~ 4 h, $\text{Hg}^0 + \text{Cl}$, respectively).

710 5.1.5 Lower stratospheric conditions

In the lower stratosphere, the chlorine atom and hydroxyl radicals initiate most of the oxidation of Hg^0 . This is because the concentrations of these species increase with altitude and the channels in which they are contained produce more photostable products such as $\text{Hg}(\text{OH})_2$ and HgCl_2 (**Fig. 8a,b**). However, the increasing photon flux as one moves up through the ozone layer increases the photolysis rate of $\text{Hg}(\text{OH})_2$ and HgCl_2 , so that the lifetime of Hg^0 above the ozone maximum extends and approaches 10 years (Saiz-Lopez et al., 2022).

Figure 7. Outline of tropospheric gas-phase Hg chemistry. Reactions of the type $\text{Hg} + \text{XO}^*$ ($\text{X} = \text{O}_2, \text{Br}$ and NO_2) directly leading to mercuric species are, for the (varying) reasons given in the text, impossible processes in the homogeneous gas phase. In the troposphere, gas phase oxidation of Hg^0 in termolecular reactions is initiated by a few radicals of which Br atoms and with some uncertainty OH radicals have the greatest importance leading to the formation of thermally and photolytically labile mercurous radical species (i.e. $\bullet\text{Hg}^{\text{I}}\text{Br}$ and $\bullet\text{Hg}^{\text{I}}\text{OH}$). These Hg^{I} species are further oxidized to Hg^{II} by the action of mainly ozone but also by abundant inorganic radicals such as NO_2 , HOO^{\bullet} , BrO^{\bullet} , OH^{\bullet} etc. It should be noted that NO_x (NO and to a lesser extent NO_2) cannot efficiently oxidize Hg^{I} to Hg^{II} but instead induce thermal reduction, e.g. $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{NO} \rightarrow \text{Hg} + \text{BrNO}$. As O_3 is a closed shell species, it directly oxidizes $\bullet\text{Hg}^{\text{I}}\text{Br}/\bullet\text{Hg}^{\text{I}}\text{OH}$ to mercuric radical species $\text{YHg}^{\text{II}}\text{O}^{\bullet}$ while for example HOO^{\bullet} and BrO^{\bullet} are added to linear mercuric molecules (e.g. $\text{BrHg}^{\text{II}}\text{OOH}$) that are photolytically labile while those resulting from e.g. NO_2 , $\bullet\text{OH}$ and Br^{\bullet} are more photostable. The photolysis of many of the major thermally more stable Hg^{II} species such as $\text{syn-BrHg}^{\text{II}}\text{ONO}$, $\text{BrHg}^{\text{II}}\text{OOH}$ and $\text{BrHg}^{\text{II}}\text{OH}$ leads as shown to several species-specific photoproducts (potentially Hg^0 , Hg^{I} species or $\text{YHg}^{\text{II}}\text{O}^{\bullet}$) with various yields (Table 3). The remarkably thermally stable YHgO radical exhibits versatile thermochemistry, such as abstracting hydrogen from VOCs, adding to double bonds and being reduced by CO. Some of its bimolecular reactions, such as with CH_4 and NO_2 , directly form fairly stable Hg^{II} compounds such as $\text{Hg}(\text{OH})_2$, $\text{BrHg}^{\text{II}}\text{OH}$ and $\text{YHg}^{\text{II}}\text{ONO}_2$. When these encounter hydrometeors, they dissolve and are re-specified by rapid equilibrations with major aqueous ligands. This leads to the formation of strong complexes, e.g. by Cl^- to chloromercurates HgCl_2 , HgCl_3^- and HgCl_4^{2-} . Thus, molecular HgCl_2 is released into the gas phase when the particle dries up. HgCl_2 is completely photostable and is enriched in the troposphere (a major Hg^{II} species) with dry and wet deposition as the only sink processes.

5.1.6 Reactions of electronically excited state Hg^0

The presence of UVC radiation above the ozone layer maximum opens completely new reaction pathways for redox cycling of stratospheric Hg. New insights into its conceptual stratospheric chemistry (Saiz-Lopez et al., 2022; 2025) and the associated anomalous isotope fractionation (Sun et al., 2022; Fu et al., 2021) have been presented. The gas-phase oxidation of Hg^0 is rapid (10^3 – 10^4 times faster than in the troposphere, Saiz-Lopez et al., 2022) and is entirely driven by the oxidation of electronically excited Hg atoms by one of the major constituents of air, O_2 .

$\text{Hg}^0(^3\text{P})$ reaction with molecular oxygen

Already involved in the discovery of the element oxygen towards the end of the 18th century, the chemistry of the system $\text{Hg} + \text{O}_2$ exhibits intricate complexity. These early observations, made independently in northern and western Europe, address an important aspect of the thermochemistry of the system. A direct combination of liquid Hg and O_2 occurs just below the boiling point of Hg to form HgO , but the reaction is reversed above 400 °C. While the reaction of ground-state Hg vapor ($\text{Hg}(^1\text{S})$) with O_2 is negligibly slow (Hall et al., 1995), deep UV light excitation of singlet to triplet Hg atoms ($\text{Hg}(^3\text{P})$) leads to significant homogeneous reactions with O_2 . In contrast, excitation of $\text{Hg}(^1\text{P}_1)$ further out in the blue and subsequent reaction with O_2 , as discussed above, is unlikely to result in the net formation of mercury oxides. The gas-phase reactions of $\text{Hg}(^3\text{P})$ have been studied in the laboratory since 1922

(Cario and Franck, 1922). In particular, those with O₂/air as a route to ozone synthesis since the mid-1920s (Dickinson and Sherrill, 1926). While larger quantities of ozone are produced by Hg photochemistry (photo-sensitization), the elemental vapor is oxidized more slowly, resulting in the deposition of a yellow-brown film of solid HgO on the reactor walls downstream of the irradiation zone (Volman, 1953). However, the Hg(³P) + O₂ mechanism is still unelaborated due to the controversy regarding the molecular intermediates and whether there is a direct route from Hg(³P) to gaseous HgO or the oxidation starts from the Hg(¹S) state remains undetermined (Callear et al., 1959; Volman, 1953; Hippler et al., 1978; Morand and Nief, 1968). A dark homogeneous reaction Hg(¹S) + O₃ → HgO + O, supported by early researchers (Callear et al., 1959; Volman, 1953; Pertel and Gunning, 1959) as driving the oxidation in the photochemical experiments can now be rejected for the reasons discussed above in **Section 5.1.1**. In any case, considering more recent results (Wang and Andrews, 2005; Hall, 1995), e.g., obtained by refined computational chemistry, the following mechanism seems to be the most plausible:

The photoexcitation (**Rxn G4**) has already been discussed, but its reverse (**Rxn G9**), i.e. the spontaneous emission of a photon that brings Hg(³P₁) to the ground state, is spin-forbidden and the radiative lifetime is relatively long (0.12 μs corresponding to k = 8.4 × 10⁶ s⁻¹). The quenching of Hg(³P) (i. e. **Rxn G6 & G10 – G12a**) for a number of gases has been carefully studied, with Hg(³P₁) atoms being 21.3 kJ mol⁻¹ more energetic than Hg(³P₀) atoms. The two main constituents of air play different roles in the quenching process, with N₂ almost exclusively deactivating Hg(³P₁) to Hg(³P₀) with k_{G10} = 5.1 × 10⁻¹¹ exp(-701/T) cm³ molecule⁻¹ s⁻¹, while O₂ quenches both Hg(³P₁) and Hg(³P₀) directly to Hg(¹S₀) with k_{G12a} and k_{G11} of 1.3 × 10⁻¹⁰ (T/300)^{-0.29} and 1.8 × 10⁻¹⁰ (T/300)^{0.167} cm³ molecule⁻¹ s⁻¹, respectively. In the stratosphere (T = 240 K), the ratio k_{G12a}/k_{G10} is ~50 suggesting that O₂ is a much better physical quencher than N₂, which is true throughout the atmosphere. Of primary interest here, however, is the spin-conserving **Rxn G12b**, which allows the oxidation of Hg, and is overall nearly thermoneutral (exothermic by ~6 kJ mol⁻¹), yielding HgO (³Π) with low vibrational energy, as noted by Saiz-Lopez et al. (2022), which is important for increasing the lifetime of this weakly bound molecule. First tentatively identified as an intermediate in a low-temperature UVC-irradiated matrix consisting of Hg, O₂ and H₂ yielding discrete Hg(OH)₂ molecules (Wang and Andrews, 2005), linear OHg¹¹O as the initial product is calculated to be 275 kJ mol⁻¹ less energetic than the reactants Hg(³P) + O₂ and therefore sufficiently stable over time to participate in barrier rearrangement to Hg(¹S) + O₂* alongside with dissociation to HgO and O. Experimental data suggest that the branching ratio between **Rxn G12b** and **G12a** is low, making oxidation the minor process. Sun et al. observed a quantum yield of up to a few % for the oxidation step in experiments using synthetic air at 46 – 88 kPa and 233 – 298 K (Sun et al., 2022). Callear et al. (1959) observed a faster reaction in air than in O₂, suggesting that Hg(³P₀) may also react with O₂ to form HgO, analogous to Hg(³P₁).

Figure 8. Computational absorption spectra of HgCl₂, Hg(OH)₂ and HgBr₂. Data from Saiz-Lopez et al. (2022) and Sitkiewicz et al. (2019).

Chemical turnover of HgO in the stratosphere. Formation of HgCl₂

The instability of the HgO molecule and its unimolecular decay to elemental Hg has been discussed earlier. Produced in larger quantities by the rapid photosensitized but nearly thermoneutral oxidation, the initially vibrational cold stratospheric HgO is more

likely to survive in the colder part of the upper stratosphere until it can react further into less unstable oxidized forms. The most abundant trace gases in this part of the stratosphere are water vapor, hydrochloric acid and ozone (Calvert et al., 2015). H₂O can oxidize Hg(³P) (Gunning and Strausz, 1963; Gruss et al., 2017) and may react with HgO:

However, the reaction $\text{Hg}(\text{}^3\text{P}) + \text{H}_2\text{O}$ is so exothermic ($\sim 200 \text{ kJ mol}^{-1}$) that the product $\text{}^*\text{Hg}^{\text{I}}\text{OH}$ can be expected to be vibrational hot and dissociate rapidly with less time for further bimolecular oxidation. A possible reaction between water vapor and HgO is strongly exothermic if the final product is singlet $\text{Hg}(\text{OH})_2$ but weakly endothermic if the triplet form is formed instead. Nevertheless, there is currently no evidence to suggest that HgO can be converted to $\text{Hg}(\text{OH})_2$ in a direct reaction with moisture. According to Saiz-Lopez et al. (2022), the reaction between stratospheric HgO and HCl is fast enough (close to the collision limit) to allow some Hg^{II} to be converted to $\text{}^*\text{Hg}^{\text{I}}\text{Cl}$ rather than being reduced to elemental vapor:

As with $\text{}^*\text{Hg}^{\text{I}}\text{OH}$ and $\text{}^*\text{Hg}^{\text{I}}\text{Br}$, the reaction between $\text{}^*\text{Hg}^{\text{I}}\text{Cl}$ and O₃ is barrierless and rapid, in this case producing ClHg^{II}O[•]:

Of the versatile tropospheric chemistry presented for YHg^{II}O[•], hydrogen abstraction (Rxn G44) is still important in the stratosphere, which is again dominated by CH₄ (which is not photolyzed and remains the reaction with the OH radical as the main sink). The product ClHg^{II}OH, like ClHg^{II}O[•], is further converted by reaction with HCl to HgCl₂ (Rxn G46 & G47), which is the most thermally and photolytically stable of the Hg^{II} molecules present. The photolytic lifetime of HgCl₂ in the upper stratosphere is close to one hour and about twice that of Hg⁰, so the oxidized Hg species dominate (of which $\geq 90\%$ is HgCl₂). From insignificant, the Hg^I concentration rises rapidly above 50 km with the increasing UVC photon flux, so the ratio $\text{}^*\text{Hg}^{\text{I}}\text{Cl}/\text{Hg}^{\text{II}}\text{Cl}_2$ approaches unity at 60 km. An overview of the gas-phase Hg chemistry in the upper stratospheric is given in Fig. 9 below.

Figure 9. At about 35 km, the stratosphere begins to contain actinic radiation, which can electronically excite Hg (at 253.7 nm), but below this it is absorbed by O₃ in the Hartley bands (with a maximum at 254 nm). Electronically excited Hg⁰ reacts primarily with O₂, with one of the exit channels leading to the formation of HgO via the intermediate OHg^{II}O. Before HgO can fully decay into the elements, it reacts further via secondary HCl-driven fast chemistry to

HgCl₂, the major constituent of Hg in the mid-upper stratosphere. A 2:1 steady state between HgCl₂ and Hg⁰ occurs because the former photo dissociates more slowly than photosensitized Hg oxidizes, both at significant rates.

810 5.2 Organic species

5.2.1 Dimethylmercury

In addition to Hg⁰, the “supertoxic” DMHg is another volatile Hg species that exists in nature, namely DMHg classified as a ‘supertoxic’ chemical (Siegler et al., 1999). In fact, DMHg has a boiling point below 100 °C, a high vapor pressure and a Henry's Law constant equivalent to Hg⁰ (Schroeder and Munthe, 1998). Both DMHg and MMHg⁺ species have been detected in ambient air
 815 (Lee et al., 2003; Bloom et al., 2005; Weiss-Penzias et al., 2018; Baya et al., 2015; Zhang et al., 2019a). DMHg has no known sources in the atmosphere. Its occurrence is mainly due to volatilization from surface waters where it is transported by upwelling conditions from the deep sea where it is formed under anoxic conditions (Conaway et al., 2009; Pongratz and Heumann, 1999). Polar sea ice harbors Hg-methylating microbes and is thought to be a source of DMHg that can be degassed as the ice melts (Schartup et al., 2020). Recently, DMHg has been automatically measured in marine air and corresponding surface water and shows an air-sea gas flux that
 820 is 1/30 of the magnitude of the simultaneously measured Hg⁰ flux (He et al., 2022). The atmospheric transformation of DMHg is the main source of atmospheric MMHg⁺ species (Sommar et al., 1997). DMHg vapor does not absorb actinic light (Terenin, 1934; Terenin and Prileshajewa, 1935) and is, therefore, not photolyzed in the planetary boundary layer, where it is only expected to be found (Sommar et al., 1996). DMHg appears to be prone to rapid gas phase transformation and, depending on the products formed, could be an important source of atmospheric MMHg⁺ on a regional scale. However, in addition to MMHg⁺ species (Niki et al., 1983a; Niki et al., 1983b), inorganic Hg compounds (Thomsen and Egsgaard, 1986; Sommar et al., 1997) have also been reported as products of radical reactions with DMHg. Aware of its acute toxicity (Siegler et al., 1999), it has been more than a quarter of a century since any laboratory kinetic and reaction mechanistic studies of the atmospheric gas-phase chemistry of DMHg have been reported and, in retrospect, some comments are worth making. There are three thermodynamically accessible bimolecular pathways that potentially can initiate the gas phase transformation of DMHg, where X• below denotes a radical oxidant:

The existence of the CH₃Hg radical formed in the latter reaction was tentatively demonstrated in a matrix isolation study (Snelson, 1970). The small dissociation energy of the methylmercury bond of the radical (Kominar and Price, 1969) together with a predicted barrierless CH₃Hg• → •CH₃ + Hg reaction (Kallend and Purnell, 1964) suggest a rapid decomposition to metallic Hg without time for e.g. reaction with O₂ to form a methylmercury peroxy radical (CH₃HgOO•). In contrast, a composite reaction such as
 835 CH₃HgCH₃ + X• → •Hg^IX + 2 CH₃• directly producing inorganic Hg are endothermic and, therefore, less plausible. In a high-pressure study of the gas phase reaction between atomic F and DMHg, of low atmospheric relevance, it was reported that ~10% of the reacted DMHg is converted to CH₃F via the above substitution reaction (McKeown et al., 1983). However, a static FT-IR study of the Cl-initiated gas-phase reaction in the presence and absence of O₂ at atmospheric pressure shows the importance of the displacement reaction that generates CH₃HgCl. The remaining CH₃ group is converted to CH₃Cl in N₂ as a bath gas in a chain reaction
 840 that regenerates Cl atoms, while the end-products of the group in air can be attributed to the self-reaction of the CH₃OO radical. The reaction CH₃HgCH₃ + •OH studied with the same static method by photolysis of a mixture of CH₃HgCH₃, ethyl nitrite, and NO in air, also primarily follows the displacement reaction. The rate constant of ~2 × 10⁻¹¹ cm³ molecule⁻¹ s⁻¹ indicates that the lifetime of DMHg in the planetary boundary layer with respect to the OH channel active during the day is a few up to tens of hours. In the nocturnally active DMHg + NO₃• reaction, studied by fast flow discharge technique with Hg/CI-MS detection (Sommar et al., 1996)
 845 and by a static long path FT-IR system (Sommar et al., 1997), both CH₃ groups contained in DMHg are accounted to react. A small but significant yield of Hg⁰ was detected along with a product with m/z = 78 (CH₃ONO₂) after the reaction of DMHg and NO₃• under fast flow discharge conditions, indicating that substitution has occurred. Assessment of the stability of HgO (Shepler and Peterson, 2003) suggests that although the quantitative carbon balances for non-Hg-containing reaction products are close to unity for both the

described by the Arrhenius expression $3.2 \times 10^{-11} \times \exp[-(1760 \pm 400)/T]$ cm³ molecule⁻¹ s⁻¹ and the reaction is fast enough to put the lifetime of DMHg during the night in the same time range as for •OH initiated degradation during the day (Sommar et al., 1997). To summarize this section, the degradation of DMHg in the atmosphere has been illustrated in **Fig. 10**.

Figure 10. Schematics of the atmospheric destiny of DMHg. The fate of HgO indicated is uncertain.

860 5.2.2 Monomethylmercury species

Although there is a lack of experimental data, gaseous MMHg^+ species are expected to react with atmospheric radicals, which leads to demethylation similar to the process that occurs when in the reaction of CH_3HgCH_3 and OH/Cl radicals. However, it is probable that the rate constant is lower, and the uptake of particles is of greater significance for the atmospheric fate of MMHg^+ species.

6. Red-ox transformations in the aqueous phase

865 **6.1 Inorganic Hg species**

870 treated separately as chemical equilibria. The aqueous speciation of Hg^{II} , where pH is often a critical parameter, is of great importance for the reaction kinetics, not least for the reduction pathways. Thus, it appears that aerobic reduction pathways in principle require the formation of specific complexes, since Hg^0 cannot be formed from Hg^{2+} by successive bimolecular (single-electron) reduction steps, since dissolved O_2 instantaneously reoxidizes $\text{Hg}^{\bullet+}$:

875 The overall forward rate constant for **Rxn W11** is at the diffusion limit ($k \sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$, Nazhat and Asmus, 1973). In contrast, Hg^0 can be formed by fragmentation of a ligand bound to Hg^{II} (reductive elimination, van Loon et al., 2000). Such photo- or thermolabile

Hg^{II} complexes are characterized by low-energy ligand-to-metal charge transfer (LMCT) excited states, which tend to induce internal redox processes leading to oxidation of a ligand and reduction of the mercuric ion. There is evidence that Hg²⁺ complexes can undergo both one- and two-electron LMCT. An example is mercuric oxalate, where 2e-LMCT is photoinduced and occurs as part of a
880 concerted series of electron rearrangements (heterolytic cleavage of σ-bonds in the complex), resulting in the oxalate ligand being eliminated as two molecules of CO₂ and the oxidation state of the metal ion decreasing by two units. This mechanism occurs without any detectable intermediates such as free radicals:

As described in **Section 8**, 1e- and 2e-LMCT reactions produce isotopic effects, the specific fractionation of which can be used to identify the reaction mechanism. In addition to the quenching of triplet complex states, the presence of dissolved O₂ leads to the
885 scavenging of radicals such as Hg^{•+} produced by the 1e-LMCT mechanism, resulting in reoxidation to Hg²⁺ (**Rxn W11**, Zhao et al., 2021). As has been previously noted (Pehkonen and Lin, 1998), in certain laboratory experiments, such as reduction experiments, sufficiently elevated Hg concentrations are employed such that the Hg⁰ formed exceeds its solubility, thereby existing predominantly as a colloidal form. **Table 4** below outlines the potentially significant redox reactions occurring in the aqueous phase, which are then elaborated upon in the subsequent text.

890 **Table 4.** Aqueous phase redox chemistry

6.1.1 Oxidation channels

The mass transfer (diffusion) of gas-phase Hg⁰ into typical size regimes of aerosols (radius of 0.1 – 10 μm) does not limit the rate of aqueous Hg⁰ oxidation. The concentration of dissolved Hg⁰ in the droplet is at a steady state governed by Henry's Law (Lin and Pekkonen, 1998a).

895 Elemental mercury

Inorganic oxidants

Rxn W1. Ozone (O₃)

The presence of O₃ in atmospheric water is mainly from the scavenging of gaseous O₃ (Henry's constant = 0.013 M atm⁻¹ at 298 K). An early study of the oxidation of Hg⁰ by O₃ in the aqueous phase was carried out by Iverfeldt and Lindqvist (1986) using a flowing system in which 70–200 ppb O₃ was introduced. Their results suggested a conversion rate of 1–4% h⁻¹ when applied to atmospheric conditions. Munthe and co-worker (Mcelroy and Munthe, 1991; Munthe, 1992) studied the ozone reaction with mercurous cation in acidic solution (pH = 1–3) in a stopped-flow system and with elemental Hg using the relative rate technique (sulfite as reference

²⁷ Methyl viologen as reference. Reduction of O₂ by e_{aq}⁻ (pulse radiolysis). Determination of K = 2.5 for WO8/WR4 and using WO8 for calculating WR4.

²⁸ Dithizone colorimetric quantification of Hg⁰ decay. HO₂[•] produced by C₂O₄²⁻ photolysis with air bubbling. [HO₂[•]] estimated from production of H₂O₂.

²⁹ After analytically determining the initial Hg⁰ concentration, the reduction process was studied by measuring the production of Hg⁰ by CV-AFS.

³⁰ The oxalate ion (C₂O₄²⁻) was identified as the sole reducing agent (complexing ligand), hence k = k_{obs}/[C₂O₄²⁻].

³¹ Based on the total concentration, the second-order rate coefficient is expressed as k = k_{obs}/([H₂C₂O₄] + [HC₂O₄⁻] + [C₂O₄²⁻]).

³² AQDS is not the reductant rather photohydroxylated reduced AQDS forms.

compound, pH 5.2 - 6.2) and obtained pH-independent rate constants of $(9.2 \pm 0.9) \times 10^6$ and $(4.7 \pm 2.2) \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively.

Rxn W2. Hydroxyl radical ($\bullet\text{OH}$)

905 The OH radical in atmospheric water can come from the air (equilibrium at 30 M atm^{-1}) or from aqueous phase production via pathways including photolysis of H_2O_2 , HONO, O_3 and NO_3^- (Finlayson-Pitts and Pitts, 2000). The reaction rate of $\text{Hg}^0 + \bullet\text{OH}$ in the aqueous phase was determined by Lin and Pehkonen (1997) using a steady-state technique with photolysis of NO_3^- as $\bullet\text{OH}$ source and C_6H_6 as $\bullet\text{OH}$ scavenger to $2.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at pH 5.6 – 5.9. Like the first step ($\text{Hg}^0 + \bullet\text{OH} \rightarrow \bullet\text{Hg}^+\text{OH}$), the second step mediated by dissolved O_2 (reaction 6) is near the diffusion limit. Gårdfeldt et al. (2001) later studied the same reaction at pH 7.9, but with the
 910 reaction between CH_3Hg^+ and $\bullet\text{OH}$ as a reference, but with similar results ($2.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$).

