Abstract. Land use change is causing substantial loss of soil organic carbon (SOC). However, little is known regarding how this loss of SOC influences the composition of carbon (C) functional groups and their microscale distribution, with this being critical to the protection and storage of SOC. In this study, we examined the
20 mechanisms influencing preservation of C forms and their distribution by comparing soils under native vegetation and cropping at two Australian sites, Waco black Vertisol (70 y cropping) and Langlands-Logie grey Vertisol (10 y cropping). Land use change caused the loss of up to 23 % (5.3 mg C g⁻¹ soil) of bulk SOC. Strikingly, the greatest loss occurred in the mineral-associated organic carbon (MAOC) fraction that accounted for 72-91 % of total SOC. Interestingly, despite losing up to 23 % of the bulk SOC, the C that remained after long-term cropping was similar
25 in speciation to that in the native soils revealed by near edge X-ray absorption fine structure spectroscopy. In a similar manner, the use of infrared microspectroscopy showed that the forms of C remained similar in the two land uses and that C was closely associated with clay minerals. This suggests that the SOC loss from mineral fraction was not due to preferential consumption of particular forms of carbon, but rather, an overall loss of SOC in the mineral fractions and an increase in overall lability. These observations provide critical evidence that
30 preservation of SOC is not driven by increasing compositional diversity or complexity in these Vertisols and that

physical protection of C is of importance. Potential exists to rebuild SOC in the mineral-associated fraction under cropping. Management practices should promote the building of organo-mineral associations.

1 Introduction

Protecting soil organic carbon (SOC) is vital for maintaining soil quality and ecosystem functions, supporting agronomic productivity and environmental resilience, and is a key component of climate change mitigation and adaptation (Kopittke et al., 2024). However, land use change has significantly reduced SOC stocks in agricultural lands. As a result, total historical CO₂ emissions from soils due to agricultural intensification are estimated to be 116 Pg of carbon (C) (Sanderman et al., 2017), accounting for almost 17 % of cumulative CO₂ emissions by humanity since pre-industrial times. Under natural conditions, soils in tropical and subtropical regions are major C sinks, retaining 36-60 % of ecosystem C in forests but are estimated to emit 0.2 Gt C y⁻¹ following land use change for crop production (Don et al., 2011). Indeed, land use changes in the tropics and subtropics account for 12% of the human-induced greenhouse gas (GHG) emissions between 2007 and 2016 (Piabuo et al., 2024) and are projected to be the second largest source of GHG emissions (Pörtner et al., 2022).

Despite high SOC loss from (sub)tropical soils and ecosystems, the potential to protect and restore some of these C remains unanswered. Therefore, there is an urgent need to better understand the mechanisms of how SOC behaves, with this being controlled by the composition of C functional groups (Gregory et al., 2016; Jones et al., 2016), their heterogeneous spatial distribution in relation to accessibility for decomposers (Poulton et al., 2018; Jensen et al., 2019) and temporal variability (Stevenson et al., 2016; Hirsch et al., 2017; Lehmann et al., 2020). It has been hypothesized that higher diversity of C functional groups can increase the metabolic investment for microorganisms to assimilate complex and diverse SOC structures, with this resulting in preservation of SOC. Furthermore, a heterogenous spatial distribution of C functional groups limits the accessibility of decomposers to C substrates (Lehmann et al., 2020), thereby further preserving SOC. This can be further enhanced with physical occlusion and protection of SOC within the occluded particulate organic C (oPOC) and mineral associated organic C (MAOC) fraction (Willard et al., 2024). Therefore, understanding the changes in C content within various SOC fractions is important for examining the preservation of SOC (Even and Cotrufo, 2024).

Previous studies have reported the impact of land use change on C functional groups based on soil extracts or hydrofluoric acid pre-treated soils (An et al., 2021). Synchrotron-based near edge X-ray absorption fine structure (NEXAFS) spectroscopy is particularly suited for the characterization of complex heterogeneous samples since absorption spectra depend directly on the local bonding environment of atoms (Lehmann and Solomon, 2010).