Rxn W3. Carbonate radical ($\text{CO}_3^{\bullet-}$)

In water, the carbonate system (HCO_3^- and CO_3^{2-}) can react with OH radicals to form the strongly oxidizing carbonate radical ($\text{CO}_3^{\bullet-}$) in fast reactions (8.5×10^6 and $3.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, respectively). In a comparative study, He et al. (2014) studied the disappearance of Hg^0 in aqueous solutions where NO_3^- was photolyzed in UV-VIS in the absence and presence of CO_3^{2-} at pH = 8. When both NO_3^- (0.23
 915 mM) and CO_3^{2-} (2.75 mM) were present in the irradiated solutions (electron paramagnetic resonance spin trapping analysis detected the presence of $\bullet\text{OH}$ and $\text{CO}_3^{\bullet-}$), the rate of oxidation of $\text{Hg}^0(\text{aq})$ (1.44 h^{-1}) was 8 times faster than that observed when only NO_3^- (which produces $\bullet\text{OH}$) was irradiated. The carbonate radical is a single-electron oxidant and reacts according to: $\text{Hg}^0 + \text{CO}_3^{\bullet-} \rightarrow \text{Hg}^{\bullet+} + \text{CO}_3^{2-}$. In addition to identifying the carbonate radical as an effective oxidant of Hg^0 dissolved in water alongside the hydroxyl radical, the study also investigated the role of $^1\Delta_g \text{O}_2$ (singlet oxygen) as an oxidant for $\text{Hg}^0(\text{aq})$. However, the latter species, an excited state of O_2 , does
 920 not initiate any measurable oxidation. It should also be noted that the absolute rate constant for $\text{Hg}^0 + \text{CO}_3^{\bullet-}$ remains to be determined.

Rxn W4. Aqueous chlorine (HOCl/ClO^-)

Aqueous chlorine is mainly formed by the scavenging of gaseous Cl_2 (Henry's constant = $7.61 \times 10^{-2} \text{ M atm}^{-1}$ at 298 K) into the aqueous phase and the oxidation of the chloride ion by $\bullet\text{OH}$. Once incorporated into the aqueous phase, it dissociates to form HOCl/OCl^- ($\text{pK}_a = 7.5$) and Cl^- , the former being the primary oxidants and increasing the solubility of total chlorine. It is a nocturnal oxidant as both Cl_2
 925 and HOCl are readily photolyzed by solar radiation. The prospects for Hg^0 oxidation by aqueous chlorine were investigated by Kobayashi (1987) and Munthe and McElroy (1992). In the former, rapid dissolution of Hg was reported when a gas stream containing Hg^0 was passed through a solution containing dissolved chlorine (HClO), while in the latter, $\text{Hg}_2^{2+}(\text{aq})$ was used as a proxy for Hg^0 , whose oxidation was observed to be "relatively fast" in a solution containing HClO . A detailed kinetic study (Lin and Pehkonen, 1998b) of the reaction between Hg^0 and HClO/ClO^- was carried out using a steady-state method with chloramine as a reservoir of free hypochlorous
 930 acid formed by hydrolysis: $\text{NH}_2\text{Cl} + \text{H}_2\text{O} \rightarrow \text{NH}_3 + \text{HClO}$. The turnover of Hg^0 was studied in the pH range 6.5 - 8.5 around $\text{pK}_a(\text{HClO})$ to investigate the influence of $\text{HClO}(\text{aq})$ and $\text{ClO}^-(\text{aq})$, which were found to be closely equivalent according to the rate constants for $\text{Hg}^0 + \text{HClO}$ and $\text{Hg}^0 + \text{ClO}^-$ of $(2.09 \pm 0.06) \times 10^6$ and $(1.99 \pm 0.06) \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, respectively. The products of both reactions (2 electrons are transferred) are chloride and hydroxide anions with a stoichiometry of 1:1 together with a mercuric cation which rapidly forms a strong complex ($\log\beta_{11} = 18.0$).

935 Rxn W5. Aqueous bromine ($\text{HOBr}/\text{BrO}^-/\text{Br}_2$)

Bromine has a higher Henry's constant (0.725 atm M^{-1}) than chlorine, but the disproportionation of Br_2 to HBrO/BrO^- ($\text{pK}_a = 8.7$) and Br^- is slow and the equilibrium is shifted in favor of Br_2 . In contrast, $\text{Br}^{\cdot-}$ is formed by the action of O_3 on bromide ions and exists in the presence of Cl^- largely as BrCl (Liu and Margerum, 2001). Aqueous bromine (Br_2 , HOBr) oxidizes Hg^0 only slowly ($0.2 - 0.3 \text{ M}^{-1} \text{ s}^{-1}$, Wang and Pehkonen, 2004). However, BrCl is likely important as it is used as an oxidant for Hg in current analytical
 940 methods, although the kinetics have not been investigated.

Organic oxidants

Rxn W6. Peroxides

H_2O_2 cannot oxidize $\text{Hg}^0(\text{aq})$ itself (Kobayashi, 1987), but participates in the metal-catalyzed oxidation of Hg^0 as in the Fenton's system. The Fenton's reagent itself $\text{Fe}^{2+} + \text{H}_2\text{O}_2$ produces OH radicals for which Hg^0 , Fe^{2+} and H_2O_2 are in competition for oxidation.

945 The latter reaction, $\text{H}_2\text{O}_2 + \bullet\text{OH}$, produces the HO_2 radical which propagates a chain reaction (Fenton's reaction) supported by Fe^{3+} acting as a catalyst to decompose H_2O_2 to O_2 and H_2O , during which a stable concentration of Fe^{2+} is produced as a source of $\bullet\text{OH}$. Hg^0 oxidation is most pronounced when the ferrous part of the Fenton reaction dominates over the ferric part, corresponding to a higher concentration of OH radicals (Liu, 2011). The -OOH functional group in organic hydroperoxides, like that in hydrogen peroxide, lacks the ability to oxidize Hg^0 , whereas that in peroxocarboxylic acids (peracetic and perbenzoic acid) seems to possess
 950 it, tentatively forming a mercuric carboxylate by a cyclic mechanism (Wigfield and Perkins, 1985b; Wigfield and Perkins, 1985a).

Rxn W7. Thiocarboxylic acids

Thiol compounds, as substituted carboxylic acids including cysteine and glutathione, can oxidize $\text{Hg}^0(\text{aq})$ both thermally under anoxic conditions (Gu et al., 2011). For example, Zheng et al. (2013) observed that 2-sulphonylpropanoic acid in greater excess (1000:1) oxidized Hg^0 at a rate of $2.18 \pm 0.13 \text{ h}^{-1}$. The presence of an electron acceptor (such as quinones) further enhanced the
 955 reaction rate. The reaction mechanism has been described as oxidative complexation. Hg^0 , which is polarizable, interacts with a thiol group, leading to ligand-induced oxidative complexation in which the hydrogen participates in charge transfer (Cohen-Atiya and Mandler, 2003).

Mercurous radical species ($\bullet\text{Hg}^{\text{I}}\text{X}$)

Inorganic oxidants

960 Rxn W11. Oxygen (O_2)

The reaction between Hg^{*+} and O_2 has been studied for a variety of ligands and over a range of pH values well into the alkaline range using pulse radiolysis with a homogeneous kinetic result (Nazhat and Asmus, 1973; Jungbluth et al., 1976; Fujita et al., 1975; Fujita et al., 1973; Liu et al., 1983; Pikaev et al., 1975). Mercurous species are formed by the reduction of corresponding mercuric species by the action of solvated electrons and H atoms derived from H_2O radiolysis: $\text{HgX}_2 + \text{e}_{\text{aq}}^- \rightarrow \bullet\text{Hg}^{\text{I}}\text{X} + \text{X}^-$ and $\text{HgX}_2 + \text{H}^\bullet \rightarrow \bullet\text{Hg}^{\text{I}}\text{X} + \text{H}^+ + \text{X}^-$.
 965 All types of $\bullet\text{Hg}^{\text{I}}\text{X}$ species react rapidly ($\geq 1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) with O_2 (aq): $\text{Hg}^{*+} + \text{O}_2 \rightleftharpoons \bullet\text{OOHg}^+ \rightleftharpoons \text{Hg}^{2+} + \text{O}_2^{\bullet-}$, where the equilibrium is very strongly shifted to the right. In one case ($\text{X} = \text{CN}$, Jungbluth et al., 1976) the reaction takes place without clear formation of a peroxy radical intermediate. In an air-saturated solution ($\sim 0.2 \text{ mM O}_2$), the lifetime of $\bullet\text{Hg}^{\text{I}}\text{X}$ is about $1 \mu\text{s}$ (Jungbluth et al., 1976).

Organic oxidants

Rxn W12. Quinones

970 Both Hg^{*+} and $\bullet\text{OOHg}^+$ are rapidly oxidized by benzoquinone ($\geq 10^9$ and $\lesssim 10^9 \text{ M}^{-1} \text{ s}^{-1}$, Jungbluth et al., 1976), which accepts an electron to form a semiquinone anion. Lalonde et al. (2001) observed that Hg^0 is oxidized ($\sim 0.6 \text{ h}^{-1}$) in UVB-irradiated aqueous solutions containing both benzoquinone (32 nM) and chloride ions (0.5 M), without being able to fix the mechanism.

6.1.2 Reduction channels

Mercuric compounds (Hg^{II})

975 Inorganic reductants

Rxn W13. Sulfite (SO_3^{2-})

SO_2 dissolves in water (Henry's constant 1.36 M atm^{-1}) to form the weak acid $\text{H}_2\text{SO}_3(\text{aq})$, which can be deprotonated to HSO_3^- and SO_3^{2-} . Oxidation of sulfite to sulfate is rapid in the atmosphere, taking a few hours under typical oxygenated conditions in atmospheric droplets. SO_3^{2-} is a soft ligand that forms strong complexes with Hg^{2+} (Table 1), such as HgSO_3 and $[\text{Hg}(\text{SO}_3)_2]^{2-}$, the latter completely
 980 dominating under natural conditions where the sulfite content greatly exceeds that of Hg^{2+} . The reduction of aqueous Hg^{II} by the sulfite system was first investigated by Munthe et al. (1991). $[\text{Hg}(\text{SO}_3)_2]^{2-}$ is stable, whereas HgSO_3 decomposes readily to Hg^0 and sulfate with first order rate constants of $<10^{-4} \text{ s}^{-1}$ and 0.6 s^{-1} , respectively. Scott and co-workers (van Loon et al., 2001, 2000) carried out a thorough re-examination and confirmed that the bis-sulfite complex is not thermally unstable, but that the reduction of HgSO_3 , which is strongly temperature dependent (k approximately quadruples with each 10°C increase in temperature) and weakly pH dependent, is more than
 985 50 times slower than reported by Munthe et al. (0.011 vs. 0.6 s^{-1} at 25°C). The reaction mechanism is intramolecular with 2e^- -LMCT and heterolytic cleavage of the Hg-S bond: $\text{Hg}^{2+} + \text{SO}_3^{2-} \rightarrow \text{Hg}^{\text{II}}\text{S}^{\text{IV}}\text{O}_3 \rightarrow \text{Hg}^0\text{S}^{\text{VI}}\text{O}_3 \xrightarrow{\text{H}_2\text{O}} \text{Hg}^0 + \text{SO}_4^{2-}$.

Rxn W14. Carbon dioxide anion radical ($\text{CO}_2^{\bullet-}$)

The carbon dioxide radical ($\text{CO}_2^{\bullet-}$) can be formed in nature by the oxidation of carboxylic acids (see above under oxalic acid). It is strongly reducing and occurs in anaerobic environments. Berkovic et al. (2010) studied the $\text{CO}_2^{\bullet-}$ -mediated reduction of Hg^{2+} at low pH by laser flash photolysis of a dilute mixture of HgCl_2 , formic acid and sodium peroxydisulfate at 266 nm. The one-electron reaction $\text{Hg}^{2+} + \text{CO}_2^{\bullet-} \rightarrow \text{Hg}^{\bullet+} + \text{CO}_2$ is exothermic with a rate constant of $1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The $\text{Hg}^{\bullet+}$ formed can only be further reduced to Hg^0 in the absence of O_2 .

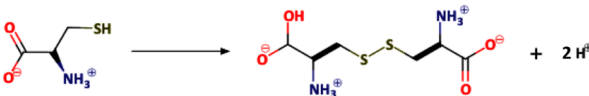

Rxn W15. Superoxide anion/hydroperoxy radical ($\text{O}_2^{\bullet-}/\text{HO}_2^{\bullet}$)

$\text{HO}_2^{\bullet}/\text{O}_2^{\bullet-}$ (pK_a 5.5) is a one-electron reductant of Hg^{2+} to $\text{Hg}^{\bullet+}$. Gårdfeldt and Jonsson (2003) determined the one-electron reduction potential for the pair $\text{HgCl}_2/\text{HgCl}^{\bullet}$ vs. NHE at $[\text{Cl}^-] = 0.05 \text{ M}$ to be -0.47 V , which together with that for $\text{O}_2/\text{O}_2^{\bullet-}$ vs. NHE of -0.155 V gives an equilibrium constant for $\text{HgCl}_2 + \text{O}_2^{\bullet-} \rightleftharpoons \text{HgCl}^{\bullet} + \text{O}_2 + \text{Cl}^-$ of 5×10^{-6} at the aforementioned $[\text{Cl}^-]$. Given the rate constant for the reaction $\text{Hg}^{\bullet+} + \text{O}_2 \rightarrow \text{Hg}^{2+} + \text{O}_2^{\bullet-}$ is $\sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Rxn W11), the bimolecular rate constant between HgCl_2 and $\text{O}_2^{\bullet-}$ can be estimated to be $5 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$. Pehkonen and Lin (1998) carried out a study of the photoreduction of mercuric ion to Hg^0 with nitrate or chloride as counterion in the presence of formic, acetic or oxalic acid at neutral (7.0) and acidic (3.9) pH in aerated solutions. Only in the presence of oxalic acid does a significant photoreduction occur and, as in the later studies by Zhao et al. (2021) and Si and Ariya (2008), an increase in the reaction rate is observed with increasing ratios of oxalic acid to Hg^{II} . It is also observed that the reduction is suppressed in the presence of Cl^- . Photoreduction results in an exponential increase in H_2O_2 formation, which is due to the presence of hydroperoxyl radicals in solution ($2 \text{HO}_2^{\bullet} \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$). In retrospect (see above), this follows from the homolytic decomposition of $\text{Hg}(\eta^2\text{-C}_2\text{O}_4)$ into radicals in an aerated solution ($\text{CO}_2^{\bullet-} + \text{O}_2 \rightarrow \text{O}_2^{\bullet-} + \text{CO}_2$) and does not necessarily mean that $\text{HO}_2^{\bullet}/\text{O}_2^{\bullet-}$ can reduce Hg^{II} to Hg^0 .

Organic reductants

In the atmospheric environment, Hg^{II} complexation by natural organic matter (NOM) plays a pivotal role in the redox chemistry of Hg (Åkerblom et al., 2015). The chemical-reducing effect of dissolved NOM (humic substances) on Hg^{II} has been recognized for nearly 50 years (Alberts et al., 1974). These heterogeneous macromolecular ligands contain not only building blocks that can form complexes with Hg^{II} , but also redox-active aromatic chromophores that can photolytically convert Hg . The fractions of NOM contributing to Hg^{II} photoreduction include the fulvic- and flavin-like fractions that contain more quinone and flavin moieties, than usual (Yang et al., 2020a). Furthermore, NOM contains several functional groups that can reduce complex-bound mercuric ions to Hg^0 by a 2e-LMCT reaction (Table 5).

Table 5. Main functional groups of NOM that can (photo)reduce ligated Hg^{2+} .

Binding atom	Ligand oxidation process
Oxygen (O)	$\text{R}-\text{CH}_2\text{OH} \longrightarrow \text{R}-\text{C}(=\text{O})\text{H} + 2 \text{H}^+$ $\text{R}-\text{C}(=\text{O})\text{OH} \longrightarrow \text{R}-\text{H} + \text{O}=\text{C}=\text{O}$
Nitrogen (N)	$\begin{array}{c} \text{H}_2\text{C}-\text{CH}_2 \\ \quad \\ \text{H}_2\text{N} \quad \text{NH}_2 \end{array} \longrightarrow \text{H}_3\text{C}-\text{CH}_3 + \text{N}\equiv\text{N} + 2 \text{H}^+$
Sulfur (S)	

Rxn W16. Organic acids

Low molecular-weight organic acids present in the atmosphere can reduce Hg^{II} to Hg^0 in the presence of O_2 . These include dicarboxylic acids, ortho-substituted aromatic carboxylic acids, and enolic acids. It has been known since 1880 (Eder, 1880) that the salt of the lightest dicarboxylic acid, oxalate, can reduce Hg^{II} in daylight. Oxalic acid is formed from, e.g., ethylene or acetylene by atmospheric oxidation over several reaction cycles (chemical aging, Warneck, 2003). Mercuric ion forms a complex with oxalate in a 1:1 ratio ($\text{Hg}(\eta^2\text{-C}_2\text{O}_4)$), characterized by $\log \beta = 9.66$, which is most photolabile under UVB irradiation. Si and Ariya (2008) studied the kinetics and products of the photoreduction of Hg^{II} in a series of experiments with different concentrations of the lightest

dicarboxylic acids C₂–C₄ at an initial pH of 3.0 and temperature of 296 ± 2 K, while the kinetic, product and isotopic study of Zhao et al. (2021) involved the system Hg^{II} + oxalic acid with ClO₄[−] as counterion in the pH range of 2.7 – 6.3 and a small temperature range of 295 – 303 K. The pH-resolved experiments show that in the C₂O₄^{2−}, HC₂O₄[−], H₂C₂O₄ – system, only the oxalate ion reduces Hg²⁺ with a k_{Hg²⁺+C₂O₄^{2−}} of 15.7 ± 2.8 M^{−1} s^{−1} at 295 ± 1 K. Si and Ariya reported a strongly divergent bimolecular rate constant between Hg²⁺ and total oxalic acid concentration of 1.2 × 10⁴ M^{−1} s^{−1} at pH 3.0. The magnitude is surprisingly large and is comparable to the rate constant between Hg²⁺ and HO₂/O₂[−] radicals (see below). When this higher rate constant based on total oxalic acid concentration is implemented in regional air quality models, the impact is significant (Bash et al., 2014). However, on the reaction mechanism, there is more consensus that it follows branched routes. Hg(η²-C₂O₄) undergoes photolysis followed by partial reductive elimination in one step (which is insensitive to the presence of O₂): Hg(η²-C₂O₄) $\xrightarrow{h\nu}$ Hg⁰ + 2 CO₂ and partly by homolysis of an Hg–O bond, which initiates a chain reaction: Hg(η²-C₂O₄) $\xrightarrow{h\nu}$ Hg^{•+} + C₂O₄^{•−}. Hg⁰ should form from the reaction of Hg^{•+} with the bulk ligand C₂O₄^{2−}, where Hg^{•+} is reformed from the reaction between bulk Hg²⁺ and the oxalyl (C₂O₄^{•−}) or carbon dioxide anion (CO₂^{•−}) radical. Reduction to Hg⁰ in the chain reaction is inhibited by O₂, which reacts rapidly with both C₂O₄^{•−} and CO₂^{•−} and also re-oxidizes Hg^{•+} to Hg²⁺. As with dicarboxylic acids, aqueous solutions of aromatic ortho- and para-substituted carboxylic acids exposed to UVB can oxidize Hg²⁺ to Hg⁰ by elimination of CO₂ and the Hg²⁺ → Hg⁰ photoreduction is attenuated but not completely inhibited by the presence of dissolved O₂ and competing counterions. Previously, He et al. (2012) studied the aqueous photoreduction of Hg²⁺ coupled with a series of aromatic carboxylic acid derivatives in the absence of O₂ at pH 4.3 and suggested that the reaction proceeds by a radical mechanism. However, studies of the same reactants in our laboratory (unpublished results, shown in Table 4) show that Hg⁰ is formed even in the presence of dissolved O₂, suggesting the existence of an additional non-radical reduction pathway. We propose that this channel requires solvo-mercuration to an arylmercurial intermediate followed by photolytically induced 2e-LMCT as part of a concerted series of electron rearrangements including cleavage of a Hg–C bond yielding Hg⁰, CO₂ and a decarboxylated aromatic as end products. Taking p-aminobenzoic acid as an example:

Photo-reduction has also been observed in the presence of dissolved O₂ when Hg²⁺ is mainly bound to the amino acid serine (HSer) as HgSer₂ (Motta et al., 2020b), which can be explained as the result of reductive elimination with CO₂ and 2-aminoethanol as by-products besides Hg⁰ and involving an intermediate with a photolabile Hg–C bond (Zhao et al., 2021). In the cysteine-mediated photoreduction (Motta et al., 2020b; Zheng and Hintelmann, 2010b), the ligand is converted from a thiol to a disulfide (Table 5). Ascorbic acid, as a representative of the enolic acids, can readily reduce inorganic divalent Hg in aqueous solution to Hg⁰. Studies in our laboratory show that the reaction is thermal and not affected by actinic light. When ascorbic acid is in excess (>10:1) relative to Hg²⁺, the reaction rate is not significantly affected by increasing ascorbic acid concentration. The reaction rate is highest in the pH range where the hydrogen ascorbate ion (HAsc[−]) is dominant and the hydrolysis of Hg²⁺ is not complete, i.e., typical pH values for atmospheric hydrometeors (≤ 5.5). Presumably, HgOH⁺ (aq) forms a reactive complex with HAsc[−], Hg(HAsc)⁺, which is labile to the elimination of water in a heterolytic process, forming Hg⁰ and dehydroascorbate as the final product. Enols act as atmospheric intermediates and it is doubtful whether they are present in high concentrations that would make them interesting as reducing agents for atmospheric Hg²⁺. In any case, k_{Hg²⁺+HAsc[−]} is relatively high (~0.17 min^{−1}, Rxn W16b, Table 4).

1055 Rxn W17. Hydroquinones and polyphenols

The quinonic (Zheng et al., 2012) and fulvic (Yang et al., 2020a) units in NOM act as key red-ox centers. How this happens at the molecular level is being investigated by studying model compounds that contain the redox-active group but lack other functional groups (Zhao et al., 2021). The simplest quinone forms a red-ox pair with the corresponding hydroquinone in the half-reaction:

Combined with the half-reaction in **Rxn 3**, this gives a $\Delta E^0 > 0$ for $\text{Hg}^{2+} + \text{C}_6\text{H}_4(\text{OH})_2 \rightarrow \text{Hg}^0 + \text{C}_6\text{H}_4(\text{=O})_2 + 2 \text{H}^+$, i.e. thermodynamically feasible. Relatively slow reduction of Hg^{2+} to Hg^0 by hydroquinone occurs in the dark in dilute aqueous solution ($8.2 \pm 2.4 \times 10^{-5} \text{ s}^{-1}$). The results are consistent with a reaction mechanism involving a hydroxyphenoxymercuric complex or via *ipso*-mercuration followed by electron shuttling and elimination of Hg^0 and H_2O :

The aqueous photochemistry of quinones is complicated and can involve both ground and excited state reactions as well as free radicals (Görner, 2019). Concerning the interaction of benzoquinone with Hg under actinic light, one study shows a significant oxidation ($\sim 0.6 \text{ h}^{-1}$) of Hg^0 in Cl^- enriched water (see above, Lalonde et al., 2001), whereas another study shows a photoreduction of $\text{Hg}^{\text{II}} \rightarrow \text{Hg}^0$ of about the same magnitude ($\sim 0.8 \text{ h}^{-1}$) under anaerobic conditions and in the absence of strongly complexing inorganic ligands (Zhao et al., 2021). An anthraquinone (AQ) derivative (AQ-2,6-disulfonate) is an effective electron shuttle that facilitates electron transfer from metal-reducing bacteria (MRB) to Hg^{II} (Lee et al., 2018), as well as from Hg^0 (aq) to organic thiols (R-SH) during oxidative complexation to form $\text{Hg}(\text{SR})_2$ (Zheng et al., 2013). Zheng et al. (2013) reported that AQDS(aq) alone is unable to oxidize Hg^0 or reduce Hg^{II} under dark and anaerobic conditions. AQDS-assisted biotic Hg^{II} reduction by the MRB *Shewanella oneidensis* MR-1 is associated with negative charge scavenging, which temporarily increases the content of reduced AQDS species, such as AQH_2DS and semiquinone radicals (Lee et al., 2018). The reduced species AQH_2DS alone is a potent reductant of Hg^{II} in the dark. On the other hand, Hg^{II} is efficiently reduced to Hg^0 in a UVB-irradiated aqueous solution containing dissolved AQDS ($\sim 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$). The reactive species is tentatively photohydrated AQDS ($\text{AQH}_2(\text{OH})\text{DS}$) interacting with Hg^{II} by forming a photolabile bidentate O-coordinated mercuric complex. In conjunction with a strong isotope effect (**Section 8.4**), photoreaction is likely to occur via a paramagnetic intermediate (a mercurous semiquinone biradical complex). The reaction rate decreases to $\sim 0.2 \text{ h}^{-1}$ in the presence of dissolved O_2 (Zhao et al., 2021). Hg^{II} interacts with ortho-QH₂ moieties such as those in natural polyphenols of humic substances and tannins (Jerzykiewicz, 2013). A direct reaction yields redox-active Hg^{I} complexes with ligands of semiquinone radical character that eventually may decompose into Hg^0 (Jerzykiewicz et al., 2015). Reaction kinetic and mechanistic studies more applicable to the environment are not available.

1080 **Rxn W18. Thiols**

Hg^{2+} and CH_3Hg^+ bind extremely strong to heavier hydrochalcogenide groups (such as RSH and RSeH) and other corresponding groups of reduced chalcogenides, such as sulfides and disulfides, etc. (Skylberg, 2011). Most relevant, both inorganic (e.g. H_2S , CS_2) and organic (CH_3SH , CH_3SCH_3), low molecular weight reduced sulfur compounds have short lifetimes (Warneck, 1988) and therefore have no effect on aqueous Hg speciation. It is questionable whether reduced sulfur/thiol groups associated with macromolecular organic compounds in aerosols influence internal Hg speciation. Photo-reduction of divalent Hg by lighter aliphatic thiols is slow ($< 10^{-7} \text{ s}^{-1}$, Si and Ariya, 2011), while that by thioglycolic is slightly faster ($2.3 \times 10^{-5} \text{ s}^{-1}$, Si and Ariya, 2015), but hardly significant in the atmosphere.

6.2 Organic mercury

6.2.1 Demethylation channels

Biogenically produced organo-Hg in the environment is almost exclusively methylated Hg, although there are a few reports of the presence of ethyl Hg (Wu et al., 2023b), which must have a natural source. However, only methylated Hg has been detected in air. As mentioned above, DMHg is a major source of MMHg^+ compounds in the atmosphere through gas-phase degradation. Gaseous MMHg^+ species (Lee et al., 2003) can potentially react homogeneously to inorganic Hg, but as MMHg^+ species are only semi-volatile and have a high Henry's constant, they are more likely to be rapidly absorbed on aerosols. MMHg^+ species have been detected in cloud water (Li et al., 2018; Weiss-Penzias et al., 2018), fog water (Weiss-Penzias et al., 2012), rain water (Conaway et al., 2010; Won et al., 2019) and snow (St Louis et al., 2007). Photolytic demethylation of dissolved DMHg occurs in pure water (Chen et al., 2024) incubated with

sunlight ($\text{CH}_3\text{HgCH}_3 \xrightarrow{h\nu, +\text{H}^+} \text{CH}_3\text{Hg}^+ + \text{CH}_4$, $\sim 0.32 \pm 0.07 \text{ d}^{-1}$, West et al., 2022). Acidolytic demethylation of DMHg to MMHg⁺ species is of very minor importance and only occurs at low pH (Maguire and Anand, 1976; Wolfe et al., 1973). A theoretical study of $\text{CH}_3\text{HgOH}_2^+$ and CH_3HgOH , which dominate the speciation of MMHg⁺ in natural waters without significant levels of Cl^- and reduced sulfur ligands including NOM, indicates that $\text{CH}_3\text{HgOH}_2^+$ can be excited to the triplet state by sunlight, and this state dissociates into CH_3 and Hg^{I} radicals (Tossell, 1998). An experimental room temperature study of the photo-degradation of CH_3HgOH (aq) when irradiated by a Xe lamp with a filter blocking wavelengths $< 290 \text{ nm}$ gave a rate constant of $(2.2 \pm 0.2) \times 10^{-4} \text{ s}^{-1}$ (Gårdfeldt et al., 2003). Rapid indirect demethylation of MMHg⁺ species by a bimolecular process with the OH radical occurs at the limit of what diffusion allows $(9.83 \pm 0.66) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, Chen et al., 2003). In natural waters, select reactive oxygen species, such as singlet oxygen (see above, Suda et al., 1993; Zhang and Hsu-Kim, 2010), have been suggested to cause Hg^{II} demethylation, but their reactivity has not been directly quantified. Instead, its presence has been suggested based on the results of added scavenger/promoter tests, some of which may give misleading results for some water compositions (Han et al., 2017). Chen et al. (2003) concluded that OH-initiated demethylation is comparable to the rates of MMHg⁺ photodegradation reported in situ in natural waters. These researchers found that, in addition to inorganic Hg^{II} , Hg^0 was a by-product of OH-initiated degradation in an O_2 -saturated system, presumably by homolytic substitution.

6.2.2 Methylation channels

The paucity of empirical data renders the budget of tropospheric MMHg⁺ species highly uncertain. A recent estimate of the MMHg⁺ pool size is 5.5 Mg, associated with a lifetime of 1.9 d, of which one of the major sources is inferred to be in-cloud methylation (Wu et al., 2024b). The potential for atmospheric biotic methylation is considered limited, despite the presence of pathogens and bacteria in aerosols and hydrometeors, because Hg methylating microbes (possessing two important methylation genes, *hgcA* and *hgcB*, Parks et al., 2013) usually thrive in anaerobic environments, in contrast to the distinctly oxic environment of atmospheric waters. However, many unknowns about the potential for Hg^{II} methylation under oxic conditions need to be resolved (Sonke et al., 2023). There have been extensive studies on the abiotic methylation of Hg^{2+} (Ullrich et al., 2001). Methylating agents that have been discussed as important for MMHg⁺ formation in the atmosphere are oxygenated hydrocarbons containing a methyl group (Yin et al., 2012; Hammerschmidt et al., 2007). Some of them have properties that allow competitive photochemical reduction and methylation of Hg^{2+} (Yin et al., 2012). Earlier studies have investigated photochemical Hg^{2+} methylation by irradiation in deep UV (Yin et al., 2012; Akagi et al., 1974; Hayashi et al., 1977), making it impossible to generalize these results to the lower atmosphere. Formation of MMHg⁺ species was observed in the dark in dilute Hg^{II} solutions (1 nM) containing an excess of acetic acid (100:1 M/M) with an apparent first-order rate constant of $5.4 \times 10^{-6} \text{ s}^{-1}$ in artificial rainwater (pH 4.9, Gårdfeldt et al., 2003). When the system is exposed to sunlight, photo-demethylation occurs which counteracts MMHg⁺ formation mediated by acetic acid/acetate and within hours the MMHg⁺ concentration enters a steady state ($\sim 2.5\%$ of inorganic Hg^{II}). Hammerschmidt et al. (2007) have pointed out that the average ratio of MMHg⁺ to reactive Hg^{II} measured in North American continental precipitation ($2.5 \pm 0.6\%$) is in agreement with the findings of the above laboratory study. The methylation takes place intramolecularly in the acetato-mercuric complexes present in solution concerted with decarboxylation (Gårdfeldt et al., 2003; Yin et al., 2012; Akagi et al., 1974): $[\text{Hg}(\text{CH}_3\text{COO})_n]^{2-n} \rightarrow \text{CH}_3\text{Hg}^+ + \text{CO}_2 + (n-1) \text{CH}_3\text{COO}^-$.

7 Multi-phase transformations

Multiphase transformations deal with the dynamics and chemistry at various interfaces and media, such as aerosol particles and cloud droplets, interacting heterogeneously with gases and solute species. Although there is a significant amount of literature in this field (Ariya et al., 2015; Subir et al., 2011, 2012), it is mostly irrelevant to the atmosphere.

7.1 Gas-particle partitioning and reactive gas uptake

The behavior of gaseous Hg^0 atoms and Hg^{II} molecules in interacting with the atmospheric condensed phase differs. The dominant Hg^0 pool is of limited water solubility, and the uptake of Hg^0 vapor is low to aerosol surfaces, to the limited extent that it has been investigated. Gas phase Hg^{II} molecules, “GOM”, have Henry’s coefficients several orders of magnitude greater than that of Hg^0 , favoring the liquid phase. Heterogeneous processes that keep GOM adsorbed, reversibly or irreversibly, modified by ligand exchange, or dissociated to Hg^0 by reduction on surfaces are key parameters that need to be characterized to appropriately parameterize chemical transport models.

7.1.1 HgCl₂

Understanding the transformation from GOM to PBM through gas phase processes (condensation, **Section 5.1.4**) and aerosol surface interaction (**Section 3.2**) is crucial for parameterizing deposition. Since the separation of GOM from PBM with current methods is tentative, the accuracy of studies of Hg^{II} distribution between gas and condensed phase, performed by preconcentration in laboratory experiments with nebulized aerosol (Rutter and Schauer, 2007b, a) and in the field (Amos et al., 2012), is retrospectively ambiguous. Fitting observational data to an equilibrium $\text{GOM} + \text{PM}_{2.5} \xrightleftharpoons{1/T} \text{PBM}$ according to a van't Hoff type relationship $\log_{10}(K_{\text{gp}}^{-1}) = a + b/T$ is used in models to calculate the volatilization of GOM from atmospheric aerosols, where K_{gp} (**Eq. 8**) is here weighted by the inverse of the mass concentration of fine particulate matter (PM_{2.5}, Shah et al., 2021). The partitioning expression does not consider that the interaction between GOM and a surface is significantly influenced by the composition of the surface layer. HgCl₂(g) has a high partitioning for particles consisting of typical alkali metal salts such as chlorides, nitrates, and sulfates (Mao et al., 2021; Malcolm et al., 2009). To compensate, global Hg models treat the uptake of GOM onto sea salt particles separately as an irreversible first-order process parameterized by wind speed and humidity. The equilibrium studies conducted at atmospheric pressure do not provide insights into the dynamics of the system, as the experiments are limited by mass transport, which negates the possibility of obtaining quantitative information on reactive uptake. As an alternative (Liu et al., 2022), partition coefficients have been calculated for individual GOM species on the basis of theoretical predictions of both adsorption and absorption (Wu et al., 2024a). The reactive uptake of HgCl₂(g) on surfaces representative of inorganic and organic primary and secondary atmospheric aerosols has recently been studied using the fast flow technique coupled to an ion drift chemical ionization mass spectrometer, (ID-CI-MS). The reported data (Mao et al., 2021; Khalizov and Mao, 2023) are summarized in **Table 6**.

Table 6. Reactive uptake of HgCl₂(g) on surfaces

Chemical	Structural formula ³³	γ_{net}^{34}		Surface coverage (θ , %)	Lifetime (τ , days)
		γ_{net}^0	$\gamma_{\text{net}}^\infty$		
Inorganic aerosol surrogates					
Na ₂ SO ₄		3.1×10^{-2}	1.7×10^{-3}	98	0.1
NaCl		2.2×10^{-2}	1.9×10^{-3}	65	0.1
(NH ₄) ₂ SO ₄		1.4×10^{-2}	7.0×10^{-4}	5.6	0.2
NH ₄ NO ₃		3.6×10^{-3}	3.3×10^{-4}	0.3	0.7
Primary organic aerosol (POA) surrogates					
Levoglucosan		1.1×10^{-2}	2.9×10^{-4}	9.6	0.2
Pyrene		2.1×10^{-3}	5.0×10^{-4}	1.3	1.2
Perylene		3.0×10^{-3}	5.2×10^{-4}	3.8	0.8
Soot		8.9×10^{-5}		0.1	20.2
Secondary organic aerosol (SOA) surrogates					
Citric acid (H ₃ cit)		$< 1 \times 10^{-5}$	$< 1 \times 10^{-5}$	< 0.02	> 242
NaH ₂ cit		6.9×10^{-5}	5.0×10^{-5}	< 0.02	35
Na ₂ Hcit		2.4×10^{-3}	2.3×10^{-4}	1.2	1.0
Na ₃ cit		8.4×10^{-3}	6.6×10^{-4}	7.5	0.3
Pimelic acid (H ₂ pim)		1.1×10^{-3}	1.8×10^{-4}	1.0	2.2
NaHpim		2.2×10^{-3}	3.1×10^{-4}	1.4	1.1
Na ₂ pim		8.2×10^{-3}	8.0×10^{-4}	11.6	0.3
Succinic acid (H ₂ suc)		9.3×10^{-4}	1.0×10^{-4}	0.02	2.6
NaHsuc		2.0×10^{-3}	3.6×10^{-4}	0.7	1.2
Na ₂ suc		8.3×10^{-3}	6.6×10^{-4}	6.2	0.3
Diocetyl sebacate		2.6×10^{-2}	7.1×10^{-3}	153	0.1

³³ For soot, a clichéd structure is used that does not claim to be accurate.

³⁴ Calculated by Eq. 5

The data in **Table 6** are for dry surfaces, where γ_{net}^0 is the initial uptake coefficient, which is relevant throughout the lifetime of the aerosol as the surface coverage by atmospheric HgCl_2 remains unchanged and low. In the presence of sea salt aerosols ($>0.6 \mu\text{m}$, initially at pH 8) that dominate in the marine air, where NaCl represents $>95\%$ of its mass, the lifetime of HgCl_2 (g) is expected to be between 4 and 20 h depending on aerosol loading (Mao et al., 2021). When the relative humidity exceeds $\sim 75\%$, a hygroscopic sea salt droplet is formed as the salt deliquesces, and a highly mobile surface phase in which Hg^{II} is equilibrated in ionic form as HgCl_4^{2-} may contribute to a more rapid GOM loss in marine air (Holmes et al., 2009). Ammonium salts such as nitrates and sulfates are primarily found in secondary particles, typically in urban and agricultural-rural air. Although HgCl_2 uptake is lower here, its lifetime is comparative due to the higher particle number and the large surface area they generally represent. These semi-volatile ammonium salts do not occur in isolation but coexist with oxygenated organics formed through photochemical activity, seeding the formation of secondary aerosols, which constitute the primary fraction of the atmospheric burden of organic aerosols (OA, Jimenez et al., 2009). The acidity of secondary organic aerosols (SOA), a dominant component of $\text{PM}_{2.5}$, affects HgCl_2 uptake by controlling the acid-base equilibria of characteristic chemical species such as aliphatic dicarboxylic acids, aromatic polycarboxylic acids, and other oxygenated multi-functional organics in the aerosol. Of the diprotic acids in **Table 6**, the reactivity becomes noticeable only after the first deprotonation step at pH 4.5 - 5.5. For the triprotic citric acid, it occurs after the second step at pH 6.5. The adsorption of HgCl_2 on primary organic aerosol (POA) surfaces is significant in the presence of levoglucosan, an anhydrosugar, which is a fingerprint of fire activity. Nevertheless, the interaction between HgCl_2 and polyaromatic hydrocarbons (PAHs) derived from carbonaceous fuel combustion is more constrained, occurring between the electrophile HgCl_2 and the π electrons delocalized over the aromatic fused ring skeleton. The observed adsorption on fresh soot, porous of the graphitic type with a high specific surface area, is more than one order of magnitude lower than for the PAHs of the minor type studied (pyrene, perylene). If morphology affects uptake, so does the state of the surface phase, as a diester of sebacic acid (close homologue of pimelic acid), octyl sebacate, a lubricant, is more reactive to HgCl_2 than the microcrystalline pimelic acid film. The adsorption of HgCl_2 on mineral surfaces (dust aerosols) represented by iron (hydr)oxides has not been studied experimentally, but calculations indicate a partition coefficient (K_{gp}) for $\alpha\text{-Fe}_2\text{O}_3$ that exceeds that for NaCl by three orders of magnitude (Tacey et al., 2018b). The studies listed in **Table 6** were performed without observing redox chemistry (i.e., no Hg^0 was detected being emitted from the HgCl_2 -exposed surfaces when heated up to 120°C), but a combined study using FF-ID-CIMS and Raman spectroscopy shows that exchange reactions between gaseous mercuric compounds are catalyzed by surfaces, such that HgCl_2 and HgBr_2 molecules in the presence of a deactivated surface produce the mixed BrHgCl molecule (Mao and Khalizov, 2021), which is also volatile. Due to the rapid exchange reactions, the prospect of accurately speciating GOM by pre-concentration on filters and cation exchange membranes, as discussed previously (**Section 4.1**), is unlikely.

7.1.2 Hg^0

A challenge in studying gas-phase or liquid-phase initiated reactions is the potential for side reactions and phase changes to occur during experiments. Thus, a portion of the loss of gas-phase Hg^0 in laboratory experiments designed to study homogeneous oxidation (e.g. by O_3 , Snider et al., 2008; NO_3^\bullet , Sommar et al., 1997 etc.) has been linked to a heterogeneous rate component (k_{surf}) occurring on new surfaces that form during experiments (product clusters undergoing particle growth in free suspension, **Section 5.1.4**) and/or on initially deactivated existing surfaces (reactor walls) that begin to catalyze Hg^0 surface oxidation as deposits form (Sommar et al., 1997; Medhekar et al., 1979). For example, in a series of spherical reactors of varying surface-to-volume ratios (S/V), Pal and Ariya (2004b) observed the loss of Hg^0 by reaction with an excess of O_3 in N_2 following:

$$-d[\text{Hg}^0]/dt = \left\{ k_{\text{gas}} + \frac{S}{V} \cdot k_{\text{surf}} \right\} [\text{Hg}^0] \cdot [\text{O}_3] = k_{\text{net}} [\text{Hg}^0] \cdot [\text{O}_3] \quad (10)$$

where k_{gas} ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) is the gas-phase reaction rate, S/V (cm^{-1}), k_{surf} ($\text{cm}^4 \text{ molecule}^{-1} \text{ s}^{-1}$) is the surface rate loss, and $[\text{O}_3]$ (molecules cm^{-3}) is the gas-phase O_3 concentration. In the S/V range $0.28 - 0.93 \text{ cm}^{-1}$, k_{net} increased by 30% simultaneously with the formation of particles (Snider et al., 2008) during the experiments, which started homogeneously. Using a fluorocarbon film smog chamber (9 m^3 , $S/V = 0.03 \text{ cm}^{-1}$), Rutter et al. (2012) studied the influence of SOA (yielding a ~ 100 -fold increase in the surface area

of the system) and secondarily formed $\bullet\text{OH}$ (at ambient level due to added scavenger) generated from an irradiated mixture of O_3 and various biogenic and anthropogenic VOCs (at a level ~one order of magnitude higher than ambient) on the oxidation of Hg atoms (at a level ~two order of magnitude higher than ambient). Neither Rutter et al. nor subsequent researchers (Lyman et al., 2022) have been able to identify evidence that interaction with photochemical smog particles significantly contributes to the oxidation of Hg^0 . Nevertheless, few studies concerning Hg^0 uptake have been conducted to a sufficiently rigorous standard, employing techniques used in the specific studies of heterogeneous processes, to produce a kinetic formalism that can be related to atmospheric models. These studies, conducted with a coated-wall laminar flow tube reactor, concern the light and moisture dependent uptake of Hg^0 (detected by CV-AFS) that may be photocatalytic, on the major metal oxides (TiO_2 , Fe_2O_3 , FeOOH , Al_2O_3) present in mineral dust aerosols (Kurien et al., 2017; Lee et al., 2022). The first three metal oxides have semiconductor properties with band gaps that allow photoexcitation in the UVA (≤ 395 nm) and visible (≤ 590 nm) regions, while Al_2O_3 , the second most abundant mineral oxide in the Earth's crust after SiO_2 , is an insulator but has some thermal conductivity. It has been established for over half a century that Hg^0 vapor in the presence of O_2 over an irradiated TiO_2 surface is consumed by reactive uptake (Kaluza and Boehm, 1971) via the following tentative mechanism:

When excited by light of a wavelength shorter than the band gap energy, the generation of electron-hole pairs (e_{CB}^- , h_{VB}^+) occurs in the conduction and valence bands (Rxn 12a). Electrons and holes transported to the particle surface initiate redox chemistry by reacting with H_2O and O_2 molecules to form reactive oxygen species (ROS, Rxn 11b, c). The oxidation potential of h_{VB}^+ exceeds +2.27 eV in the TiO_2 , Fe_2O_3 and FeOOH cases, which is sufficient to generate hydroxyl radicals from surface water (Rxn 11c) that can oxidize adsorbed Hg^0 (Rxn 11d). The reported uptake coefficients are in the range of $<10^{-10}$ to $>10^{-4}$ (based on BET surface area), with the relative reactivities $\text{Fe}_2\text{O}_3 \lesssim \text{FeOOH} < \text{Al}_2\text{O}_3 < \text{TiO}_2$, where $\gamma_{\text{net}}^{\circ}$ without irradiation is below the detection limit. The uptake of Hg^0 on the iron (hydr)oxides is less than 10^{-8} under both UV and visible light, and inhibited by humidity, as was the case for Al_2O_3 , which shows measurable uptake under UV irradiation ($\gamma_{\text{net}}^{\circ} = 1.2 \times 10^{-8}$). The photo-initiated uptake of Hg^0 on TiO_2 is significant, especially in UV light at low humidity ($\gamma_{\text{net}}^{\circ} > 3 \times 10^{-5}$, diffusion-controlled limit). However, as with Al_2O_3 , it shows reversibility (desorption of Hg^0) in the presence of water vapor during darkness (Lee et al., 2022), while Hg^0 exhibits almost irreversible binding to iron (hydr)oxides at the temperatures studied ($< 150^\circ\text{C}$, Kurien et al., 2017). Based on the limited published data, only under conditions of low humidity and very high mineral dust aerosol loading can the uptake of Hg^0 be discussed as having any effect on the atmospheric cycling of Hg^0 . It is worth noting that there is no corresponding experimental data for HgCl_2 uptake on mineral dust surrogates.

The uptake of Hg^0 on ice, studied by migration of radioactive Hg isotopes into ice spheres in a packed bed flow tube exposed to a strong temperature gradient, can be described by reversible adsorption without significant solvation. The observations were in accordance with a Langmuir isotherm, where the adsorption equilibrium can be described thermodynamically by Bartels-Rausch et al. (2008):

$$-RT \ln K = \Delta H_{\text{ads}}^0 - T \Delta S_{\text{ads}}^0 = -28000 + 38 \cdot T \quad (11)$$

where K is the Langmuir absorption constant (Eq. 7), R is the gas constant, T is absolute temperature, ΔH_{ads}^0 and ΔS_{ads}^0 are the enthalpy and entropy of adsorption, respectively. Compared to the Henry's law equilibrium for Hg^0 (0.18 at 5°C), the Langmuir adsorption coefficient on ice, both expressed in a dimensionless way, is much smaller even at temperatures lower than its freezing point (2.2×10^{-5} at 220 K), which is most relevant for polar regions and the upper troposphere. Therefore, in the atmospheric and polar environment, uptake of $\text{Hg}^0(\text{g})$ on ice surfaces is negligible.

7.2 Reduction of mercurial species on surfaces

Computational chemistry studies report that adsorption of mercuric halides on dry salt- or mineral-like surfaces reduces the energy required for reduction to Hg^0 (Tacey et al., 2016), and that reduction of HgCl_2 and HgBr_2 to Hg^0 on iron oxide aerosols requires the presence of actinic light (Tacey et al., 2018a). Breaking the first Hg-X bond is possible either thermally or photolytically, while the second requires photons with $\lambda \leq 461$ nm. To release Hg^0 from the surface, an excitation energy of 2.59 eV ($\lambda \leq 479$ nm) is required in a photoinduced charge transfer process between the surface and the adsorbate.

The photoreduction of particle-bound Hg^{II} has been the subject of experimental investigation (Tong et al., 2013; Tong et al., 2014). In these experiments, aerosolized surrogates, doped with HgCl_2 , were generated and dried in laboratory air and subsequently captured on filters, which were then exposed to light with three spectral options in a flow-through reactor. Photoreduction on NaCl aerosols occurs in actinic light (both in UV and visible light, with approximately 2.5% and 2.0% of Hg^{II} reduced, respectively, during a 30-minute exposure, normalized per 100 W m^{-2} irradiation). However, the presence of iron species (mainly Fe^{III} rather than Fe^{II}) has been observed to exert some inhibitory effects (Tong et al., 2013). In contrast, photoreduction on carbon-based synthetic aerosols has been demonstrated to be more significant but also more variable. For example, Hg^{II} on adipic acid aerosols exhibits a comparatively 8% reduction (per same time unit and normalization as above), while on levoglucosan it is less than 2% (Tong et al., 2014). It should be noted, however, that these experiments were carried out without O_2 in the carrier gas stream.