60 NEXAFS spectroscopy provided a way of probing this complex chemistry without the need for wet-chemical
analysis techniques that profoundly change the nature of a sample whilst trying to measure it (Barnard et al.,
2024). Whereas traditional wet chemistry studies require processes, as a consequence, spatial information of SOC
distribution and organo-mineral associations was compromised (Weng et al., 2021). Infrared micro-spectroscopy
(IRM) can provide *in situ* spatial information of organic C speciation in the soil. The higher brightness of
65 synchrotron sources (100-1000 times brighter than traditional IR light source) is especially useful when mapping
C in soils due to the comparatively low C concentration in most soils (Weng et al., 2022). Such analyses provide
microscale maps revealing the spatial distribution of specific C functional groups in soils that can be linked to
their functions (Hondroudakis et al., 2024; Weng et al., 2024).

The objective of this present study was to examine the impact of land use change on C functional composition
70 and their distribution in microaggregates using high resolution and non-invasive approaches to better understand
preservation of SOC forms. Two soils, a Waco black Vertisol and a Langlands-Logie grey Vertisol, were studied
under native vegetation (grassland for Waco and forest for Langlands-Logie) and following transition to cropland
(70 y for Waco and 10 y for Langlands-Logie). Cropped soils experience greater mechanical disturbance and
larger fluctuations in water and plant inputs compared with the undisturbed sites. We hypothesised that (1) in
75 addition to the depletion of C content driven by land use change, subsequent cropping can affect functional
composition of SOC with preservation of complex C forms after SOC loss and (2) strong correlations between
the lateral distribution of C forms and clay minerals can provide physical protection of SOC, however, such
correlation can be weakened following land use change.

2 Materials and methods

80 2.1 Site description

The study sites, soil management, and agricultural practices are detailed in the Supplementary Information.
Briefly, the study sites are located near Chinchilla, Queensland (Australia), being at 27°1'S, 151 14'E for Waco
and 26°47'S, 150°53'E for Langlands-Logie. The field sites have a mean annual rainfall of 630 mm, with a mean
annual temperature of 19.4°C at the time of sampling in 1986 (Dalal and Mayer, 1986). Cooler months (April-
85 September) receive 35 % of the annual rainfall, with the climate classified as subtropical. The mineralogical
properties of the native and cropped sites were similar for both locations at Waco and Langlands-Logie. At Waco,
the soil texture for the native site consists of 13 % sand, 14 % silt, and 72 % clay whilst the cropped site contains

14 % sand, 12 % silt, and 75 % clay. The Waco soil is described as deep black to greyish brown cracking clays, alkaline at depth, with dominant clay minerals being smectite and kaolinite. The parent material is clay alluvium
90 derived from basalt. At Langlands-Logie, the soil texture for the native site consists of 35 % sand, 16 % silt, and 49 % clay whilst the cropped site contains 32 % sand, 17 % silt, and 51 % clay. The Langland-Logie soil is dominated by quartz and kaolinite and is classified as deep dark greyish brown to dark brown cracking clay, alkaline at surface and acidic at depth. Parent material is alluvial clayey sediments formed from light grey shales, silt-stones, and fine to medium sandstones. Cropping increased bulk density compared with native vegetation
95 from 0.84 to 1.01 g cm⁻³ at Waco and 0.99 to 1.15 g cm⁻³ at Langlands-Logie ($P < 0.01$; Dalal and Mayer, 1986a). For the cropping site at both locations, monocropping was practiced every year with winter crops consisting of 90 % wheat, 9 % barley, and 1 % oat, and summer crops consisting of 92 % sorghum and 8 % sunflower (Supplementary Information).