The reduction of Hg^{II} in ice in the presence of organics has been studied in an ice-coated flow tube at atmospheric pressure under irradiation with light between 300 nm and 420 nm (Bartels-Rausch et al., 2011). O_2 -free ice matrices containing 60 nM Hg were doped with a stoichiometric excess (up to 50:1 M/M) of either benzophenone (a strong photosensitizer), oxalic acid-oxalate (forming photolabile Hg^{II} complexes), or humic acid (ditto photolabile complexes), which upon irradiation accelerated the release of Hg^0 with a maximum rate constant of $\sim 5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ observed for benzophenone at high pH. The presence of O_2 (20% in the gas stream), the introduction of sea ice-like conditions, or a large drop in temperature (from 270 to 250 K) or pH (to 4) resulted in diminished photoreduction. The mechanism by which the Hg^{II} reduction is sensitized by benzophenone is challenging to ascertain. One potential mechanism involves the dissociation of an excited state of the major species, $\text{Hg}(\text{OH})_2$, which has been reported to be photolabile as a solute in water (Xiao et al., 1994). A controlled laboratory study of light-irradiated natural snow samples at a temperature of -10°C revealed that the release of Hg^0 follows first-order kinetics with a coefficient between 0.18 and 0.25 h^{-1} , corresponding to a natural lifetime of 4 – 5.6 h (Dommergue et al., 2007). However, no monitoring of Hg^{II} in the condensed phase was conducted. Given that light does not penetrate the entire snowpack, it can be assumed that a Hg^{II} gradient towards depletion at the top is established.

Brominated mercurials that are present in the Arctic environment during AMDE may play a role in light-induced Hg re-emission from the cryosphere to the atmosphere (cf. Fig. 2). A computational study (Carmona García, 2024) suggests that HgBr_2 in solution has an increased absorption cross section for wavelengths longer than 290 nm compared to HgBr_2 in the gas phase, while the bromomercurate anions ($\text{Hg}^{\text{II}}\text{Br}_3^-$ and $\text{Hg}^{\text{II}}\text{Br}_4^{2-}$) have a comparatively even higher absorption in actinic light. The low-energy excited states of HgBr_2 , $\text{Hg}^{\text{II}}\text{Br}_3^-$, and $\text{Hg}^{\text{II}}\text{Br}_4^{2-}$ in solution are characterized by electronic transitions in which the electron density is mainly transferred from the Br atoms to the Hg atom, indicating a significant photoreductive character upon light absorption leading to generation of Hg^{I} species ($\bullet\text{Hg}^{\text{I}}\text{Br}$, $\bullet\text{Hg}^{\text{I}}\text{Br}_2$ and $\bullet\text{Hg}^{\text{I}}\text{Br}_3^{2-}$) and a bromine atom. The photoreductive character is also recognized for the aforementioned Hg^{I} species in their electronically excited states, which plausibly dissociate via an LMCT mechanism with Hg^0 as end product. Predicted peak photolysis constants for the polar spring (March, $\sim 80^\circ\text{N}$) are 3.9×10^{-6} , 3.8×10^{-4} and $7.9 \times 10^{-5} \text{ s}^{-1}$ for HgBr_2 , HgBr_3^- and HgBr_4^{2-} , respectively.

For pure heterogeneous reduction, there is experimental evidence that $\text{SO}_2(\text{g})$ can reduce $\text{HgO}(\text{s})$ at room temperature via $\text{Hg}_2^{2+}\text{SO}_4$ (Zacharewski and Cherniak, 1987) to Hg^0 , HgS and HgSO_4 as stable products (Scott et al., 2003), and that $\text{O}_3(\text{g})$ in the presence of actinic light can reduce $\text{HgCl}_2/\text{HgBr}_2(\text{s})$ to mercurous species (Ai et al., 2023, which may tentatively undergo $\text{Hg}^0/\text{Hg}^{\text{II}}$ disproportionation). In the latter exploratory study, single-particle reactors, 10–50 μm in size, synthesized from mercuric halides in a single-walled carbon nanotube, were prepared and made to levitate during the experiments using optical means. The turnover of HgX_2 by breaking an Hg-X bond was measured by time- and position-resolved Raman spectroscopy, which also showed that

1275 the decomposed X atom was bound to the carbon material (X = Cl, Br). Heterogeneous reactions of this type, i.e.,

may explain why KCl coated denuders do not work as a robust quantitative method for measuring GOM in ambient air (Lyman et al., 2010). Since a gas-phase reaction $\text{HgX}_2 + \text{O}/\text{O}_3 \rightarrow \cdot\text{Hg}^{\text{I}}\text{X} + \text{XO}^\bullet (+ \text{O}_2)$ is endothermic ($\geq 66 \text{ kJ mol}^{-1}$) and therefore unlikely, the results of a steady-state study (Tong et al., 2021) claiming gas-phase photoreduction of HgX_2 in the presence of O_3 and light can instead be attributed to the above-mentioned heterogeneous reactions.

1280 Additionally, voltammetry can provide valuable insights into the redox chemistry of mercury. Hg^0 is frequently employed as the working electrode, exhibiting a high overpotential for the reduction of H_3O^+ to H_2 . This enables the utilization of standard potentials as negative as -1 V in acidic solutions and -2 V in basic solutions. The surface of the hanging mercury drop electrode (HMDE) can be readily renewed by extruding a new drop. In a study by Giannakopoulos et al. (2012), the interfacial adsorption mechanism of gallic acid onto HMDE was investigated, and a series of easily reducible Hg^{II} complexes with mono-, di-, or tridentate gallic acid
 1285 ligation were identified.

7.3 Dark oxidation of Hg^0 accelerated by freeze-concentration effects

Slow oxidation of dissolved Hg^0 by O_2 occurs in aquatic systems in the presence of Cl^- ions (Amyot et al., 2005; Wang et al., 2023). However, upon freezing, most of the solutes are separated from the forming ice phase and concentrated in the remaining liquid at a significantly reduced pH (Bartels-Rausch et al., 2011). In experimental mimics of the micro-pockets of solution that occur in ice,
 1290 experiments in the presence of O_2 , H_2O_2 , and HONO each result in significant Hg^0 oxidation. It has been postulated that protonated forms, $\text{HO}-\text{OH}_2^+$ and ONOH_2^+ , are responsible for the oxidation processes, which can be classified as strongly exothermic based on the provided thermodynamic data (O'connubhair et al., 2012). It should be added that neither dilute H_2O_2 (aq) nor HONO (aq) will oxidize Hg^0 (aq) to any significant extent at room temperature (Kobayashi, 1987).

7.4 Surface-catalyzed reduction of Hg^{II} in aqueous solution

1295 In the presence of a solid phase of ferric (hydr)oxide and dissolved di- or monocarboxylic acids under oxic conditions, reduction of Hg^{II} in aqueous solution to Hg^0 occurs upon UV irradiation (Lin and Pehkonen, 1997). Systems studied that show photoreduction of Hg^{II} are goethite ($\alpha\text{-FeOOH}$) + oxalate/formate, hematite ($\alpha\text{-Fe}_2\text{O}_3$) + oxalate, and maghemite ($\gamma\text{-Fe}_2\text{O}_3$) + oxalate. The experiments with filtered Xe light were conducted with $10 \mu\text{M}$ HgCl_2 , 1 mM organic acid, and 0.1 g L^{-1} ferric hydr(oxide) suspension, with a starting pH of 3.9. During some of the experiments, the pH increased substantially, resulting in the dominance of oxalate over
 1300 hydrogen oxalate. Unlike oxalate, formate alone is not capable of reducing Hg^{II} to Hg^0 in actinic light. It requires irradiation in the deep UV by processes such as (Leonori and Sturgeon, 2019):

One study describes Hg^{II} reduction mediated by the carbon dioxide radical anion ($\text{CO}_2^{\bullet-}$) generated from formic acid via photo-sensitization by visible light-excited naphthoquinone (Berkovic et al., 2012). Iron(III) complexes with formate and oxalate are photolabile in the UVA and into the visible, where a fast $1e^-$ LMCT step generates Fe^{2+} and eventually $\text{CO}_2^{\bullet-}$ that initiates a chain
 1305 process (Mangiante et al., 2017; Baxendale and Bridge, 1955):

The oxic reaction system described by **Rxn 14** reaction formulas contains a number of ROS with different designations, such as the strongly reducing $\text{CO}_2^{\bullet-}$ and the strongly oxidizing HO^{\bullet} as extreme cases. One subsystem is the Fenton's reagent (**Section 6.1.1, Rxn W6**), which produces HO^{\bullet} for which each of $\text{Hg}^{0/\text{I}}$, Fe^{2+} , and H_2O_2 competes to be oxidized. Except for the heterolytic photolysis of $\text{Hg}(\eta^2\text{-C}_2\text{O}_4)$, which produces Hg^0 from Hg^{II} in a single step (**Section 6.1.2, Rxn W16**), the remaining redox steps involving metals are of the single-electron type. The reduction of Hg^{II} occurs by reaction with the $\text{HCO}_2^{\bullet} | \text{CO}_2^{\bullet-}$ nucleophiles (**Section 6.1.2, Rxn W14**), and both homogeneously and heterogeneously with dissolved and adsorbed ferrous species, respectively. A second-order homogeneous reaction coefficient of ~ 120 to $313 \text{ M}^{-1} \text{ s}^{-1}$ has been determined in the near neutral pH range, with $\text{Hg}(\text{OH})_2$ and FeOH^+ identified as the reactive species in solution (Amirbahman et al., 2013; Schwab et al., 2023). In anoxic conditions, the rate of Hg^0 production derived from the surface-catalyzed reduction on hematite and goethite has been described by the expression $k_{\text{het}}[\text{Fe}^{\text{II}}][\text{Hg}(\text{OH})_2]$, with k_{het} of ~ 89 and $\sim 78 \text{ M}^{-1} \text{ s}^{-1}$, respectively (Amirbahman et al., 2013). In an O_2 -saturated, non-bubbled solution, a photo-stationary state between Hg^{II} and Hg^0 occurs, indicating the reduction pathways (**Rxn 14 red.**) are gradually balanced by the oxidation pathways (**Rxn 14 ox.**, Ababneh et al., 2006). In the absence of Hg^0 removal, solubility limitations are easily exceeded during experiments (Lin and Pehkonen, 1997; Ababneh et al., 2006), resulting in the precipitation of colloidal Hg^0 . The removal of dissolved Hg^0 by sorption on hydrous iron oxides, which is relevant here, is also documented (Richard et al., 2016). In the presence of competing anions, such as chloride, the rate of reduction decreases, in part due to the formation of metastable poorly soluble dimeric mercurous salts that compete with the disproportionation of Hg^{I} to Hg^0 and Hg^{II} (Pasakamis et al., 2013).

7.5 Field observations of photoreduction in precipitation, cloud and fog

In precipitation and clouds, a strong correlation between Hg and total organic carbon was observed (Li et al., 2018; Åkerblom et al., 2015), suggesting that Hg-organics complexes are also important in aerosols. Authentic rain samples, where Hg-organics complexes dominate, show photoreduction rates in the range of $0.02 - 0.2 \text{ h}^{-1}$ (Yang et al., 2019; Saiz-Lopez et al., 2019; Fu et al., 2021). There have been a handful of measurements of Hg in cloud water (Li et al., 2018; Weiss-Penzias et al., 2018; Malcolm et al., 2003; Gerson et al., 2017; Huang et al., 2016a), but so far there seems to be only a few studies of the photoreduction rate in this category of waters (Li et al., 2018; Zhen et al., 2023; Gao et al., 2023). Photolysis rates in cloud water samples of $0.07 - 0.21 \text{ h}^{-1}$ measured in situ under actinic light and in the laboratory under UV ($> 290 \text{ nm}$) light are consistent with those observed in precipitation. Whether the photoreduction rates observed in rain- or cloud water are representative of atmospheric aerosols is questionable. Hg^{II} in snowfall or in freshly fallen snow has been reported to be labile for photoreduction (Steffen et al., 2008; Faïn et al., 2013). In temperate urban and pristine rural snow, it has been demonstrated that within 24 h, approximately 50% (Lalonde et al., 2003; Lalonde et al., 2002) and within 48 h, up to 90% (Poulain et al., 2004) of the newly deposited Hg can be effectively recycled back to the atmosphere. Reduction is reportedly strong even in cloudy conditions and is not limited by light (Faïn et al., 2013). In general, less than 5% of the Hg content of a snowpack is in the elemental form (Hg^0), which is concentrated stratigraphically in the first few centimeters. Nevertheless, if the rates are implemented as a mean value ($\sim 0.07 \text{ h}^{-1}$), determining the lifetime of atmospheric Hg against wet deposition, then modelled wet deposition underestimates the observations by an average of 25% globally. Current global chemistry and transport models (GMOS-Chem) consider photoreduction on particles with the pool of Hg^{II} complexed with organic ligands as the reactant (Shah et al., 2021).

8 Mercury isotope systematics and fractionation

Natural Hg contains seven stable isotopes with the mass numbers 196, 198, 199, 200, 201, 202 and 204. In the 1920s, a significant separation of Hg into its isotopes was achieved through vaporization in a vacuum (Harkins and Mulliken, 1921; Mulliken, 1923; Brønsted and De Hevesy, 1921), a process that is conducted on a preparative scale through electromagnetic (Love, 1973) and photochemical (Vyazovetskii, 2012) methods. When the feed flow is in the form of DMHg, total gram quantities of highly enriched

1345 Hg isotopes can be obtained through cascade centrifugation (Babaev et al., 2010). The longest-lived radioisotope is ^{194}Hg at 444 y. Since it does not occur naturally, it cannot be used in the dating typical of ^{14}C . Two additional unstable isotopes (^{197}Hg and ^{203}Hg with a half-life of 64.1 h and 46.6 d, respectively) are of value in instrumental neutron activation analysis and radio-labeled Hg compounds, due to their decay by emission of readily detectable γ rays. It was not until after the turn of the century, 80 years later, with the development of high-precision analytical instruments such as multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS), that it became possible to measure differences in the natural stable Hg isotope composition in the environment (Jackson, 2001; Lauretta et al., 2001). Natural processes can alter the isotopic composition, i.e., causing stable isotope fractionation, such as redox reactions, complexation, sorption, precipitation, dissolution, evaporation, diffusion and biological processes. Stable isotope analyses can, therefore, provide a previously untapped source of valuable information on the sources and biogeochemical cycling of natural and anthropogenic Hg. Isotopic fractionation refers to the division of a sample into two (or more) parts with different ratios of "heavy" and "light" isotopes than the original ratio. In isotopic jargon, if one part contains more heavy isotopes, it is said to be "enriched," while the other part is said to be "depleted". Hg has an extremely large isotopic variation in nature, which, when normalized by the relative mass difference between isotopes, approaches that of the traditional light element isotopes (Wiederhold, 2015). However, the overlapping signals from different fractionation processes can be a major challenge in deciphering natural isotope signatures when tracing sources. It is important to determine the Hg stable isotope fractionation for *individual* key processes, which can be done, inter alia, through controlled laboratory and field experiments. Stable isotope variations are reported as relative values compared with a reference standard (NIST SRM 3133 Hg solution, Blum and Bergquist, 2007):

$$\delta^{xxx}\text{Hg} = 1000 \cdot (R_{\text{sample}}^{xxx/198} / R_{\text{NIST3133}}^{xxx/198} - 1) \quad (12)$$

where R is the ratio of the isotopes with mass numbers xxx and 198. Parenthesized: ^{196}Hg is not an alternative because of its low occurrence of only 0.15%. The standard unit for δ values is per mill (‰). The fractionation factor α determines the distribution of isotopes between any two parts (A and B) of a system as follows:

$$\alpha_{A-B} = \frac{1000 + \delta_A}{1000 + \delta_B} \quad (13)$$

1365 Actual δ -values are usually very close to unity. Therefore, it is usually more practical to use an enrichment factor:

$$\epsilon_{A-B} = \delta_A - \delta_B = 1000 \cdot (\alpha_{A-B} - 1) \cong 1000 \cdot \ln \alpha_{A-B} \quad (14)$$

The last similarity is only valid for δ values less than 10‰. Many kinetic processes can be described as Rayleigh fractionation, which is an irreversible process in an open system involving the progressive removal of a fraction of a trace substance from a larger reservoir. It is described by the following differential equation:

$$d \ln R = (\alpha - 1) \cdot d \ln f_R \quad (15)$$

If the fractionation factor is constant, the differential equation can be integrated directly into the expression:

$$R/R_0 = f_R^{\alpha-1} \quad (16)$$

1370 where R_0 is the isotope ratio of the initial reservoir (when $f_R = 1$), R is the isotope ratio of the reservoir at a given time when the fraction of initial material remaining in the reservoir is defined by f_R . In the literature, the following expression is often used to evaluate the fractionation factor:

$$\ln \frac{1000 + \delta}{1000 + \delta_0} = (\alpha^{xxx/198} - 1) \ln f_R \quad (17)$$

The process tends to enrich the heavier isotopes in the reservoir ($\alpha < 1$, normal kinetic isotope effect) rather than remove the heavier isotopes from the reservoir more rapidly ($\alpha > 1$, inverse KIE).

1375 8.1 Conventional mass-dependent and mass-independent fractionation

Scaling factor β describes the relationship between the fractionation factors as follows:

$$\alpha_{xxx/198} = \alpha_{202/198}^{\beta} \quad (18)$$

where β for mass-dependent equilibrium fractionation ($\beta_{\text{EIE-MDF}}$) and kinetic fractionation ($\beta_{\text{KIE-MDF}}$) are as follows (Young et al., 2002):

$$\beta_{\text{EIE-MDF}} = \frac{1/m_{198} - 1/m_{\text{xxx}}}{1/m_{198} - 1/m_{202}} \quad (19)$$

$$\beta_{\text{KIE-MDF}} = \frac{\ln(m_{198}/m_{\text{xxx}})}{\ln(m_{198}/m_{202})} \quad (20)$$

The equilibrium MDF resulting from the differences in zero-point vibrational energy (ZPE) distances and the kinetic MDF resulting from the differences in dissociation energies between the isotopologues and their respective effects can be expressed in two rules of thumb: the heavier isotopes are concentrated in the compounds in which the element is most stiffly bound (with the highest force-constant), and compounds with heavier isotopes have greater potential energy, so less energy is required to break the bonds of compounds with lighter isotopes, which therefore preferentially enter the chemical reaction and are enriched in the product (Criss, 1999). By combining kinetic and equilibrium MDF, a limit of ~10‰ fractionation is possible (Sun et al., 2022).

Properties of nuclei, such as nuclear size and shape or the presence of non-zero nuclear spin may trigger isotope fractionation that does *not* follow the expected MDF relationships. The first effect, called nuclear field shift (NFS, Rosenthal and Breit, 1932), detected in atomic spectra, results from the interaction of nuclear volume on electrons (also called nuclear volume effect, NVE, Schauble, 2007) and is highly relevant for the very heavy metals, which besides Hg also include, e.g., Tl, Pb and U. NFS is a shift in the ground electronic energy of an atom or molecule due to differences in nuclear size and shape between isotopes. The shift caused by an odd (neutron number) nucleus scales non-linearly between those of the even isotopes of the next higher and lower atomic mass. The odd neutron isotope level is shifted towards the next lower even nucleus (*odd-even staggering*). Due to its smaller size and greater surface charge density, the electronic energy of a light isotope is lower than that of a heavier isotope. The amount of shift is a product of two factors: The electron density at the nucleus and the charge, size and shape of the nucleus and the change in the latter two between isotopes. Hg 6s-orbital electrons significantly overlap with the nucleus, whereas 5p-, 5d- and 4f-orbitals do not, although f-electrons in inner shells have a smaller screening effect on 6s-valence electrons (Bigeleisen and Wolfsberg, 1957). The lowest energy of a system occurs when the heavier isotopes of Hg are enriched in the chemical species with the lowest number of s-electrons in the bonding or the valence orbital. The largest shifts, therefore, occur when the number of Hg 6s electrons is greatly reduced by the formation of a bond of an ionic nature (to an electronegative element), while the influence of a more covalent bond is less significant. Examples of Hg species in the former category are chloro- or aqua-complexes with high coordination numbers (HgCl_4^{2-} and $[\text{Hg}(\text{H}_2\text{O})_6]^{2+}$) and the latter category includes soft ligands with typical linear bi-coordination ($\text{Hg}(\text{SH})_2$ and $(\text{CH}_3)_2\text{Hg}$). The scale factor of nuclear volume fractionation (β_{NFS}) is defined:

$$\beta_{\text{NFS}} = \frac{\langle r_{198}^2 \rangle - \langle r_{\text{xxx}}^2 \rangle}{\langle r_{198}^2 \rangle - \langle r_{202}^2 \rangle} \quad (21)$$

where $\langle r^2 \rangle$ describes the mean-square nuclear charge radii of different isotopes. Coincidentally, MDF and NFS with ^{198}Hg , ^{200}Hg and ^{202}Hg show almost identical β -values, but ^{199}Hg , ^{201}Hg and ^{204}Hg and to a lesser extent ^{196}Hg show distinct non-mass dependent signatures due to NFS. Only a small proportion of the NFS is mass-independent because it creates a deviation from MDF (Yang and Liu, 2015). The mass-dependent part of the two effects can be synergistic (increasing total fractionation) or antagonistic (decreasing total fractionation), the former being dominant for Hg redox chemistry (Hintelmann and Zheng, 2011; Jiskra et al., 2012). Regular MDF scales are proportionate to $1/T^2$, whereas NVF scales are proportionate to $1/T$ and more prominent than regular MDF for the Hg red-ox reactions studied (Schauble, 2007). Among the commonly measured isotopes 198-202, a minor to moderate level of MIF has been experimentally observed isolated in the odd isotopes 199 ($\leq 0.6\text{‰}$) and 201 as a result of NFS. NFS has been described for equilibrium exchange reactions but has never been extended to kinetic processes. In contrast to the small magnitude observed in natural samples, the possibility has recently been suggested that nonequilibrium isotopic effects of NFS in photodissociation may give rise to a significant magnitude of MIF (Motta et al., 2020b).

The only effect that has been documented to lead to significant odd-mass number Hg MIF (odd-MIF) in present-day surface ecosystems is the magnetic isotope effect (MgIE). MgIE is a purely kinetic effect triggered by the formation of a long-lived radical pair after a primary process that causes homolysis of a Hg - ligand bond upon photolytic excitation. (Fig. 11). Among the stable

isotopes of Hg, only ^{199}Hg and ^{201}Hg (odd mass numbers) have non-zero nuclear spin and momentum, with half-integer ($1/2$ and $3/2$, respectively) spins. MgIE arises when hyperfine coupling (HFC) acts on a spin-coherent solvent-separated radical pair after dissociation by changing the rate of intersystem crossing from singlet to triplet ($S \leftrightarrow T$) or vice versa ($T \leftrightarrow S$) in the odd Hg isotopes. Radical pairing and MgIE are suppressed in mercuric complexes with strong spin-orbit coupling (containing bromine and iodine ligands), favoring spin mixing and return to the ground state, while S-, Cl- and C-bonded complexes with generally weak spin-orbit coupling favor strong MgIE (Motta et al., 2020a). If the radical pair is born in the triplet state (lower panel of **Fig. 11**), HFCs are induced, enriching odd isotopes in the resulting singlet state. The singlet radical pair can then recombine to the ground state, resulting in an odd isotope enrichment in the reactant, expressed as (+)MgIE. When the radical pair is in the singlet state (top panel of **Fig. 11**), the overall effect is to deplete odd isotopes in the reactant, as expressed by (-)MgIE, because mainly the odd isotopes with the majority in the triplet radical pair dissociate into free radicals. A computational study has provided an explanation as to why photodissociation of monomethyl Hg species in nature is observed to yield only (+)MgIE, whereas photolysis of inorganic mercuric complexes may yield positive or negative MgIE, depending on the reaction conditions and the complex ligation (**Section 8.4**).