A total of 25 soil cores (46-mm internal diameter) were sampled to 1.2 m depth at each field site on a 5 m × 8 m
100 grid over 0.1 ha to ensure representativeness. Soil samples were collected at 0-0.1 m depth sectioned from 0-1.2 m cores during April-July from both sites. Five of these soil cores were combined to yield a total of five replicate samples from each field site (five composite samples were obtained for each sampling depth). The soil samples were sealed in plastic bags in the field, transported to the laboratory and kept at 4 °C until further processing for analysis. The samples were dried at 25 °C, sieved to < 2 mm and stored in sealed plastic containers.

105 For background analyses, soil pH was measured using 1:5 soil:water suspension. Mineralogy was assessed for the native soils using X-ray diffraction. The total organic C and total N were determined through Dumas high-temperature combustion with soil pre-treated with 1 M sulfurous acid to remove inorganic C and measured using a CN elemental analyser (LECO Trumac CN analyzer, MI) (Rayment and Lyons, 2011).

2.2 Density fractionation

110 The density fraction method was conducted on above-mentioned soil samples as described by Kölbl and Kögel-Knabner (2004) and Steffens et al. (2009). The bulk soil was introduced to a sodium polytungstate (1.8 g cm⁻³) and the floating free particulate organic matter was collected by aspiration. To separate the aggregate-occluded particulate organic matter from the remaining sample, the soil was subject to sonification in two waves of 200 J mL⁻¹ (total of 400 J mL⁻¹) and then centrifuged and collected by aspiration. The free particulate organic matter
115 was manually washed, and the aggregate-occluded particulate organic matter washed using pressure filtration (5 bar) with ultrapure Milli-Q water until the filtrate for both fractions had an electrical conductivity (EC) < 5 μS cm⁻¹. Both fractions were freeze-dried at -60 °C. The remaining mineral-associated organic matter fraction was

washed using pressure filtration to an EC < 50 $\mu\text{S cm}^{-1}$ and then sieved under gravity using a 53 μm steel sieve to separate the fine fraction of mineral-associated organic matter (< 53 μm) from the coarse fraction of mineral-associated organic matter (> 53 μm). Both mineral fractions were oven dried at 50 °C.

We have measured C contents for four fractions: free particulate organic matter ('fPOC'), aggregate-occluded organic matter ('oPOC'), organic matter associated with the coarse mineral fraction (> 53 μm ; 'coarse MAOC') and the organic matter associated with the fine mineral fraction (< 53 μm ; 'fine MAOC'). Isotope ratio mass spectrometry was used to measure fPOC and oPOC given that the sample mass for these fractions was not sufficient for a CN elemental analyser. In addition, coarse and fine MAOC were analysed by a CN elemental analyser. Preliminary tests showed no difference in C contents between mineral fractions with and without acid pre-treatment. For N, the results giving the N contents of each fraction were termed the 'fPON', 'oPON', 'coarse MAON' and 'fine MAON'.

2.3 Near edge X-ray absorption fine structure (NEXAFS) spectroscopy

For near edge X-ray absorption fine structure (NEXAFS) analysis, five field replicates were composited from each of the two locations (Waco black Vertisol and Langlands-Logie grey Vertisol) and two land uses (native vegetation and cropped) because of the limited synchrotron beamtime. Three laboratory replicates of the composite bulk soils were analysed (n=3). The finely powdered soils without acid pre-treatment were loaded onto stainless-steel rulers and analysed as described below.

The synchrotron-based NEXAFS analyses were performed at the SXR Spectroscopy beamline (14ID) at the Australian Synchrotron (Clayton, Australia). The NEXAFS C and N K-edge spectra were collected using partial electron yield with the floodgun engaged to minimise charging from the samples. The C K-edge spectra were collected between 275-325 eV and N K-edge spectra between 380-420 eV at 0.1 eV step size and at an angle of 55° to the beam. A graphite standard was used for energy calibration by collecting the I_0 and sample spectra. The double normalisation of the spectra was based on the I_0 and a photodiode measurement from the UHV analytical chamber (Stöhr, 2013). A pre- and post-edge linear subtraction was applied for the background normalisation using the Igor software.

Deconvolution and peak fitting of the double normalized spectra was carried out using MANTiS 2.3.02 (Lerotic et al., 2014). A non-linear least square fitting of multiple gaussians and one arctangent function were used to fit all the NEXAFS data, following the procedure described in Solomon et al. (2007). Briefly, two arctangent

functions at 290.5 eV for aromatic/aliphatic C and 292.0 eV were set for hydroxylated aromatic C with full-width at half-maximum (FWHM) of 0.4 eV to generate a continuum of spectrum up to 294 eV. The FWHM of the Gaussian peaks was set at 0.4 eV and six Gaussian functions representing the main $1s-\pi^*$ transitions at 284.4, 285.2, 286.6, 287.6, 288.5, and 289.3 eV were resolved. Measures of the goodness of fitting using R^2 values of better than 0.999 to reflect the proportion of variance explained.

2.4 Infrared microspectroscopy (IRM)

For IRM, bulk soil was separated into microaggregates (53-250 μm) by dry sieving using the method described by Weng et al. (2018). These microaggregates contained all C fractions and were different from the above-mentioned fractionation samples. Dry sieving can minimise the dissolution and translocation of various dissolved organic C forms into different aggregate fraction that may be caused by wet sieving. We focused on the microaggregates (53–250 μm) because this size fraction has been reported to undergo rapid turnover and is less protected therefore prone for change (Kölbl and Kögel-Knabner, 2004; Steffens et al., 2009). Approximately 30 microaggregates were selected on glass-fibre filter papers and humidified gradually over 18 h (Lehmann et al., 2005). The aggregates were frozen at -20°C before being sectioned (200 nm thick) using a diamond knife without embedding media via a cryo-ultramicrotome at -55°C . Thin sections were taken from the core of the aggregates after removing edges. A total of 8-10 sections per sample were directly collected on CaF_2 windows (IR transparent, 13 mm diameter, 0.5 mm thickness).

The sections taken from intact microaggregates were placed on CaF_2 windows and analysed at the IRM beamline at the Australian Synchrotron. Details of the system are described by Hernandez-Soriano et al. (2018). Briefly, a Bruker Hyperion 3000 infrared microscope is coupled with a V80v Fourier transform infrared spectrometer. The measurements were conducted in the transmission mode (64 scans, 4 cm^{-1} resolution, and $5\text{ }\mu\text{m}$ step size). Background scans were repeated every 15 scans.

IRM maps were processed using the software OPUS 8.2 (Bruker Optik GmbH, Germany), featuring O-H groups of clays ($3550\text{-}3740\text{ cm}^{-1}$), aliphatic C ($2800\text{-}3000\text{ cm}^{-1}$), aromatic C ($1500\text{-}1750\text{ cm}^{-1}$), and polysaccharide C ($950\text{-}1170\text{ cm}^{-1}$) (Hernandez-Soriano et al., 2018). Integration of the areas of these absorbance peaks was calculated. A linear regression between the integrals of C forms and clay mineral was conducted. Vertisols in this study are rich in smectites and illites (and kaolinites) with the Si-O band absorbing strongly and prominently at around 1020 cm^{-1} (Pentrák et al., 2012; Parikh et al., 2014). To minimise the interference of clay minerals with

175 the absorbance of polysaccharide, we can conduct second derivative for the range 950-1170 cm^{-1} . IRM data were processed following the methods (Huang and Wang, 1995; Schindelin et al., 2015) as outlined in the Supplementary Information.

2.5 Correlation analysis of NEXAFS and IRM

180 A hierarchical clustering dendrogram indicates the similarity relationships between C functional groups from NEXAFS (first derivatives), their abundance from IRM, and total SOC content across land uses and soil types. The heatmap shows the colour-coded correlation coefficient. The first derivative of the NEXAFS spectra (281-296 eV) for each land use and soil type were divided into 30 bins and pairwise correlations between each energy segment and distribution of aromatic C, aliphatic C, polysaccharide C, clay O-H from IRM and total SOC content were assessed to explore relationships between C-speciation and C-distribution. This was achieved using functions in the R packages “*prospectr*” (Stevens and Ramirez-Lopez, 2024) and “*gplots*” (Warnes et al., 2016).