Thus, odd-MIF results from both the MgIE and NFS mechanisms. MgIE is most effective in a viscous solvent, where a “solvent cage” environment is possible (Turro, 1983). In addition, a seemingly enigmatic even mass number Hg isotope MIF (even-MIF) has been observed in samples of atmospheric origin or deposition. However, an analog atmospheric photochemical anomalous isotope fractionation is well known for the lighter (traditional) elements for which MIF (containing three or more stable isotopes) can be detected, such as oxygen and sulfur. However, understanding the underlying causes of multi-isotope anomalous fractionation is limited because the investigation requires detailed quantum mechanical calculations at the molecular isotope level for, e.g., photo absorption and photodissociation. Recently, rock records have revealed significant even-MIF in the Archean atmosphere, which lacked an ozone (O_3) layer to filter UVC from actinic light, suggesting that contemporary UVC-induced atmospheric chemistry may be responsible for the coupled changes in even-MIF for both Hg and sulfur (Zerkle et al., 2020). Correlations between these entities have also been observed in marine aerosols in the southern hemisphere (Auyang et al., 2022).

MIF (denoted with capital delta, Δ) is defined as the difference between the measured δ -value and that predicted from the measured $\delta^{202}\text{Hg}$ value and the scale factor for kinetic MDF ($\beta_{\text{KIE-MDF}}$) and is approximated for δ -values $< 10\text{‰}$ according to:

Figure 11. General scheme for the photolysis of a molecule to produce a spin-correlated radical pair (RP). The singlet and triplet RPs can be interconverted by intersystem crossing. Both the singlet and triplet RPs can escape from the solvent cage. Only the singlet RP can recombine. Adopted from Turro (1983) and Motta et al. (2020a).

$\Delta^{196}\text{Hg} = \delta^{196}\text{Hg} + 0.508 \cdot \delta^{202}\text{Hg}$, $\Delta^{199}\text{Hg} = \delta^{199}\text{Hg} - 0.252 \cdot \delta^{202}\text{Hg}$, $\Delta^{200}\text{Hg} = \delta^{200}\text{Hg} - 0.502 \cdot \delta^{202}\text{Hg}$, $\Delta^{201}\text{Hg} = \delta^{201}\text{Hg} - 0.752 \cdot \delta^{202}\text{Hg}$ and $\Delta^{204}\text{Hg} = \delta^{204}\text{Hg} - 1.493 \cdot \delta^{202}\text{Hg}$. The MIF enrichment factor $E^{\text{xxx}}\text{Hg}$ for a process is calculated by:

$$E^{\text{xxx}}\text{Hg} = \epsilon^{\text{xxx}}\text{Hg} - \epsilon^{202}\text{Hg} \cdot 0.252 \quad (22)$$

1445 where xxx is the mass number.

The non-mass-dependent odd isotope fractionation observed in nature spans a range of more than 12% (Kwon et al., 2020).

8.1.1 MIF Signatures as Additional Tracer

The isotopic measurement of Hg results in up to six useful isotopic signatures ($\delta^{202}\text{Hg}$, $\Delta^{196}\text{Hg}$, $\Delta^{199}\text{Hg}$, $\Delta^{200}\text{Hg}$, $\Delta^{201}\text{Hg}$ and $\Delta^{204}\text{Hg}$). In addition, pairs of these signatures have been utilized to distinguish between fractionation mechanisms. The relationship between these
 1450 signatures is typically illustrated using a three-isotope plot. To interpret experimental results satisfactorily, specific robust linear regression methods are recommended (Stephan and Trappitsch, 2023). Based on early results (Bergquist and Blum, 2007), it was assumed that photoreduction of Hg^{II} to Hg^0 would result in a $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ ratio of unity. Several investigated photoreactions exhibit just a ratio of 1 within the margin of error (refer to **Table 4, Section 8.4**). However, further data has shown that this is not always the case, as the slope depends on factors such as the complexing ligand and reaction conditions. Clearly, the odd-MIF signature for the
 1455 photolysis of organomercurials is different from that stipulated for inorganic Hg. The photolytic degradation of MMHg^+ species exhibits a variation of $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ ranging from 1.17 to 1.38 depending on reaction conditions (Bergquist and Blum, 2007; Chandan et al., 2015; Rose et al., 2015; Malinovsky et al., 2010). NFS gives rise to a generally much weaker MIF than for MgIE with a larger anomalous fractionation of ^{199}Hg compared to ^{201}Hg , approaching a ratio of ~1.6. However, confirmation of the NFS should be done using alternative methods when the experimentally measured NFS is too limited to determine a definitive odd-MIF ratio (Motta et al., 2020b). Another
 1460 commonly used parameter is $\Delta^{199}\text{Hg}/\delta^{202}\text{Hg}$, which describes the degree of odd-MIF in relation to conventional MDF. The even-MIF signature of $\Delta^{200}\text{Hg}$ to $\Delta^{204}\text{Hg}$, which is negative in natural samples (air, rainfall and fish), is discussed in **Section 8.2.4**.

8.2 Isotopic characteristics of atmospheric mercury

Fig. 13 summarizes the magnitude of isotopic observations reported in the literature on the main fractions of Hg in the atmosphere, namely gaseous Hg dominated by Hg^0 , particle-bound Hg and Hg associated with hydrometeors (rain, snow and water from clouds
 1465 and fog). Here, $\delta^{202}\text{Hg}$, $\Delta^{199}\text{Hg}$, and $\Delta^{200}\text{Hg}$ are shown to describe MDF, odd-MIF, and even-MIF, respectively. The number of isotopically resolved samples has increased dramatically in recent years, and the reader should consult the literature regularly to keep up to date. On the other hand, this development justifies revisiting the topic, even though it has been dealt with satisfactorily in the recent past (Kwon et al., 2020). It should be noted that the spatial distribution of available data is heavily skewed toward North America, Europe, and East Asia, and observations from large parts of the world are missing (**Fig. 13**). However, as far as the marine
 1470 remote regions are concerned, recent oceanographic expeditions have contributed to an increasing amount of data. Further below, the in situ and laboratory experiments performed so far to study the gas exchange of Hg^0 between air and water, soil and foliage in terms of isotope fractionation are discussed.

8.2.1 Gaseous Hg

The following part excludes an early series of measurements where the air was not filtered prior to sampling (Rolison et al., 2013).
 1475 The referenced series of measurements should be considered as total airborne Hg, not total gaseous mercury (TGM). TGM shows a significant spread for $\delta^{202}\text{Hg}$ (−3.75 to 1.52‰) and $\Delta^{199}\text{Hg}$ (−0.62 to 1.32‰), but is more limited for $\Delta^{200}\text{Hg}$ (−0.22 to 0.11‰). Analogous to Hg^{II} deposited in biomass and fossil fuels such as coal (Sun et al., 2014), Hg^0 in natural gas (Washburn et al., 2018) and in smoke from spontaneous combustion in coal fields (Sun et al., 2023) has strongly negative $\delta^{202}\text{Hg}$ -values. This differs from the majority of Hg^0 in ambient air, which is isotopically heavy (often with positive $\delta^{202}\text{Hg}$ values). Terrestrial background air (rural,
 1480 subpolar and forest in **Fig. 13a**) has higher $\delta^{202}\text{Hg}$ values because it is modified by vegetation, which preferentially incorporates lighter isotopes of Hg^0 into the foliage. Foliar uptake of Hg^0 is discussed in more detail in **Section 8.6.2**. The estimate of atmospheric

Hg⁰ dry deposition to vegetation has recently been revised upward and constrained to about 2300 Mg yr.⁻¹ (Feinberg et al., 2022), and together with the large negative $\epsilon_{\text{foliage/air}}$ of the process, the global atmospheric Hg⁰ pool is estimated to have a $\delta^{202}\text{Hg}$ mean of 0.5‰, in contrast to that of Hg⁰ from anthropogenic sources (global bulk mean of -0.7‰, Sun et al., 2019). Specific studies of the vertical distribution of Hg⁰ concentration from near the ground to above the canopy for different forest types show clear gradients averaging 10 (Wang et al., 2022) and 20% (Fu et al., 2016b) of ambient Hg⁰, respectively. Under stable conditions, such as during summer nights, Hg⁰ levels were observed to be strongly depleted below the canopy (Fu et al., 2016b; Mao et al., 2008; Poissant et al., 2008; Lan et al., 2012; Fu et al., 2019a). Thus, isotopic measurements of above-canopy air versus in-canopy air (Wang et al., 2022; Fu et al., 2016b) and daytime air versus nighttime air in the forest (Kurz et al., 2020) show statistically significant differences ($p < 0.01$) in $\delta^{202}\text{Hg}^0$. For a deciduous forest in northeast China, Fu et al. (2019a) observed that $\delta^{202}\text{Hg}^0$ in biweekly air samples during the growing season was 0.35 to 0.99‰ higher than during the dormant season. In a subtropical perennial forest in southwest China with little seasonal variation in photosynthetic activity of the vegetation, the existing seasonal variation in $\delta^{202}\text{Hg}^0$ (amplitude 0.4‰) can be related to the influence of long-range transported anthropogenic emissions, which occur mainly during the warmer seasons. However, in the last 5 to 7 years the air concentrations of Hg⁰ have been falling rapidly in the two mentioned forest reserves due to decreasing regional anthropogenic emissions, as can be seen in the median value of $\delta^{202}\text{Hg}^0$ shifting from 0.42 to 0.46‰ and from 0.17 to 0.57‰. The marine $\delta^{202}\text{Hg}^0$ data ($n = 112$) are significantly lower (Wilcoxon test, $p < 0.01$) than those from the forest ($n = 113$). Based on coastal measurements in the Gulf of Mexico, Demers et al. (2015) determined that the measured marine-influenced air isotopically represents background air modified by Hg⁰ emitted from the sea after being formed in surface water by photoreduction. Measurements in the marine boundary layer (MBL) of the offshore East China Sea indicated that airborne Hg⁰ is essentially a binary mixture of anthropogenic outflow from mainland China and air masses from the sea (significantly correlated $\delta^{202}\text{Hg}^0$ and $\Delta^{199}\text{Hg}^0$ vs. $C_{\text{Hg}^0}^{-1}$), with an extrapolated $\Delta^{199}\text{Hg}^0$ of -0.26‰ for the marine component. The extrapolated $\Delta^{199}\text{Hg}^0$ -value agrees well with observations made in Hawaii with passive samplers (Szponar et al., 2020) as well as with the signatures of a larger number of samples from Mauna Loa (3397 m a s l) in the free troposphere (Tate et al., 2023; Yamakawa et al., 2024).

The generally negative $\Delta^{199}\text{Hg}^0$ in the background air can be considered to reflect Hg⁰ added to the pool after Hg^{II} photoreduction in Earth's surface reservoirs interacting with the atmosphere and aerosols (of the variant that induces (+)MgIE in the reactant and complements it by depleting the product Hg⁰ isotopically in odd isotopes). This is supported by atmospheric Hg⁰ exhibiting $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ slopes close to unity (Kwon et al., 2020), similar to aqueous photoreduction of inorganic Hg^{II}. However, not all photo-controlled Hg⁰ re-emissions from terrestrial ecosystems contribute to negative $\Delta^{199}\text{Hg}^0$ in the atmosphere. A branch-level study of air-foliage Hg⁰ gas exchange in a subtropical perennial beech forest revealed bidirectional fluxes, where leaf uptake of Hg⁰ from ambient air is balanced by reemission of Hg⁰ that was previously metabolized and bound as Hg^{II} in the leaf interior, but subsequently photo-reduced and recirculated, and not as a retro flux of recently deposited Hg⁰ at the leaf surface (data in Fig. 17a). This re-emission is isotopically distinct in that it is enriched in odd isotopes compared to ambient air (Yuan et al., 2019b), indicating that leaf photoreduction induces (-)MgIE, as reported for Hg^{II} bound to organic ligands containing sulfur or nitrogen of low oxidation states (Motta et al., 2020b; Zheng and Hintelmann, 2010b). A mass balance based on isotope measurements indicates that re-emission from the beech foliage compared to uptake of Hg⁰ from the air gradually increases from emergence to senescence with an average of 30% (Yuan et al., 2019b). Observations from a temperate deciduous forest with 0.06 – 0.09 ‰ higher $\Delta^{199}\text{Hg}^0$ values during the growing season compared to winter suggest that foliar Hg⁰ efflux contributes to the enrichment of odd Hg isotopes in the atmosphere (Fu et al., 2019a).

The large spread in the odd-MIF shown by Hg⁰ in polar air (Araujo et al., 2022; Yu et al., 2021; Sherman et al., 2010, Fig. 13a) is due to the part of the collected data that includes AMDEs of Hg⁰ in the spring and summer period, when Hg⁰ is enhanced by a contribution of reemissions from the cryosphere. Fig. 12 shows the isotopic composition of fractionated airborne Hg into Hg⁰ and Hg^{II} (RM) during the Arctic spring (at three stations) compared to the corresponding data from a background station in the Pyrenees (Fu et al., 2021). With respect to $\Delta^{199}\text{Hg}$, a dichotomy between the polar and temperate data is striking for both Hg⁰ and Hg^{II} (RM), in that montane oxidized Hg is enriched in a limited range (0.14 to 0.77‰) while the polar is depleted in a greater range (-2.15 to -0.18‰), with a complementary relationship existing for Hg⁰ (-0.31 to -0.16‰ versus -0.22 to 1.32‰). This relationship could be caused by surface layer airborne Hg

1525 strongly influenced by the oxidation of Hg^0 to Hg^{II} controlled by halogen atoms during AMDEs, processes characterized by E^{199}Hg of -0.37% and -0.23% for Cl^\bullet -initiated and Br^\bullet -initiated oxidation (Sun et al., 2016). In this way, the remaining reactant is driven to higher $\Delta^{199}\text{Hg}^0$ and the molecular products assume negative $\Delta^{199}\text{Hg}^{\text{II}}$ values. However, this interpretation is not supported by the measured $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ ratio in airborne Hg of close to unity, which is more typically a reflection of the Hg^{II} photo-reduction ((-)MgIE) taking place in the snow, and it has been proposed that this process also operates in aerosols of the boundary layer, with Hg^0 reemissions giving
1530 such a strong positive imprint that the entire boundary layer of the Hg^0 pool becomes enriched in odd isotopes (Araujo et al., 2022). Isotopic measurements of $\text{Hg}^{\text{II}}(\text{g})$ separated from $\text{Hg}^{\text{II}}(\text{p})$ using CEM have commenced and are anticipated to elucidate the mechanisms underlying the pronounced fractionation of odd isotopes in airborne Hg^0 and Hg^{II} . Several such datasets are currently in preparation for publication. Furthermore, Hg^0 in the Arctic during the dark period of the year and from the Antarctic Peninsula throughout the year (Yu et al., 2021) share a consistently slightly negative $\Delta^{199}\text{Hg}^0$ with other background air (represented by montane air in Fig. 13a). In the late
1535 Arctic summer, minimum $\Delta^{199}\text{Hg}^0$ values (approaching -0.5%) are observed uniformly without much variation from coastal stations around the Arctic Ocean, which are thought to result from photoreduction of cryospheric Hg^{II} , a substrate which has been strongly depleted of odd isotopes during months of long sunshine (Araujo et al., 2022).

$\Delta^{200}\text{Hg}^0$ is generally negative for the non-fossil/anthropogenic sources, while the remainder is significantly shifted to higher values (Wilcoxon T-test, e.g., natural gas vs. arid data, $p < 0.01$). As mentioned above, even-MIF is generated exclusively by atmospheric
1540 chemical processes, which may be mainly limited to molecular $\text{Hg}^{\text{I,II}}$ photolysis processes (Sun et al., 2022), of which Hg^0 is a product. The marine and polar $\Delta^{200}\text{Hg}^0$ data have the most negative values. For example, a recently published TGM record from Mauna Loa (not shown in Fig. 13) in the Pacific Ocean has $\Delta^{200}\text{Hg}$ values down to -0.20% (Yamakawa et al., 2024). The polar pool as a unit shows a significant shift towards lower $\Delta^{200}\text{Hg}^0$ values compared to the forest pool (Wilcoxon T-test, $p < 0.05$). One can only speculate as to the reason, but it should be mentioned in the context of a halogen-rich environment that any presence of Cl-initiated
1545 Hg^0 oxidation in the gas phase will result in depletion of ^{200}Hg in the reactant pool ($\text{E}^{200}\text{Hg} \sim 0.06\%$, Sun et al., 2016). Due to its relatively limited range, ambient $\Delta^{200}\text{Hg}^0$ & $\Delta^{204}\text{Hg}^0$ is considered a conservative tracer of atmospheric Hg^0 deposition, and terrestrial surface and water $\Delta^{200}\text{Hg}$ & $\Delta^{204}\text{Hg}$ values can constrain the relative contribution of Hg^0 to Hg^{II} deposition. Throughout, a median value of -0.05% (IQR -0.02 to -0.08%) of $\Delta^{200}\text{Hg}^0$ was used to calculate this contribution in atmospheric transfer to soil ($\Delta^{200}\text{Hg}^{\text{II}} \sim 0\%$, Enrico et al., 2016; Zhou et al., 2021; Zheng et al., 2016) and oceans ($\Delta^{200}\text{Hg} \sim -0.04\%$, Jiskra et al., 2012). Quantitative
1550 AMDEs observed in Alaska are isotopically mass-balanced in that $\Delta^{200}\text{Hg}^{\text{II}}$ in snow (-0.06%) corresponds, within the measurement uncertainty, to that in ambient Hg^0 (-0.05%).

8.2.2 Aerosol-bound Hg

While Hg^0 has a relatively long lifetime and $\text{Hg}^{\text{II}}(\text{g})$ a short lifetime, the lifetime of particle-bound Hg (PBM, Hg_p^{II}) reflects that of particles, which varies from days to months due to their size and composition. Isotopic analyses have been performed on airborne $\text{PM}_{2.5}$,
1555 PM_{10} , and TSP, as well as on particles in precipitation. In the literature, studies of urban air, regionally polluted air, and air associated with anthropogenic emissions (CFPP, traffic and waste incineration, etc.) are well represented and strongly biased toward Asia. As reviewed and discussed in Kwon et al. (2020), attempts to decipher the cause of seasonal variations etc. in urban and industrial air are challenging in an environment with a plethora of local and regional emission sources. However, it is clear that primary particles from fossil fuel and biomass combustion inherit the clearly negative but highly variable $\delta^{202}\text{Hg}^{\text{II}}(\text{p})$ and the less negative $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$ of the
1560 material. The large range in $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$ (-0.93 to 1.5%) around the origin depends on $\text{Hg}^{\text{II}}(\text{p})$ photoreduction with (+)MgIE, halogen atom-initiated Hg^0 oxidation or, more speculatively, $\text{Hg}^{\text{II}}(\text{p})$ photoreduction with (-)MgIE, driving the data to extremes. In a series of papers, including field measurements of particle-bound isotopic Hg in regionally polluted air (Huang et al., 2016b; Huang et al., 2019; Qiu et al., 2022; Zhang et al., 2022) and laboratory experiments (Huang et al., 2021; Huang et al., 2015), Chen and colleagues have drawn attention to the effect of (+)MgIE photoreduction, which is accelerated in the presence of a particle surface liquid layer (wet haze)
1565 and water-soluble organic carbon as a reducing agent (Zhang et al., 2022). Several peripheral monitoring stations in China, primarily receptors of long-range particles transported domestically or transboundary, generally measure positive $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$ (Fu et al., 2019b). A strong anticorrelation between $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$ (up to $\sim 1.2\%$) and the concentration of particle-bound Hg, rationalized as caused by photo

reduced Hg^0 loss from the aerosol that initially has a near-zero $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$, was observed for the stations with northeastern China and the regions along the lower reaches of the Yangtze River to its mouth, respectively, as the major potential source area (Fu et al., 2019b). The results indicate that the globally modeled tropospheric lifetime of Hg^{II} against photoreduction in aerosols and clouds of nearly two weeks (Horowitz et al., 2017) is significantly shorter in the East Asian region plausibly due to a higher fraction of organic aerosol. As can be seen in **Fig. 13b**, there is a statistical anomaly in the PBM polar data for all reported isotopic signatures: positively shifted $\delta^{202}\text{Hg}^{\text{II}}(\text{p})$, negatively shifted $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$ and negatively shifted $\Delta^{200}\text{Hg}^{\text{II}}(\text{p})$. It is represented in both Arctic (Araujo et al., 2022; Zheng et al., 2021) and Antarctic (Auyang et al., 2022; Li et al., 2020a) data in conjunction with AMDEs. In the high Arctic ($\sim 83^\circ\text{N}$), there is good isotopic agreement between ambient Hg^0 and PBM associated with nearly complete AMDEs, as would be expected. At the same time, for less quantitative oxidation, PBM is found to be isotopically lighter than Hg^0 , analogous to kinetic isotope fractionation during oxidation and subsequent uptake of $\text{Hg}^{\text{II}}(\text{g})$ on particles (such as Arctic haze). As described above, halogen atom-driven gas-phase oxidation induces negative $\Delta^{199}\text{Hg}^{\text{II}}$ (Sun et al., 2016; Auyang et al., 2022), which is consistent with the observed signature in PBM. The interpretation of Zheng et al. (2021) that gas-phase oxidation uniquely shapes isotopic fractionation has been challenged by Araujo et al. (2022) who instead consider $(-)\text{MgIE}$ photoreduction in the aerosol as the imprinting source. The uniquely high positive $\delta^{202}\text{Hg}^{\text{II}}(\text{p})$ values (up to $\sim 3\text{‰}$ and anticorrelated with $\Delta^{199}\text{Hg}^{\text{II}}(\text{p})$) measured in coastal Antarctica interpreted as originating from air masses transported by katabatic winds from the inland plateau, where oxidation of Hg^0 persists during summer (Li et al., 2020a). Under precipitation (**Section 8.3**), the high $\Delta^{200}\text{Hg}^{\text{II}}$ values measured in southern Canada are addressed, noting that this also applies to the particulate fraction in precipitation, which is included in the rural PBM category (**Fig. 13b**).

8.2.3 Hg in precipitation

Measurements of Hg isotopes in precipitation samples (including fog and cloud water) have been reported at sites in the Northern Hemisphere (map in **Fig. 13c**), most in North America. Precipitation samples show the largest scatter in both $\Delta^{199}\text{Hg}$ and $\Delta^{200}\text{Hg}$ compared to Hg^0 and PBM. Nevertheless, the isotopic distribution pattern in precipitation water is generically similar to that of PBM, which is scavenged in precipitation during rainout and washout processes. Precipitation in the vicinity of anthropogenic emission sources (such as CFPP) tends to be isotopically distinct with particularly negative $\delta^{202}\text{Hg}^{\text{II}}$ values (Sherman et al., 2012). Precipitation from more pristine areas has $\delta^{202}\text{Hg}^{\text{II}}$ that is shifted in a positive direction (significant for marine, polar and rural categories, Wilcoxon t-test, $p < 0.01$) compared to urban precipitation and precipitation near point sources. General differences between Hg^0 and precipitation/PBM in terms of MIF signatures (negative $\Delta^{199}\text{Hg}^0$ & $\Delta^{201}\text{Hg}^0$ vs. positive $\Delta^{199}\text{Hg}^{\text{II}}$ & $\Delta^{201}\text{Hg}^{\text{II}}$ and negative $\Delta^{200}\text{Hg}^0$ & positive $\Delta^{204}\text{Hg}^0$ vs. positive $\Delta^{200}\text{Hg}^{\text{II}}$ & negative $\Delta^{204}\text{Hg}^{\text{II}}$, respectively) are explained by atmospheric redox processes (Auyang et al., 2022; Kwon et al., 2020). In the case of even-MIF, chlorine atom-initiated gas-phase oxidation is known to induce a limited positive $\Delta^{200}\text{Hg}^{\text{II}}$ in the product. However, its observed magnitude definitely cannot explain the highest $\Delta^{200}\text{Hg}^{\text{II}}$ measured in precipitation (Kurz et al., 2021; Chen et al., 2012; Yuan et al., 2022) in North America. Cai and Chen (2015) reported a trend towards increasing $\Delta^{200}\text{Hg}^{\text{II}}$ in background precipitation as one moves northwards along the mid-latitudes of the Northern Hemisphere ($\sim 20\text{--}45^\circ\text{N}$), but only with data from a unique station anomalous with higher statistical significance. A one-year measurement north of Lake Ontario (Chen et al., 2012), separated by a full decade from measurements at the same site limited to the colder parts of the year (Yuan et al., 2022), have together shown that precipitation in winter often contains high values of $\Delta^{200}\text{Hg}^{\text{II}}$ (and at the same time strongly negative $\Delta^{204}\text{Hg}^{\text{II}}$ values). During the full-year measurement in 2010, filtered precipitation samples showed $\Delta^{200}\text{Hg}^{\text{II}}$ in the range of 0.21 to 1.24‰, while during the colder months around the turn of the year 2020–21, the same category of samples contained between 0.25 to 1.19‰ and between -1.97 to -0.37‰ for $\Delta^{200}\text{Hg}^{\text{II}}$ and $\Delta^{204}\text{Hg}^{\text{II}}$ respectively. During the last campaign, isotopic analysis was also performed on precipitation particles, which showed comparatively significantly lower positive $\Delta^{200}\text{Hg}^{\text{II}}$ values (up to 0.37‰) and less negative $\Delta^{204}\text{Hg}^{\text{II}}$ values (down to -0.84‰). Intermittently, the particle phase has the opposite sign to the solute phase in the same precipitation sample with respect to both odd- and even-MIF. This, together with a time series of unrelated odd-MIF and even-MIF trends during events with large fluctuations in these values, has been interpreted as the influence of the circumpolar vortex with varying contributions of tropospheric and stratospheric air, with transport of the latter airmasses explaining more extreme even-MIF values (Yuan et al., 2022). Rain samples compared to snow samples from the Canadian station north of Lake Ontario generally show more moderately positive $\Delta^{200}\text{Hg}^{\text{II}}$ values, consistent with observations in the

mid-latitudinal USA (Kurz et al., 2021; Demers et al., 2013; Gratz et al., 2010; Sherman et al., 2015), Europe (Fu et al., 2021; Enrico et al., 2016), the Tibetan Plateau (Yuan et al., 2015) and over the Pacific Ocean (Motta et al., 2019; Washburn et al., 2021). Although cloud water (Fu et al., 2021; Zhen et al., 2024) and fog water (Washburn et al., 2021) have been isotopically analyzed, there are no apparent differences between them or significant differences with rain samples. In cloud water, Hg speciation with increasing complexation to DOM has been shown to correlate with odd-MIF (Zhen et al., 2024), consistent with the view that these mercuric complexes are photolabile. Polar precipitation samples (only those from AMDEs are reported in the literature, Araujo et al., 2022; Sherman et al., 2012; Zheng et al., 2021) consistently show slightly negative $\Delta^{200}\text{Hg}^{\text{II}}$, which differs from precipitation samples of all other provenances, which show positive median values. The reason for these observations is plausibly that oxidation is so advanced during these AMDEs that Hg^{II} scavenged by precipitation approaches the same isotopic values as Hg^0 in the polar air had before the AMDE.

1620 8.2.4 Even-MIF ($\Delta^{200}\text{Hg}/\Delta^{204}\text{Hg}$) ratios in atmospheric samples

Early studies by Gratz et al. (2010) and Chen et al. (2012) showed that MIF anomalies of even mass number isotope ^{200}Hg are regularly present in atmospheric precipitation. Later, measurements (Demers et al., 2013) were also made at $\Delta^{204}\text{Hg}$, which is more challenging due to the limitations of ion beam collector designs (Blum and Johnson, 2017). The anomaly of $\Delta^{204}\text{Hg}$ was generally larger and of the opposite sign to that of $\Delta^{200}\text{Hg}$. The $\Delta^{200}\text{Hg}/\Delta^{204}\text{Hg}$ ratio has been calculated based on spatial averages and exclusively on precipitation samples, which are usually above measurement uncertainty. For example, a slope of -0.5 was previously reported (Blum and Johnson, 2017) and later adjusted to -0.4 (Kwon et al., 2020) using this method as more data became available. However, when all individual precipitation data up to 2020 were combined, Kwon et al. (2020) obtained a significantly lower regression slope of -0.24 . **Fig. 14** shows the even-MIF data ($\Delta^{200}\text{Hg}$ vs. $\Delta^{204}\text{Hg}$) binned into geographical regions (categorized as Hg^0 , rain/mist/cloud, PBM, RM, and snowfall samples). Linear regression of York type $\Delta^{200}\text{Hg}$ against $\Delta^{204}\text{Hg}$ gives slopes between -0.07 and -0.53 for data grouped by site and category for data of statistical significance ($p \leq 0.05$, indicated by *). When the global data grouped by sample type are analyzed separately, significant ($p < 0.001$ ***) slopes of -0.51 ± 0.02 ($n = 45$, Kurz et al., 2021; Yuan et al., 2022), -0.41 ± 0.03 ($n = 108$, Fu et al., 2021; Demers et al., 2015; Enrico et al., 2016; Sherman et al., 2012; Yuan et al., 2022; Demers et al., 2013; Donovan et al., 2013; Motta et al., 2019; Washburn et al., 2021), -0.29 ± 0.06 ($n = 58$, Fu et al., 2019b) and -0.11 ± 0.02 ($n = 295$, Fu et al., 2021; Kurz et al., 2020; Demers et al., 2015; Tate et al., 2023; Araujo et al., 2022; Enrico et al., 2016; Kurz et al., 2021; Demers et al., 2013; Yamakawa et al., 2017; Jiskra et al., 2019; Fu et al., 2016a; Wu et al., 2023a) are obtained for snowfall, rain and fog, particulate matter and Hg^0 respectively. The reaction mechanism triggering even-MIF could be due to photo-dissociation in the gas phase (Sun et al., 2022) or on surfaces (Fu et al., 2021). This should lead to varying fractionation depending on the species undergoing decomposition. As a result, atmospheric Hg^{I} and Hg^{II} species will differ in fractionation from one another, possibly explaining the divergent $\Delta^{200}\text{Hg}/\Delta^{204}\text{Hg}$ for $\text{Hg}^{\text{II}}(\text{aq})$, $\text{Hg}^{\text{II}}(\text{p})$, and $\text{Hg}^0(\text{g})$.

Figure 12. A comparison of the MDF and odd-MIF signatures for atmospheric Hg^0 and RM, measured during Arctic AMDEs and in the Pyrenees during winter, reveals notable contrasts.

1650 8.3 Isotope fractionation during gas-phase oxidation

Data on Hg stable isotopic fractionation during gas-phase chemical reactions of Hg are limited. However, in addition to the published studies on the fractionation during the oxidation of Hg^0 initiated by Cl and Br atoms (Sun et al., 2016) and during the oxidation of electronically excited Hg^0 in the presence of synthetic air (Sun et al., 2022), a thesis work of provides additional data (Sun, 2018), which are highlighted here.

1655 8.3.1 Ground-state Hg^0 oxidation in air

Isotope fractionation during the oxidation of Hg^0 vapor in the ground state has been studied for the reactions initiated by $\text{Cl}^\bullet/\text{Br}^\bullet/\text{OH}/\text{O}_3/\text{BrO}^\bullet$ in air at 750 torr and 298 K as listed in Table 7. Fig. 15 shows that the Br^\bullet and OH reactions produce a lighter isotope enrichment in the reactant, unlike the other reactions that follow the kinetic isotope effect (KIE). This deviation from KIE occurs because the Hg^0 to Hg^{I} step (Rxn G1-G3, Table 3) in the overall Hg^0 to Hg^{I} oxidation is reversible. The equilibrium isotope effect (EIE) is especially invoked for the OH and Br^\bullet channels being affected by thermal and photolytic dissociation (BrI , OH1), creating a cyclic replenishment of Hg^0 at higher temperatures, as discussed in Section 5.1.2. EIE predicts the enrichment of heavier isotopes in species with a stronger bonding environment (e.g., HgBr_2 , $\text{Hg}(\text{OH})_2$, Schauble, 2007). However, at temperatures in the upper atmosphere and during AMDEs in polar regions, the rate of $\text{BrIb}/\text{OH1b}$ becomes much lower and the oxidation mechanism moves towards irreversibility, potentially leading to dominance of KIE at lower temperatures. The chlorine-atom-initiated reaction already displays KIE at 298 K, which is related to the relative thermal stability of the HgCl intermediate. All the atmospherically relevant reactions investigated (Cl^\bullet , Br^\bullet and OH) give rise to (+) odd-MIF, which is most pronounced for the Cl-initiated reaction ($E^{199}\text{Hg} = -0.37\text{‰}$) compared to the others ($E^{199}\text{Hg} = -0.23\text{‰}$ and -0.18‰ for the Br and OH reactions, respectively). Analogous to $\text{OH} + \text{OH}$ recombination yielding H_2O_2 in the gas phase (Velivetskaya et al., 2016; Velivetskaya et al., 2018), odd-MIF plausibly occurs due to MgIE triggered by radical-radical ($^\bullet\text{HgX} + \text{Y}^\bullet$) interactions that occur during reactions leading to the formation of

1670 $\text{XHg}^{\text{II}}\text{Y}$ species. It should be noted that the diagnostic ratio of $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg} \sim 1.9$, which is observed for the $\text{Hg}^0 + \text{Cl}^\bullet$ system, differs significantly from the ratios reported in the photoreduction of Hg^{2+} complexes in water (Section 8.4.1).

Figure 15. Linearized Rayleigh diagram for $\delta^{202}\text{Hg}$ in Hg^0 during Cl, Br, OH, O_3 and BrO oxidation experiments at ~ 298 K showing normal and inverse KIE. Each point represents a single experiment.

Table 7. Experimental fractionation factors (ϵ , E) determined in the gas-phase oxidation studies.

Oxidant	Precursor	Bath gas	$\epsilon^{202}\text{Hg}$ (‰)	$E^{199}\text{Hg}$ (‰)	Even-MIF
Cl^\bullet	$\text{CCl}_3\text{C}(\text{O})\text{Cl} + \text{h}\nu$	air	-0.590	-0.370	detected
Br^\bullet	$\text{CHBr}_3 + \text{h}\nu$	air	0.740	-0.230	
O_3	n/a	air	-0.370	-0.120	
$^\bullet\text{OH}$	$\text{H}_2\text{O}_2 + \text{h}\nu$	air	0.580	-0.180	
"BrO"	$\text{CHBr}_3 + \text{O}_3 + \text{h}\nu$	air	-3.105	1.009	

1675 **8.3.2 Hg^0 oxidation initiated by photosensitized reactions**

Ancient rock samples show a significant occurrence of even-MIF in the Archean atmosphere (~ 2.5 Ga, Zerkle et al., 2020), which lacked an O_3 layer to filter out deep UV in the actinic light. However, in the modern atmosphere, even MIF does not appear to occur significantly in Hg redox processes at the Earth's surface. A current atmospheric budget reveals notable imbalances between the $\Delta^{200}\text{Hg}$ in Hg emissions from and deposition to the Earth's surface ($0.025 \pm 0.032\text{‰}$ vs. $0.073 \pm 0.019\text{‰}$, Fu et al., 2021). To maintain a steady state, even-MIF sources in the atmosphere are necessary. Studies have shown that UVC-induced Hg^0 vapor in the electronically excited state, $\text{Hg}^*(^3\text{P}_1)$, undergoes chemical transformation under both artificial (Mead et al., 2013) and modern (Sun et al., 2022) atmospheres, resulting in large MIF of both odd and even Hg isotopes. There are claims (Blum and Johnson, 2017; Mead et al., 2013) that the $\Delta^{200}\text{Hg}/\Delta^{204}\text{Hg}$ ratios found in nature are similar to those present in the glass housing of compact fluorescent lamps (CFLs). However, the $\Delta^{199}\text{Hg}^{\text{II}}$, $\Delta^{200}\text{Hg}^{\text{II}}$, and $\Delta^{204}\text{Hg}^{\text{II}}$ in the CFL housing exhibit opposite signs to those observed in nature (cf. Fig. 13 & 14). Laboratory experiments have shown that the net oxidation of Hg^0 by reaction between excited state Hg^0 and atmospheric O_2 , identical to the driving photosensitized reaction for the turnover of Hg^0 in the upper stratosphere (Rxn G12b counteracted by Rxn G71, Table 3), scrambles the systematics of all Hg isotopes in an entirely mass-independent manner. These laboratory experiments and atmospheric samples show similar observations for the $\Delta^{200}\text{Hg}/\Delta^{204}\text{Hg}$ ratio, suggesting that photodissociation is a potential chemical mechanism for triggering even-MIF in the atmosphere (Sun et al., 2022). This review outlines new findings on atmospheric Hg chemistry, supporting the fundamental importance of photodissociation processes (Sections 5.1.2 and 5.1.4). In addition to the gas phase, surface-mediated photolysis of mercurous halide species has also been proposed to give rise to even-MIF (Fu et al., 2021). However, theoretical challenges still need to be solved at the quantum mechanics level to generically expand our understanding of anomalous isotope effects for traditional and non-traditional elements (Lin and Thiemens, 2024). Nevertheless, further research in this area should be encouraged, including both field studies and laboratory experiments.

1695 8.4 Isotope fractionation during aqueous-phase red-ox transformation

Hg transformation in the aqueous phase has been reviewed extensively, including stable Hg isotope studies (Hintelmann and Zheng, 2011). This article will not focus on biotic processes, such as microbial reduction, methylation and demethylation, and phototrophic microbial reduction. Kritee et al. (2013) and Tsui et al. (2020) provide overviews of this field. The focus is on abiotic processes, excluding those involving coordination with macromolecular heterogeneous ligands such as dissolved organic matter or fractions, and instead on low molecular weight ligands, including those with N-, O-, S-, or (pseudo)halide donors. This includes inorganic and organic ligands, and oxidizing and reducing processes (**Section 6**).

8.4.1 Reduction

To recapitulate **Section 8.1**, in addition to conventional MDF, isotopic effects in NFS and MgIE occur for Hg during chemical transformation in the aqueous phase. MDF and NFS are present in all reactions to varying magnitude and in all mechanisms and have a thermodynamic nature. In contrast, MgIE is the kinetic effect and is indicative of spin-selective reactions involving a paramagnetic intermediate. Therefore, MgIE is the only isotope effect that detects the mechanism of the reaction. MgIE can be both thermally and photolytically induced and can be two-dimensional (+ or – depending on the reaction conditions, Zheng and Hintelmann, 2010b) or one-dimensional (exclusively +) depending on the identity of the Hg^{II} complex (Motta et al., 2020a). In cases where the spin-selective reaction can be induced thermally, the radical pair is generated almost exclusively as a singlet (Buchachenko, 2018), which is spin-forbidden to react (dissociate) further into products. For a singlet spin forbidden reaction compared to a triplet spin allowed reaction, the magnitude of the MgIE-MIF is more limited. However, many Hg^{II} complexes have a narrow energy separation of a variety of excited states, indicating that the intermediate radical pair can evolve in a triplet or singlet state. From studies of Hg^{2+} photoreduction in the presence of organic ligands (which consistently follow a pseudo-first-order kinetic pathway), it has been shown that, depending on the degree of $\text{Hg}^{2+}(\text{aq})$ turnover, weak MIF is initially induced by NFS and then, when most of the $\text{Hg}^{2+}(\text{aq})$ has been converted, there is a shift to strong MIF induced by MgIE, the onset of which coincides with strong suppression of MDF (Motta et al., 2020b; Zheng and Hintelmann, 2010b). One explanation why MgIE first appears closer to complete Hg^{II} reduction is, at least in part, that the termination radical-radical step when Hg^0 is split off (in a bimolecular reaction, such as $\text{Hg}^{+\bullet} + \text{C}_2\text{O}_4^{\bullet-}/\text{CO}_2^{\bullet-}$ in the photoreduction of $\text{Hg}(\eta^2\text{-C}_2\text{O}_4)$) is favored by a decreasing concentration ratio of oxidized Hg to bulk ligand (Zhao et al., 2021). As shown in **Fig. 11**, (–)MgIE is induced when the radical pair is generated in a singlet state and (+)MgIE is induced when the excitation occurs in a triplet state. Ligand field strength, in combination with atomic orbital hybridization theory, has been used to illustrate MgIE in the (photo)reduction of Hg^{II} complexes. This has been suggested to vary as a function of, among other things, the arrangement of the ligands around Hg^{2+} , the coordination strength of the ligands, and the presence/absence of light along with its wavelength (Epov, 2011a; Epov, 2011b). As discussed in **Section 4.2**, reduced S- and reduced N-containing groups are soft (strong field) ligands, whereas O-donating groups are hard (weak field) ligands. Epov (2011a) rationalized mercuric complexes with strong field ligands such as cysteine ($\text{Hg}(\text{cys})_2^{2+}$) and ethylenediamine ($\text{Hg}(\text{en})^{2+}$) as bright singlets (i.e. in the presence of light) with an sp-hybridization at the central atom Hg in two binding orbitals. To undergo a singlet-triplet evolution by hyperfine coupling between magnetic nucleus (^{199}Hg and ^{201}Hg) and electrons to a paramagnetic state, Hg must change its orbital hybridization from sp-linear to sp^2d -planar square so that the transfer of electrons from the soft ligand to Hg can be accomplished.

1730 **Figure 16.** Mechanism proposed by Epov (2011b) for the photoreduction of $\text{Hg}(\text{en})^{2+}$ via a bright singlet excited complex undergoing intersystem crossing preferentially for the odd isotope to the closest triplet state, which can dissociate following a complex reaction.

The figure above shows this schematically for $\text{Hg}(\text{en})^{2+} + \text{light}$ showing $(-)\text{MgIE}$. Analogously, it is postulated that mercuric complexes with O-binding ligands possess a bright triplet state that is more likely (spin allowed) to undergo Hg reduction via 1e-LMCT with an imprint of $(+)\text{MgIE}$.

1735 For a change in spin state to occur, spin-orbit coupling (SOC) must be induced, but if SOC is elevated, spin relaxation or phosphorescence can be induced, which prevents the formation of a separating radical pair during dissociation, making MgIE less relevant (cf. **Fig. 11**). Coupling constants are known experimentally for only a few Hg-containing radicals ($\text{CH}_3\text{Hg}^\bullet$, Karakyriakos and Mckinley, 2004; $^\bullet\text{HgF}$, Knight Jr. et al., 1981; $^\bullet\text{HgCN}$, Knight Jr. and Lin, 1972; $^\bullet\text{HgH}/^\bullet\text{HgD}$, Stowe and Knight, 2002). Recently published theoretical electronic structure simulations have been performed on environmentally interesting Hg halides (Cl, Br, I) and pseudohalides (methanethiol). The study (Motta et al., 2020a) shows that the coupling for reactions involving $^\bullet\text{Hg}^{\text{I}}\text{Br}$ and $^\bullet\text{Hg}^{\text{I}}$ is so high that radical pair formation is inhibited, while for $^\bullet\text{Hg}^{\text{I}}\text{Cl}$ and $\text{CH}_3\text{SHg}^\bullet$ it is sufficient in the caged pair as well as at a low level in the separated pair geometries, allowing MgIE to form. Depending on the identity of the Hg–ligand bond that undergoes homolysis to a radical pair, either quadruple ($X = \text{Cl}, \text{S}$) or double ($Y = \text{C}$) degeneracy can occur between the low-lying electronically excited levels and the ground state in HgX_2 and HgXY compounds, respectively, allowing the photoreduction of HgX_2 to exhibit $(+)\text{MgIE}$ or $(-)\text{MgIE}$ while that of HgXY (i.e. MMHgX) exhibits only $(+)\text{MgIE}$. This is based on the premise that the photolysis of MMHgX is exclusively by cleavage of the weaker Hg–C bond rather than the stronger Hg–X bond. $(+)\text{MgIE}$ is most evident for the photoreduction of MMHg^+ species, as its $^3\sigma\sigma^*$ 1e-LMCT state is energetically separated from other excited states in the paramagnetic intermediate, leading to maximization of MgIE (Motta et al., 2020a). Stable Hg isotopes provide insight into the dynamics and metabolism of inorganic and methylated Hg in biota. In particular, exposure to the former results in subtle odd-MIF with a $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ ratio close to unity at sampling, while for the latter this ratio is higher (~ 1.3) with large odd-MIF (up to $\sim 5\%$ in fish, Li et al., 2022b).

From **Table 8**, which summarizes the isotopic effects quantitatively observed in aqueous-phase laboratory studies, MgIE can have different signs for the same reactant depending on the reaction conditions, as exemplified by the Hg-cysteine-light system. Depending on the degree of photoconversion, reduction of Hg^{II} in the presence of water-soluble diesel soot (aromatic polyacids and humic-like structures) exhibits swings in the direction of MgIE (Huang et al., 2021). A further example of the influence of pH/complexation on the evolution of MgIE can be seen in the UVC photodegradation of MMHg^+ in acidic and alkaline (adjusted with NH_3) solution, where $(+)\text{MgIE}$ is significant in the first case but very limited in the second. For traditional elements with the same reaction mechanism, the strength development of MgIE depends on various factors, including viscosity, triplet sensitizer, and excited state quenchers (Turro, 1983; Buchachenko, 2013). As in the laboratory experiments, both $(+)$ and $(-)$ net Hg MgIE have been observed in samples related to the natural atmosphere, as previously reported in **Section 8.2**. The reaction conditions also affect the degree of turnover of the Hg reactant at which the onset of MgIE occurs, which incidentally does not correlate with a change in the overall reduction rate. Experimental research is needed to better interpret odd-MIF signatures and systematically elaborate the roles of reaction parameters (pH, presence of O_2 , light wavelength, Rose et al., 2015, etc.) in excited state kinetic isotope effects. For example, dissolved O_2 is a well-known quencher of excited triplet states, but radical- O_2 reactions have also been described to induce significant MgIE (Pliss et al., 2019). For the photoreduction of Hg in the presence of multifunctional ligands (such as NOM), stoichiometry (Hg:L ratio) has been shown to play an important role in the magnitude of MgIE induced. For the dissolved organic matter (DOM) fraction from Dorset Lake, Ontario, Zhang and Hintelmann (2009) observed in anoxic photo-experiments an $-E^{199}\text{Hg}$ optimum ($\geq 5\%$) associated with a ligation mode where all S–bonding functional groups are saturated by Hg^{2+} cations and the proportion of Hg–O bonds increases, which increases the ratio of bright triplets to bright singlets and the MgIE becomes increasingly positive. As the Hg:L ratio is further increased, the reduction rate (driven by Hg–O complexes) is significantly affected. The triplet-singlet spin evolution is limited to fewer HgL radical pairs, resulting in a lower $-E^{199}\text{Hg}$ (Epov, 2011a). Photo experiments with Hg^{II} in the presence of DOM extracted from marine phytoplankton give rise to $(-)\text{MgIE}$ during reduction, in contrast to freshwater DOM (Kritee et al., 2018).

As shown in **Table 8**, photo reduction of Hg²⁺ is often, but by no means always, associated with high odd-MIF. For macromolecular entities such as DOM and fulvic acids, and a selection of smaller organic ligands that use O-, N- and S-donor atoms to complex with Hg²⁺, MgIE is induced initially in the photoreduction process, whereas for the amino acid serine, MgIE is triggered only after a significant turnover of Hg²⁺, the onset of which varies significantly depending on the reaction conditions (Zheng and Hintelmann, 2010b; Motta et al., 2020b). The experimental Δ¹⁹⁹Hg/δ²⁰²Hg data are described to follow the same trajectory, regardless of when MgIE kicks in during the serine-assisted photo-reduction. When oxalic acid was screened with a single light experiment (anoxic, pH 6, f_R = 0.11), (+)MgIE was observed, while anoxic time series experiments with UV-B irradiation at pH 3.9 and 5.2 showed no evidence of MgIE in the range investigated down to f_R = 0.01. This is evidence that Hg oxalate complexes can be directly photodegraded by homolysis (Hg(η²-C₂O₄) $\xrightarrow{h\nu}$ Hg^{•+} + C₂O₄^{•-}) as well as heterolysis (Hg(η²-C₂O₄) $\xrightarrow{h\nu}$ Hg + 2 CO₂). Heterolytic photoreduction does not induce MgIE, but shows NFS with limited (-)odd-MIF, as is the case for ligation with the substituted aromatic carboxylic acids shown in the table. This also applies to thermal (dark) reduction by a uni- (e.g. Hg-QH⁺ → Hg⁰ + Q + H⁺) or bimolecular (e.g. Hg²⁺ + Sn²⁺ → Hg⁰ + Sn^{IV}) processes. Although the NFS is a general isotopic effect, its magnitude depends on the shift in the 6s orbital electron density, which is greater for a red-ox reaction than for ligand exchange or evaporation. In turn, ionic Hg complexes have a greater NFS than more covalent complexes upon reduction to Hg⁰. NFS typically produces a characteristic Δ¹⁹⁹Hg/Δ²⁰¹Hg slope of ~1.54 to 1.66 as determined from experimental studies and theoretical calculations. However, the application of linear regression to NFS odd-MIF data (Δ¹⁹⁹Hg vs. Δ²⁰¹Hg) is limited in several cases because the observations are distributed over such a small range that it approaches the scale of the corresponding analytical precision. **Table 8** gives two standard deviations of the slope of the linear fits using York's regression, and intermittently the uncertainty is so large that it does not allow a definitive Δ¹⁹⁹Hg/Δ²⁰¹Hg ratio to be determined. In these cases, it has been suggested that a better indicator of NFS is instead to confirm that the patterns of Hg isotope fractionation observed mimic the odd-even staggering pattern of nuclear charge radii (Motta et al., 2020b). The description of NFS is limited to equilibrium fractionation (**Eq. 21**) and predicts,

1795

³⁹ Refers to closed system

⁴⁰ iApplies to dark conditions, under UVA irradiation demethylation gradually counteracts MMHg⁺ formation.

⁴¹ Potentially explained by photo-degradation of MMHg⁺

like EIE-MDF (Eq. 19), the enrichment of heavier isotopes in the oxidized fraction of the red-ox pair. Calculations performed for a series of Hg^{II} complexes, both binary and heterogeneous, containing simple hard and soft ligands relative to Hg^0 , show that NFS makes the most significant contribution to $\epsilon^{202}\text{Hg}$ in most cases (ranging in total from 46 to 85% at 25°C, Jiskra et al., 2012). The expected mass-independent enrichment $E^{199}\text{Hg}_{\text{NFS}}$ can be calculated based on the calculation of $\epsilon^{202}\text{Hg}_{\text{NFS}}$, using the scale factors $\beta_{\text{KIE-MDF}}$ and β_{NFS}

(Jiskra et al., 2012):

$$E^{199}\text{Hg}_{\text{NFS}} = \epsilon^{202}\text{Hg}_{\text{NFS}} \cdot (\beta_{\text{NFS}} - \beta_{\text{KIE-MDF}}) \approx -0.2 \cdot \epsilon^{202}\text{Hg}_{\text{NFS}} \quad (23)$$

Reduction by Fe^{II} and p-substituted benzoic acids results in one of the highest magnitudes of experimentally observed kinetic MDF (Table 8). The former system has been studied anoxically both as an open and closed system (Schwab et al., 2023), where the fractionation is of Rayleighian model (kinetic) and equilibrium type, respectively. The closed system permits overprinting with the signature of isotopic equilibrium fractionation between Hg^0 and hydrolyzed Hg^{2+} , which has been consistently determined in two independent studies to be -2.63 (Wang et al., 2021) and -2.44‰ (Schwab et al., 2023), respectively. As will be demonstrated below, the magnitude of equilibrium isotope enrichment factors ($\epsilon^{202}\text{Hg}$) between Hg^0 and thiol-bound Hg^{II} is significantly lower (1.1 – 1.6‰), as related to a lower vibrational energy in Hg-S bonds than in Hg-O/Cl bonds.

8.5 Isotope fractionation during complexation, sorption and surface-catalyzed reduction

8.5.1 Processes interfacing the aqueous phase

Theoretical computations of EIE based on MDF and NVE generally agree with experimentally determined fractionation factors for complexation. Competitive complexation of Hg^{II} between one of the typical hard ligands HO^- and Cl^- and a soft one in the form of a thiol resin results in a lighter isotopic signature of the sulfur-bound Hg^{II} pool ($\epsilon^{202}\text{Hg}$ of -0.62 and -0.53‰ , respectively), which is related to increased covalent bonding and electron density in the 6s Hg orbital (Wiederhold et al., 2010). For the sorption of dissolved Hg^{II} on $\alpha\text{-FeOOH}$, the observed isotopic fractionation ($\epsilon^{202}\text{Hg} \sim -0.4\text{‰}$) is exclusively determined by the process in solution, where a vanishingly small pool ($< 0.1\%$) of isotopically lighter cations is in equilibrium with a bulk of neutral Hg^{II} molecules, only the former being sorption active (Jiskra et al., 2012). Equilibration and kinetic fractionation have been reported to describe the precipitation process of $\beta\text{-HgS}$ and HgO , respectively, from an initially acidic solution, with $\epsilon^{202}\text{Hg}$ between precipitate and supernatant being -0.63‰ and -0.32‰ , respectively (Smith et al., 2015). As with the adsorption on goethite, the observed fractionation during the precipitation of metacinnabar is interpreted as an effect of solution chemistry, in this case, a transition from O– to S–bonding for Hg^{II} . In addition to the homogeneous phase reduction of Hg^{II} by Fe^{II} in aqueous solutions (Table 8), the heterogeneous phase reduction of Hg^{II} by surface-bound (adsorbed Fe^{II} on goethite/boehmite) or structural Fe^{II} (magnetite $\text{Fe}^{\text{II}}\text{Fe}_2^{\text{III}}\text{O}_4$, Schwab et al., 2023 and siderite/green rust FeCO_3 , Wang et al., 2021) has been studied isotopically. As shown in Table 9, the isotopic fractionation in heterogeneous reduction is well related in magnitude to that of the homogeneous one by Fe^{II} (Table 8), except in the case of magnetite (in whose structure iron is present in different oxidation states) with much more limited MDF and MIF ($\epsilon^{202}\text{Hg} = -1.38\text{‰}$ and $E^{199}\text{Hg} = 0.13\text{‰}$, respectively). All these processes, when possible to be determined with confidence, demonstrate $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg}$ ratios within the range of 1.56 to 1.62, which indicates that the observed MIF ($E^{199}\text{Hg}$ in the range of 0.13 to 0.34‰) is caused by NVE.

8.5.2 Processes interfacing the gas phase

Section 8.4.1 and Table 8 refer to a study of Hg^{II} photoreduction of aqueous diesel soot, which includes experiments with a stationary soot phase mixed with HgCl_2 on a quartz plate over which a slow flow of Ar gas passes, as discussed below (Huang et al., 2021). In comparison, photoreduction in aqueous and solid phase diesel soot shows equivalent enrichment of heavier isotopes in the Hg reactant of 1.26–1.75‰. This overlaps with the value typical of Hg redox chemistry (Table 8). In contrast to the aqueous phase, the photoreduction in the solid shows a continuous strong MIF (this time positive MgIE induced in the Hg^0 product) throughout the reaction, whereas in the latter case, a large MIF of opposite sign sets in only after $\sim 60\%$ of the reaction. Furthermore, the reduction

rate increases with the carrier gas's humidity. The photo-triggered MgIE is highest when the carrier gas is dehumidified, but decreases rapidly as the RH increases (Table 9)

Table 9. Experimental fractionation factors determined for Hg^{II} complexation, sorption, surface-catalyzed reduction and processes interfacing the gas phase.

8.6 Isotopic fractionation during air-surface Hg⁰ gas exchange

The interaction between atmospheric Hg and the Earth's reservoirs has been discussed only briefly in Section 4.2, as this area has recently been covered by literature review (Sommar et al., 2020). It is crucial to acknowledge that the gas exchange of volatile Hg is bidirectional. Consequently, the net flux of Hg over an ecosystem may represent a delicate balance between opposing processes, including deposition/uptake versus re-emission. The end members of the Hg exchange between surface (biosphere, pedosphere, lithosphere, hydrosphere, and cryosphere) and atmosphere are all isotopically distinguishable (Liu et al., 2024). A combination of bulk measurements and analysis of stable Hg isotope composition allows to separate the contribution of, atmospheric Hg^{II} and Hg⁰ deposition, as well as the local partitioning between Hg⁰ deposition and re-emission. The isotopic composition of atmospheric Hg has been presented and discussed in Section 8.2. In addition to these data, an updated compilation of complementary isotopic Hg data for the reservoirs that are in contact with the atmosphere and thus can exert gas exchange has been produced during the preparation of this review (Liu et al., 2024).

8.6.1 Mixing and fractionation modeling of Hg⁰ deposition and post-depositional processes

Deposition

Isotope-based modeling by binary and ternary mixing with MDF, odd-MIF, and even-MIF signatures of atmospheric Hg⁰ and other Hg pools as end members has been applied to distinguish the fraction of Hg⁰ deposition via vegetated surfaces (Wang et al., 2020b; Enrico et al., 2016; Obrist et al., 2017; Wang et al., 2019b; Li et al., 2022a; Li et al., 2023a; Li et al., 2023b), soil (Zheng et al., 2016; Obrist et al., 2017; Wang et al., 2019b; Wang et al., 2020a), water (Jiskra et al., 2021; Zhang et al., 2023a), throughfall (Wang et al., 2020b) and snow run-off (Douglas and Blum, 2019), estimated to be 60–90%, 32–105%, 50–85%, 34–82% and > 75% of total deposition, respectively. As a proxy for atmospheric Hg⁰, foliage/litter Hg has been used as an end-member in mixing modeling of Hg⁰ inputs to soil (Demers et al., 2013; Jiskra et al., 2015; Zhang et al., 2013), runoff (Jiskra et al., 2017), and stream water (Woerdle et al., 2018), which may introduce bias because a significant fraction of the gross air Hg⁰ incorporated as Hg^{II} in foliage is re-emitted after photoreduction (Yuan et al., 2019b). The contribution of Hg⁰ deposition to vegetation Hg uptake is greatest in foliage, followed by branches, bark, stem and roots (Wang et al., 2020b; Liu et al., 2021a; Sun et al., 2017). The new

1860 Hg isotope evidence has demonstrated that Hg throughfall via canopy and along stems, which were previously assumed to be derived mainly from wet and dry deposition of atmospheric RM (Wright et al., 2016), contains a larger proportion of Hg excreted from biomass, where it originated mainly from Hg⁰ uptake followed by translocation.

Post-deposition

Isotopic and concentration measurements of Hg⁰ jointly in near-surface air and surface pore air/water, in addition to other isotopic data, allow to infer processes by mass balance or Rayleigh-type models at the air-soil interface and in the surface soil (Jiskra et al., 2019; Li et al., 2023a; Yuan et al., 2021; Chen et al., 2023). For boreal poorly drained organic soil horizons (histosols), in contrast to podzols, mixing modeling indicates a significant reductive loss (24–33%) to the atmosphere by abiotic reduction (Jiskra et al., 2015). A further multi-process model is presented herewith, which is designed to elucidate the dynamic evolution of post-depositional Hg (>90% from litterfall) on subtropical forest floor over a period of 500 yr. (Yuan et al., 2020). The results indicate that photolytic and microbial reduction processes exert an influence during the initial few years, but are subsequently superseded by dark redox processes (exhibiting NVE) in the compost, where Hg^{II} became finally inert at depths of >10 cm in the horizon after approximately 420 years. Studies of forest soils in different climatic zones have shown that microbial reduction ($\epsilon^{202}\text{Hg} = -0.4\%$, $E^{199}\text{Hg} \approx 0$, Kritee et al., 2007) plays a dominant role (Yuan et al., 2021; Chen et al., 2023), which for rainforests can explain up to 90% of the Hg^{II} reduction in the upper soil horizon (Yuan et al., 2023b). In an open boreal peatland, photoreduction dominated the post-depositional process, accounting for the transformation of 30% of the annually deposited Hg (Li et al., 2023a).

8.6.2 Enclosure and related flux measurements

Experimental investigations employing dynamic flux chambers (DFCs) have been conducted in both ambient and controlled environments with the objective of elucidating the isotopic dynamics of Hg⁰ exchange between the atmosphere and vegetation at the branch level (Yuan et al., 2019b; Chen et al., 2023), as well as between air and soil (Yuan et al., 2021; Chen et al., 2023; Zhu et al., 2022; Zhang et al., 2020), water (Zhang et al., 2023a), and snow (Sherman et al., 2010). For this application, in addition to traditional chambers (Demers et al., 2013; Chen et al., 2023; Zhu et al., 2024), a type was used that produces a uniform surface friction velocity over flat ground to couple with ambient shear conditions to scale to the ambient flux (Yuan et al., 2021; Yuan et al., 2023b; Lin et al., 2012). The surface-atmosphere Hg⁰ flux is the result of complicated bidirectional processes, including Hg⁰ efflux from surface and direct atmospheric Hg⁰ deposition.

1885 Deposition and sink processes

When direct Hg⁰ deposition is measured absolutely and isotopically with a DFC, enrichment factors for MDF ($\epsilon^{202}\text{Hg}_{\text{air/surface}}$) and odd-MIF ($E^{199}\text{Hg}_{\text{air/surface}}$) may be calculated using a linearized Rayleigh fractionation model (Zhu et al., 2022; Mariotti et al., 1981):

$$\begin{aligned} \delta^{202}\text{Hg}_{\text{DFC}}^0 - \delta^{202}\text{Hg}_{\text{air}}^0 &= \epsilon^{202}\text{Hg}_{\text{surface-air}} \cdot \ln \left(c_{\text{DFC}}^{\text{Hg}^0} / c_{\text{air}}^{\text{Hg}^0} \right) \\ \Delta^{199}\text{Hg}_{\text{DFC}}^0 - \Delta^{199}\text{Hg}_{\text{air}}^0 &= E^{199}\text{Hg}_{\text{surface-air}} \cdot \ln \left(c_{\text{DFC}}^{\text{Hg}^0} / c_{\text{air}}^{\text{Hg}^0} \right) \end{aligned} \quad (24)$$

where c represents concentration and the indices air and DFC refers to the air entering and exiting the DFC, respectively. Alternatively,

Eq. 24 is applied for extracting $\epsilon^{202}\text{Hg}_{\text{surface-air}}$ using measurements of c^{Hg^0} and $\delta^{202}\text{Hg}^0$ at two pristine sites with and without vegetation (Enrico et al., 2016) or using day vs. night-time segregated ambient air data at the same site (Jiskra et al., 2019). When direct deposition is measured isotopically with a DFC, the residual Hg⁰ in the chamber outlet shifts to be preferentially isotopically heavier, with a large but variable discrimination observed over soils ($\epsilon^{202}\text{Hg}_{\text{soil-air}} = \sim 0$ to -5.8% , Chen et al., 2023; Yuan et al., 2023b; Zhu et al., 2022) and over vegetation ($\epsilon^{202}\text{Hg}_{\text{foliage/air}} = \sim -1$ to -4.2% , Yuan et al., 2019b; Enrico et al., 2016; Demers et al., 2013; Jiskra et al., 2019; Chen et al., 2023). Deposition in contact with any surface does not result in a significant change in $\Delta^{199}\text{Hg}^0$, unlike the situation with $\delta^{202}\text{Hg}^0$.

1895 Information on the sink processes of Hg⁰ in the soil can be obtained by pursuing measurements of isotopic Hg⁰ in the soil pore air under sub-ambient concentration regimes. In tundra (Jiskra et al., 2019) and peatlands (Li et al., 2023a), isotopic difference between the ambient Hg⁰ and pore gas Hg⁰, whose concentration is sub-ambient ($\sim 0.4 - \sim 0.6$ and $\sim 0.2 - \sim 0.7 \text{ ng m}^{-3}$) and therefore mediates Hg⁰ net diffusion into the substrate, have via **Eq. 24** been linked to DOM-driven anaerobic oxidation in soil water exhibiting EIE (Zheng et al., 2019). Investigations of the Hg⁰ level in the pore air of forest soils give a mixed picture, ranging from sites with highly depleted air (Obrist et al., 2014) to sites with up to ten times enriched pore air (Yuan et al., 2019a) compared to the above ambient concentrations. In subtropical (Yuan et al., 2019a) and subalpine (Chen et al., 2023) forest soils, the concentration of Hg⁰ in pore air

is typically higher than in near-surface ambient air and shows seasonal isotopic variations (in MDF and odd-MIF), suggesting complexity in Hg^0 gas exchange between air and soil. In tropical forest soils, pore air shifts from being near-ambient during the rainy season to being markedly sub-ambient during the dry season (Yuan et al., 2023b). To resolve Hg^0 flux partitioning here, a combination of DFC measurements of net fluxes and forced unidirectional efflux, soil pore air, and Hg isotope composition in forest soil depth profiles are employed as input into isotope mass balance models based on odd-MIF (Yuan et al., 2021). Net fluxes measured by DFC are interpreted as a ternary mixing of deposition, Hg^0 losses from the surface soil via Hg^{II} photoreduction, and a term generated by Hg redox processes (dark/microbial reduction vs. oxidation) in the organic soil horizon. Although associated with considerable uncertainties, the estimated gross deposition to the forest floor is between -7.8 and $-1.8 \text{ ng m}^{-2} \text{ h}^{-1}$ for the subtropical site 1905 (Yuan et al., 2021) and between -6.7 and $-4.4 \text{ ng m}^{-2} \text{ h}^{-1}$ for the tropical site (Yuan et al., 2023b), depending on the season, and between -4.9 and $-2.0 \text{ ng m}^{-2} \text{ h}^{-1}$ for the subalpine site, depending on the type of forest floor (Chen et al., 2023).

Figure 17. Statistical summary of observations from isotopic studies of Hg^0 exchange between the atmosphere and various groups of Earth's surface reservoirs. In the air-forest group, data were taken from Yuan et al. (2019b) and Chen et al. (2023). In the air-snow group, data were taken from Sherman et al. (2010) and Douglas and Blum (2019). In the air-water group, data were taken from Zhang et al. (2023a; 2021a). In the air-soil group, data were taken from Zhang et al. (2020), Zhu et al. (2022), Yuan et al. (2021; 2023b) and Chen et al. (2023).

Foliar oxidation of Hg^0 drives its reactive uptake and is the most important step in the accumulation of initially dry deposited Hg^0 by plants (Liu et al., 2021b). Direct bio-oxidation from Hg^0 to Hg^{II} has been traced to heme enzymes that catalyze the degradation of H_2O_2 , specifically to a ferryl ($\text{O}=\text{Fe}^{\text{IV}}$) catalase radical cation complex (Ogata and Aikoh, 1984) that swiftly oxidizes Hg^0 ($1.4 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, Wigfield and Tse, 1986):

here, E represents the heme group attached to the enzyme, which can provide an electron, reducing the formal oxidation number of iron from five to four. The divalent Hg will readily bind to soft functional groups on the enzyme as soon as it is formed. MDF fractionation during oxidation of the absorbed isotopically light Hg^0 causes the product pool to be heavier than the reactant, consistent with observations that Hg^{II} incorporated into leaf shoots is only slightly lighter than Hg^0 in ambient air. Then it should be mentioned that, in contrast to the Hg pool in the leaf shoots, the Hg in the growing foliage of the current year shifts rapidly in the first months towards clearly negative $\delta^{202}\text{Hg}^{\text{II}}$ signatures, the causes of which have been discussed elsewhere (Yuan et al., 2019b).

In contrast to the observations regarding the air modified by interaction with soil and foliage, the residual Hg^0 in the outgoing air is significantly lighter than that in the incoming air ($\delta^{202}\text{Hg}_{\text{air}}^0 - \delta^{202}\text{Hg}_{\text{DFC}}^0 = 0.38\%$), as observed by DFC, for deposition regimes over freshwater surfaces (Zhang et al., 2023a). This may be interpreted as the dissolved $\text{Hg}^0(\text{aq})$ being consumed by oxidation, whereby the rapid exchange of Hg isotopes between the remaining Hg^0 and the formed Hg^{II} (Section 8.4.2) causes the former, which is partially returned to the gas phase, to exhibit a more negative $\delta^{202}\text{Hg}^0$. In surface waters, photolytic re-reduction is also possible, which is another source involved in determining the isotopic composition of dissolved Hg^0 (Zhang et al., 2021a).

During colder seasons with limited solar radiation, there is a small but persistent net Hg^0 dry deposition over the snow-covered Arctic interior tundra (Obrist et al., 2017), whose interstitial snow air has sub-ambient concentrations (0.69 vs. 1.07 ng m^{-3}) with comparatively more positive $\delta^{202}\text{Hg}^0$ -values (1.08 vs. 0.77% , Jiskra et al., 2019). Using the exclusion method, this trajectory may reflect Hg^0 uptake by ground lichens (Olson et al., 2019). Compared to the hinterland ($\sim 50 \text{ ng m}^{-2}$), the Arctic coastal snowpack has regionally much higher Hg^{II} pools ($>2000 \text{ ng m}^{-2}$), which are characteristically released as an ionic pulse in the runoff during snowmelt. High Hg^{II} concentrations in the coastal marine cryosphere are partially explained by AMDEs (described in Section 5.1.1, Douglas et al., 2017). However, most of the coastal AMDE deposition is re-emitted as Hg^0 to the atmosphere before the snow melts (see below). In contrast, the pulse in the runoff appears related mainly to the reactive uptake of Hg^0 on the marine snow, which is rich in halogen compounds and other reactive species (see Section 7.3) (Douglas et al., 2017). In support of a significant reactive uptake of Hg^0 on salt-laden snow, the analogous odd-MIF signatures between ambient air Hg^0 and snowmelt Hg^{II} have been referenced ($\Delta^{199}\text{Hg}$ values documented in Fig. 17b, Douglas and Blum, 2019).

Net exchange, source processes and flux partitioning

Due to the length of time (typically a few days) required to accumulate sufficient Hg to perform isotopic analysis, samples from a DFC measurement are a composite of periods of net emission and net deposition, unless the Hg^0 concentration in the inlet is manipulated so that emission or deposition becomes persistent within the chamber. The MDF and odd-MIF signatures from DFC measurements in ambient air ("net Hg^0 exchange") are calculated as follows (Zhu et al., 2022):

$$\begin{aligned} \delta^{202}\text{Hg}_{\text{exchange}}^0 &= \left(\delta^{202}\text{Hg}_{\text{DFC}}^0 \cdot c_{\text{DFC}}^{\text{Hg}^0} - \delta^{202}\text{Hg}_{\text{air}}^0 \cdot c_{\text{air}}^{\text{Hg}^0} \right) / \left(c_{\text{DFC}}^{\text{Hg}^0} - c_{\text{air}}^{\text{Hg}^0} \right) \\ \Delta^{199}\text{Hg}_{\text{exchange}}^0 &= \left(\Delta^{199}\text{Hg}_{\text{DFC}}^0 \cdot c_{\text{DFC}}^{\text{Hg}^0} - \Delta^{199}\text{Hg}_{\text{air}}^0 \cdot c_{\text{air}}^{\text{Hg}^0} \right) / \left(c_{\text{DFC}}^{\text{Hg}^0} - c_{\text{air}}^{\text{Hg}^0} \right) \end{aligned} \quad (25)$$

In the special case of using Hg-free air (zero air) to feed the DFC, $\delta^{202}\text{Hg}_{\text{emission}}^0$ and $\Delta^{199}\text{Hg}_{\text{emission}}^0$ can be determined. The enrichment factors during net Hg^0 exchange and emission are calculated using the following set of equations:

$$\begin{aligned} \epsilon^{202}\text{Hg}_{\text{exchange}} &= \delta^{202}\text{Hg}_{\text{exchange}}^0 - \delta^{202}\text{Hg}_{\text{surface}} & \epsilon^{199}\text{Hg}_{\text{exchange}} &= \Delta^{199}\text{Hg}_{\text{exchange}}^0 - \Delta^{199}\text{Hg}_{\text{surface}} \\ \epsilon^{202}\text{Hg}_{\text{emission}} &= \delta^{202}\text{Hg}_{\text{emission}}^0 - \delta^{202}\text{Hg}_{\text{surface}} & \epsilon^{199}\text{Hg}_{\text{emission}} &= \Delta^{199}\text{Hg}_{\text{emission}}^0 - \Delta^{199}\text{Hg}_{\text{surface}} \end{aligned} \quad (26)$$

In a series of light, temperature and substrate moisture controlled laboratory experiments with untilled (forest) and tilled (agricultural) soils, both with elevated Hg levels, enclosed in a DFC fed with Hg-free air, large Hg^0 fluxes ($\geq 500 \text{ ng m}^{-2} \text{ h}^{-1}$) were unanimously

with the most negative $\delta^{202}\text{Hg}_{\text{emission}}^0$ (−2.9 to −2.2‰ and −4.4 to −4.2‰ for agricultural and forest soils, respectively) were observed when substrates were exposed to elevated temperatures in the dark (100–130 °C vs. 40 °C), while treatments with light, moisture, or
1555 a combination of both at room temperature produced more moderately negative $\delta^{202}\text{Hg}_{\text{emission}}^0$ (−2.1 to −1.6‰ and −3.3 to −2.6‰ for agricultural and forest soils, respectively, Zhang et al., 2020). $E^{199}\text{Hg}_{\text{emission}}$ of agricultural and forest soils displays a value of approximately 0.2 ‰ and $\Delta^{199}\text{Hg}/\Delta^{201}\text{Hg} \sim 1.55$ in the temperature controls, suggesting that the treatment caused Hg^0 loss propelled by dark thermally driven Hg^{II} reduction (**Section 8.4.1**). In the light and light-moisture exposure controls, the substrates differed in the observed $E^{199}\text{Hg}_{\text{emission}}$, which for agricultural soils was 0.67 to 0.76‰ (mean) and for forest soils of a small magnitude, both
1560 positive and negative (−0.03 to 0.18‰, mean). The $E^{199}\text{Hg}_{\text{emission}}$ dichotomy may be interpreted as deriving from a composite with $\Delta^{199}\text{Hg}$ contributions from both (−)MgIE and (+)MgIE inducing Hg^{II} photoreduction pathways, almost completely dominated by (−)MgIE processes (Hg^{II} bound to, e.g., N, S-containing ligands) for agricultural soils, and for forest soils with a larger contribution from (+)MgIE processes (Hg^{II} bound to e.g. O-containing ligands) balancing the odd-MIF fractionation from (−)MgIE processes. However, the aforementioned agricultural soil placed under water (rice paddy) photoemits Hg^0 characterized by negative $\Delta^{199}\text{Hg}^0$
1565 ($\Delta^{199}\text{Hg}_{\text{emission}}^0 = -0.38 \pm 0.18\text{‰}$, Zhang et al., 2024), which is indicative of all observed Hg^{II} photoreduction in natural freshwaters studied in the laboratory as well as in situ.

A field study with DFC of cultivated or managed soils measured exchange fluxes (an MDF Rayleigh model yielded 10–27 % contribution from deposition) that showed net Hg^0 emissions (fraction of) associated with average $\epsilon^{202}\text{Hg}_{\text{exchange}}$ of −1.1 to −0.1‰ and −1.6 to −0.2‰ and average $E^{199}\text{Hg}_{\text{exchange}}$ of −0.27 to −0.13‰ and 0.00 to 0.14‰ for rural and urban soils, respectively. The
1570 above enrichment factors and $E^{199}\text{Hg}_{\text{exchange}} \approx E^{201}\text{Hg}_{\text{exchange}}$ indicate that the emitted Hg^0 comes mainly from the pool produced by photoreduction. The air concentration positively influences the magnitude of the deposition to soils so that at a critical concentration level (compensation point) the net flux tends to change direction. This is reflected in the apparent $\epsilon^{202}\text{Hg}_{\text{exchange}}$, which varies with the ambient Hg^0 concentration (Zhu et al., 2022). Analogous to the laboratory experiments, in situ experiments on the subtropical forest floor show soil emissions of Hg^0 that have strongly negative $\delta^{202}\text{Hg}_{\text{emission}}^0$ (mean −3.0‰, Yuan et al., 2021), while the
1575 magnitude of $\delta^{202}\text{Hg}_{\text{emission}}^0$ for the tropical rainforest floor is much smaller, but still negative (mean −0.7‰, Yuan et al., 2023b). $E^{199}\text{Hg}_{\text{emission}}$ for subtropical forest soils exhibits positive values for all seasons over a considerable range (mean 0.1 – 0.7‰), whereas for rainforests, $E^{199}\text{Hg}_{\text{emission}}$ is consistently positive, albeit to a lesser extent (mean 0.2 – 0.3‰). Limited negative $\delta^{202}\text{Hg}_{\text{exchange}}^0$ (mean −0.26, −0.54, −0.07 and −0.09 ‰) and consistently positive $E^{199}\text{Hg}_{\text{exchange}}$ (mean 0.42, 0.23, 0.39 and 0.30 ‰) are observed in net Hg^0 gas exchange experiments over subtropical (Yuan et al., 2021), tropical (Yuan et al., 2023b), sub-alpine (Chen et al., 2023)
1580 and temperate (Demers et al., 2013) forest soils, respectively. In conclusion, bare or cultivated soils result in a greater degree of MDF isotope fractionation associated with Hg^0 gas exchange with the atmosphere, compared to forest soils, where the effect of photic and thermal processes is limited by canopy shading. Temporally extensive chamber measurements conducted globally over the forest floor indicate net emissions (Yuan et al., 2019a). For the first three forest soil studies mentioned above, the DFC data set also contains sufficient isotope data to enable the modeling of net flux partitioning into gross emission and gross deposition.

1585 Re-emissions of Hg^0 from perennial foliage of three beech species show an average positive $\epsilon^{202}\text{Hg}_{\text{emission}}$ and $E^{199}\text{Hg}_{\text{emission}}$ of 0.6 and 0.3‰, respectively. The studied net exchange of Hg^0 between foliage and air for the montane evergreen deciduous (Yuan et al., 2019b) and spruce (Chen et al., 2023) forests is mostly on the uptake side, which gives that $\delta^{202}\text{Hg}_{\text{DFC}}^0$ is generally more positive than that of ambient air (**Fig. 17a**, mean shift of 0.72‰ for the latter site). The presence of bidirectional fluxes is, however, reflected in the observation that the $E^{199}\text{Hg}_{\text{exchange}}$ for both sites is consistently positive (mean 0.08 and 0.13‰, respectively), albeit
1590 modestly, due to a contribution from Hg^0 emissions resulting from (−)MgIE-induced photoreduction.

Isotopic studies of air-snow Hg^0 interaction and post-depositional processes have typically been conducted in the Arctic (Araujo et al., 2022; Sherman et al., 2010; Zheng et al., 2021; Jiskra et al., 2019; Obrist et al., 2017; Douglas and Blum, 2019), with occasional studies at mid-latitudes (Kurz et al., 2021; Yuan et al., 2022). Hg in aging snowpack exhibits by far the most extensive distribution of $\Delta^{199}\text{Hg}^{\text{II}}$ among Earth's surface reservoirs, with observations of $\Delta^{199}\text{Hg}$ progression reported in both positive (Kurz et al., 2021)
1595 and negative (Sherman et al., 2010; Zheng et al., 2021; Douglas and Blum, 2019) directions relative to fresh snow. As previously

discussed in **Section 8.2.1**, the larger $\Delta^{199}\text{Hg}$ spread observed in polar airborne Hg (Hg^0 and RM) when compared to, for instance, high-altitude air from mid-latitudes, can be attributed to the influence of AMDEs (during spring after sunrise and during summer) on a significant proportion of the collected polar data. Snow(fall) during the polar night is characterized by positive or near-zero $\Delta^{199}\text{Hg}$ signatures, as is the case for most global precipitation data (**Fig. 13c**), while the $\Delta^{199}\text{Hg}$ of polar Hg^0 for the same period is all slightly negative, consistent with the global Hg^0 background pool (**Fig. 13a**). Only sporadic isotopic DFC measurements have been conducted over snow, yet ample measurements of the polar air and snow as endmembers still offer an understanding of air-surface Hg^0 exchange following Hg^{II} deposition associated with AMDE. A seminal set of isotope data (Sherman et al., 2010) demonstrating a substantial odd-MIF triggered as a consequence of Hg^{II} photoreduction in snow was obtained from samples collected during a 9-day AMDE at the Alaskan Arctic coastline in conjunction with periods of minimal snowfall carrying high concentrations of scavenged Hg^{II} ($0.5 \pm 0.4 \mu\text{g L}^{-1}$, Johnson et al., 2008). Fresh snow, surface snow, and drifting snow showed, in order, rapidly increasing negative $\Delta^{199}\text{Hg}^{\text{II}}$ values of -0.95 to -1.20‰ , -2.41 to -2.63‰ , and -3.84 to -5.08‰ , which, according to Rayleigh fractionation, can correspond to 5–30%, 35–50%, and 65–75% of photo-reduced Hg^{II} , respectively. A chamber measurement was conducted on AMDE-impacted drifting snow that had undergone substantial photoreduction ($\Delta^{199}\text{Hg} \sim -5.0\text{‰}$) for 10.5 h of sunlight. The total DFC throughput, inclusive of Hg^0 emissions corresponding to 6% of Hg^{II} in the snow plot (whose $\Delta^{199}\text{Hg}^{\text{II}}$ dropped to $\sim -5.4\text{‰}$), exhibited a $\Delta^{199}\text{Hg}^0$ of -1.87‰ . A regression (-3.32 ± 1.19 , Kurz et al., 2021) corresponding to the Alaska DFC experiment $\Delta^{199}\text{Hg}$ plotted against $\delta^{202}\text{Hg}$ data (-3.44 ± 0.70 , Sherman et al., 2010) has also been observed, given the uncertainty in the line fit, in mid-latitude snow (MI, USA) belonging to polar vortex transported air masses from subarctic regions where the presence of AMDEs is well known (Poissant et al., 2001).

Perennial data from the Canadian High Arctic show that Hg^{II} deposited on snow during the most frequent phase of AMDEs just after polar sunrise until early May, partly characterized by low temperatures and Arctic haze, has a significantly higher susceptibility to photoreduction and loss as Hg^0 (up to 60%) than that deposited later ($<20\%$, Zheng et al., 2021). Regression of the Alaskan DFC experiment $\Delta^{199}\text{Hg}$ plotted against $\delta^{202}\text{Hg}$ data (-3.44 ± 0.70). As previously stated in **Section 5.1.4**, airborne Hg^{II} originating from high Arctic AMDEs undergoes rapid conversion to the particle phase between March and April, while unconverted GOM remains the dominant form between May and June. The cause of the reactivity of deposited Hg^{II} is unclear (Sherman et al., 2010; Kurz et al., 2021). It has been speculated that components of Arctic haze, such as black carbon, that cause photoreactivity of co-particulate Hg^{II} would be the cause of the observed (–)MgIE signature (Zheng et al., 2021), which is supported by water-phase experiments with Hg^{II} and dissolved black carbon (**Table 8**, Li et al., 2020b). Concurrently, the restricted Hg^{II} reduction observed in Arctic snow towards the conclusion of spring is consistent with concurrent observations of substantial reactive uptake of Hg^0 (see above; Douglas and Blum, 2019), indicating that the snowpack then contains species with a predominant oxidative capacity. However, during snowmelt on the inland tundra, net Hg^0 deposition is disrupted by shifts in isotopic signatures of snow interstitial air to those indicative of photoreduction, $\Delta^{199}\text{Hg}$ down to -1.37‰ in snow, -0.62‰ in snow interstitial air, consistently lower than in ambient air ($-0.23 \pm 0.06\text{‰}$). In contrast to Arctic snow, snow sampling in the U.S. Great Lakes area (with the exceptions noted above) generally shows increasing positive $\Delta^{199}\text{Hg}^{\text{II}}$ values (up to 3.51‰) in aging snow (Kurz et al., 2021). Indicative of (–) and (+) MgIE triggering the photoreduction, respectively, the snow data from coastal Alaska (Sherman et al., 2010; Douglas and Blum, 2019) and the Great Lakes region (Kurz et al., 2021) show steeper $\Delta^{199}\text{Hg}/\delta^{202}\text{Hg}$ trajectories than is the case for any of the well-studied Hg^{II} complex photoreductions in the laboratory (**Table 8 & 9**), leaving the question of which snow Hg^{II} complexes are involved.

The mean MIF values ($\Delta^{199}\text{Hg}^{\text{II}}$ and $\Delta^{200}\text{Hg}^{\text{II}}$) in the pool of fresh and seawaters are situated between the mean values of global atmospheric Hg^0 and wet precipitation. However, the variation is particularly pronounced for $\Delta^{199}\text{Hg}^{\text{II}}$ in coastal seawater, lakes, and river water (Liu et al., 2024). After studying three different categories of lakes with DFC, a $\Delta^{200}\text{Hg}$ isotope mass balance model was used to partition the overall net emission fluxes into gross emission and deposition, which ranged from 2.1 to $4.2 \text{ ng m}^{-2} \text{ h}^{-1}$ and -2.3 to $-1.2 \text{ ng m}^{-2} \text{ h}^{-1}$, depending on the lake (Zhang et al., 2023a). Hg^0 gross deposition exceeds the measured wet deposition over these lakes and is 56–85% of the total deposition (Feng et al., 2022). The anomalous observation of preferential deposition of heavier Hg isotopes over water has already been discussed. The results of the volatilization experiments of dissolved Hg^0 in water (DGM) indicate an MDF enrichment factor ($\epsilon^{202}\text{Hg}^0_{\text{air-water}}$) of -0.45‰ and a negligible $E^{199}\text{Hg}^0_{\text{air-water}}$ (Zheng et al., 2007). Emission-

controlled experiments for one of the lakes give $E^{199}\text{Hg}_{\text{emission}}$ of -0.38% and $\epsilon^{202}\text{Hg}_{\text{emission}}$ of -0.31% , which are subject to large
 2040 uncertainties, with a resulting $E^{199}\text{Hg}_{\text{emission}}/\epsilon^{202}\text{Hg}_{\text{emission}}$ trajectory of 1.26 ± 0.72 that agrees within the margin of error with that for
 Hg^{II} photoreduction mediated by fulvic acids (1.15 ± 0.07 , Bergquist and Blum, 2007). The isotopic tracing of the formation of
 dissolved Hg^0 in peat-covered groundwater from Hg^{II} in rainwater (1.24 ± 0.68) has also suggested that this process is of the same
 type of photoreduction (Li et al., 2023a). The $E^{199}\text{Hg}_{\text{exchange}}$ was between -0.76 and -0.32% , with the highest absolute value for a
 clear mountain lake fed mainly by glacial water, indicating that (+)MgIE photoreduction plays an important role, as has been shown
 2045 early on in laboratory experiments on natural freshwater (Bergquist and Blum, 2007; Zheng and Hintelmann, 2009). The observed
 substantial positive $\Delta^{199}\text{Hg}^{\text{II}}$ shift of sampled lake surface waters relative to Hg^{II} in precipitation can be interpreted as an effect of
 partial photoreduction of Hg^{II} . However, other sources, including MMHg photodegradation (Chen et al., 2016). As discussed in
Section 4.2, Hg^0 emissions from the ocean represent a primary source of Hg in the atmosphere. However, the isotopic signatures of
 this emission source remain largely unknown. In the absence of in situ sampling, photoexperiments with Hg^{II} in the presence of DOM
 2050 extracted from marine phytoplankton produce (–)MgIE during reduction, in contrast to freshwater DOM (Kritee et al., 2018).

9. Future perspectives

Knowledge of the atmospheric cycle of mercury has increased significantly in recent decades, as described in this paper. This is
 particularly evident in the field of computational chemistry, which has made seminal contributions to our understanding of gas-phase
 $\text{Hg}^{(\text{I,II})}$ molecules in terms of their geometries, energies, UV-VIS spectra, and reaction kinetics. The treatment of strong relativistic
 2055 effects, which largely determine the chemistry of Hg-containing species, is crucial for accurate results. Ab initio thermochemical
 calculations for atmospheric Hg species are performed at a higher level of theory, which incorporates core-valence electron
 correlation and extended basis sets (coupled-cluster methods). This approach yields more accurate results, with an accuracy of ≤ 1
 kcal mol⁻¹, in accordance with high-quality experimental data. The undertaking of ab initio kinetics calculations is a considerably
 more arduous task than that of ab initio thermodynamics calculations. It is more challenging to calculate the energies of transition
 2060 states (TS) with high accuracy than those of relative minima (meta-stable species). Furthermore, the rate is not solely dependent on
 the TS vs. reactant free energy difference, which can often be accurately calculated at sufficiently high levels. It is also essential to
 consider excited states when carrying out spectroscopic calculations (Ariya and Peterson, 2005; Ariya et al., 2009).

Absolute determination of rate constants experimentally with pulsed laser-assisted methods (reaction time typically < 0.1 ms) such
 as PLP-LIF is facilitated when secondary reactions are negligible and therefore do not contribute to the measured values. In general,
 2065 the absolute determination is conducted by obtaining pseudo-first order conditions, whereby the more stable reactant is present in a
 density exceeding tenfold that of the other reactant. However, for Hg, this method is viable only for studies that are conducted at
 elevated temperatures. At standard atmospheric conditions, the relatively low vapor pressure of Hg^0 (in comparison to, for instance,
 DMHg) precludes the possibility of such experiments. Despite the challenges for Hg^0 , a flow PLP-LIF system has many advantages,
 including the ability to measure the rate coefficient over a wide range of temperatures and pressures and to test the effect of a change
 2070 in bath gas (third body). These advantages have been exploited by alternative methods where the Hg species is not in excess, but
 where the excess is $X = \text{Cl}$ and Br in the study of the reaction $\text{Hg} + X^\bullet + M$, while this is instead $Y = \text{O}_3$, NO_2 , NO and O_2 in the
 study of the interaction between $^\bullet\text{Hg}^{\text{I}}\text{Br}$ and Y . Despite being in excess, the X^\bullet concentration decreases over time due to the rapid
 three-body recombination of the species to X_2 and M . This results in a non-trivial Hg^0 exponential decay. To achieve a fit to the
 observed Hg^0 time profiles, rate coefficients must be obtained through numerical integration. This requires monitoring both the X^\bullet
 2075 and Hg^0 time profiles using LIF, with the absolute concentration of X atoms known with precision. The measurements of the rate
 coefficients for the $\text{Hg} + X^\bullet + M$ reaction experimentally by Donohoue et al. are in accordance with the findings of the theoretical
 computational studies. The study of the conversion of $^\bullet\text{Hg}^{\text{I}}\text{Br}$ by bimolecular elimination (reduction; Wu et al., 2020; Wu et al.,
 2022), addition (oxidation assisted by M , Wu et al., 2020), or abstraction (Gómez Martín et al., 2022) is constrained by the capacity
 to generate sufficiently high densities of $^\bullet\text{Hg}^{\text{I}}\text{Br}$ through the gas-phase photolysis of HgBr_2 in the deep UV. Because the vapor
 2080 pressure over HgBr_2 is low (less than one-tenth that of Hg^0), it is necessary to keep the HgBr_2 source at least 30°C and the flow tube
 reactor at least 10°C higher to prevent vapor condensation. A higher temperature increases the thermal dissociation of $^\bullet\text{Hg}^{\text{I}}\text{Br}$ and

therefore a large excess of Y is required for the $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{Y}$ reaction to completely dominate the conversion of $\bullet\text{Hg}^{\text{I}}\text{Br}$. However, in the context of laboratory experiments necessitating deep UV irradiation, it is essential to consider that oxygen atoms are formed through the partial photolysis of O_3 and NO_2 , thereby enabling $\text{O}(^3\text{P})$ to also react with $\bullet\text{Hg}^{\text{I}}\text{Br}$ ($\text{O} + \text{HgBr} \bullet \rightarrow \text{Hg} + \text{BrO} \bullet$). The experimentalists' intention to study the title reactions of $\bullet\text{Hg}^{\text{I}}\text{Br}$ with NO_2 and O_3 will inevitably result in the observation of a partially reversible oxidation process. This is due to the occurrence of secondary chemistry, including the reactions **G14**, **G23**, **G24**, and **G29**, which takes place concurrently with the title reactions **Br7** and **Br9**. Furthermore, to elucidate the influence of secondary chemistry on the observed $\bullet\text{Hg}^{\text{I}}\text{Br}$ disappearance, a comprehensive series of experiments must be conducted, with pressure, temperature, $[\bullet\text{Hg}^{\text{I}}\text{Br}]$, $[\text{Y}]$, and $[\text{O}]$ as variables. Subsequently, numerical modeling is essential to isolate the individual rate constants. While the laboratory study of $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{O}_3$ gives an experimental rate constant for the reaction **G22** that is in good agreement with computational predictions (Castro Pelaez et al., 2022), experimental kinetic data for $\bullet\text{Hg}^{\text{I}}\text{Br} + \text{NO}_2$ (**Rxn 20**), which must be decoupled in termolecular oxidation (**Rxn 20a**) and reduction (**Rxn 20b**), respectively, indicate that computational methods give overestimated rate constants for both channels (Wu et al., 2020). In the later experimental investigation it is however found that **Rxn 20** cannot fully account for observations, but that significant losses of $\bullet\text{Hg}^{\text{I}}\text{Br}$ must occur via side reactions, probably involving **Rxn G23**, which was unexplored at the time. In view of the above-mentioned intractable shortcomings, it is very challenging to validate the majority of the proposed reaction steps by computational quantum chemistry in the atmospheric Hg redox cycle, including $\text{YHg}^{\text{II}}\text{O} \bullet$ chemistry, through experimental means. In fact, many of the proposed key intermediate Hg species lack any experimental characterization (such as spectral proofs). For example, apart from LDI-TOF MS experiments utilizing solid HgO as a source (Jayasekharan and Sahoo, 2014), there is a paucity of information of gaseous HgO . In order to assess the stability and potential reactions of HgO , it is necessary to employ advanced laser spectroscopic methods, which could potentially generate robust levels of HgO through the spin-allowed $\text{Hg}(^1\text{S}) + \text{O}(^1\text{D})$ reaction.

From a computational chemistry standpoint, the reaction between $\text{YHg}^{\text{II}}\text{O} \bullet$ and CO has been identified as crucial in assessing the atmospheric burden of Hg^{II} . However, the calculated rate constant is subject to significant uncertainty, within a factor of 10 being a reasonable estimate. A direct reaction between water vapor and $\text{YHg}^{\text{II}}\text{O} \bullet$ has recently been proposed for $\text{Y} = \text{OH}$ (Saiz-Lopez et al., 2022). If this reaction is realized with the given rate expression in models, it will result in the conversion of essentially all $\text{HOHg}^{\text{II}}\text{O} \bullet$ to the completely stable $\text{Hg}(\text{OH})_2$ in the tropics. The question of whether iodine-induced Hg^0 oxidation is a significant process in the troposphere and lower stratosphere has been raised based on atmospheric observations (Murphy et al., 2006; Lee et al., 2024) and the emerging role that O_3 is thought to play in rapidly oxidizing $\bullet\text{Hg}^{\text{I}}\text{X}$ to $\text{XHg}^{\text{II}}\text{O} \bullet$ species. As discussed in **Section 5.1.2**, the current evidence for $\bullet\text{Hg}^{\text{I}}$ in terms of binding strength, thermal and photolytic stability is too uncertain to make an informed assessment.

The current limitations and challenges to accurately measuring speciated atmospheric mercury (Gustin et al., 2024; **Section 4.1**) mean that the basis for verifying model studies is insufficient, despite generally reliable measurements of Hg^0 and Hg^{II} wet deposition. The difficulties of accurately determining the speciation of Hg^{II} in atmospheric water through equilibrium modelling, and thus identifying the pool of reducible complexes, have been elucidated (**Section 4.3**). Additionally, the potential for simulating the gas-particle distribution of atmospherically oxidized Hg has been explored (**Section 7.1.1**). The use of isotope data to constrain the Hg redox chemistry in the atmosphere has begun (Song et al., 2024; Zhen et al., 2024), but there are profound knowledge gaps that require state-of-the-art theoretical and experimental investigations. The discovery, made over a decade ago, that atmospheric samples contain a significant level of the even-mass-number isotope MIF, which has been observed to exhibit seasonal and geospatial variations, has been a source of both benefit and puzzlement for scientists ever since (**Section 8.2.3 & -4**). As the even Hg MIF variation is limited to samples from a few localities so far (compare **Figs. 13 & 14**), $\Delta^{200}\text{Hg}$ & $\Delta^{204}\text{Hg}$ in the environment is considered a conservative tracer due to its generally narrow range, and values of $\Delta^{200}\text{Hg}$ & $\Delta^{204}\text{Hg}$ on the land surface and in water confine the relative contribution of Hg^0 to Hg^{II} exchange process with the atmosphere. Nevertheless, the underlying chemical processes that give rise to the anomalous MIF and the atmospheric conditions that facilitate its occurrence remain to be elucidated in greater detail. In addition to laboratory-based investigations, future field experiments that report on the vertical profiles of isotopic Hg^0 and Hg^{II} in the atmosphere may prove invaluable in further constraining the sources of even-MIF.