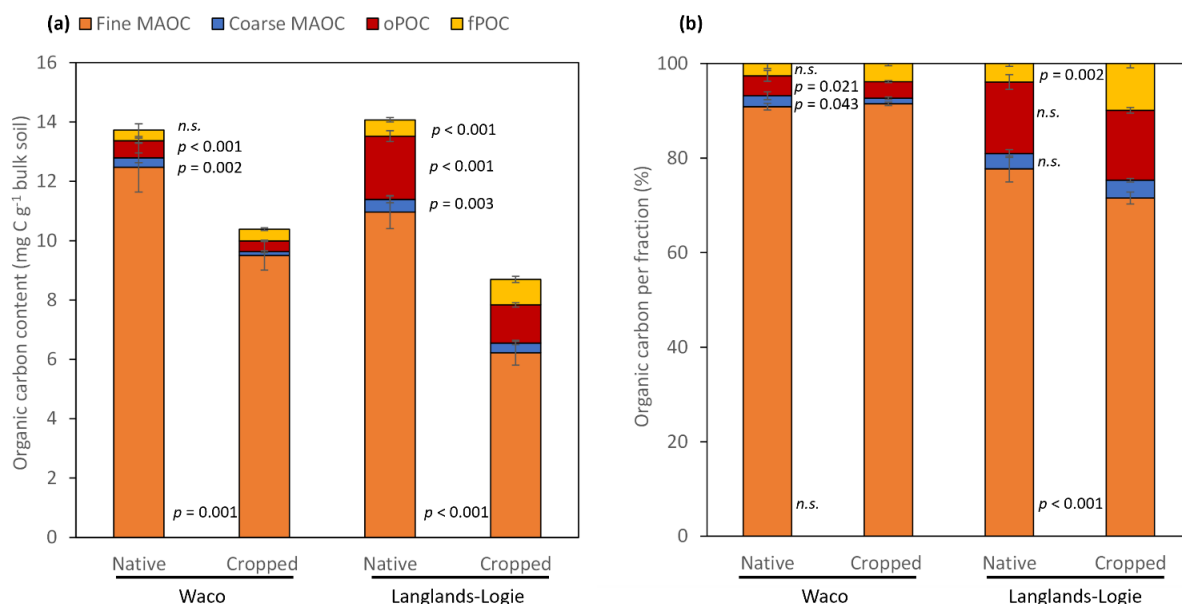

185 2.6 Statistical analyses

All statistical analyses were run using R version 4.2.1 (Core, 2022). When F-tests were significant, means were separated using *t*-tests to identify significant differences in SOC content between land uses for each fraction within each soil type/ site. *p* values were provided in Figures. Confidence intervals were provided for NEXAFS spectra ($P = 0.05$).

190 3 Results

3.1 Changes in soil organic carbon in bulk soils and their aggregate size fractions

Long-term cropping significantly decreased the organic C concentration of bulk topsoils ($P < 0.01$): Waco black Vertisol (1.54 vs. 1.27 %, being a 17 % decrease) and Langlands-Logie grey Vertisol (1.44 vs. 1.11 %, being a 23 % decrease) (Fig. 1).

195

Figure 1: The organic carbon content (a) and the percentage of organic C (b) for each soil fraction within the bulk soil from topsoils (0-10 cm) collected from Waco and Langlands-Logie from two land uses. fPOC is free particulate organic C, oPOC is aggregate-occluded particulate organic C, coarse MAOC is coarse grained (> 53µm) mineral-associated organic C and fine MAOC is fine grained (< 53µm) mineral-associated organic C. Letters indicate least significant differences (95 % confidence level for each comparison) between the same fractions across land uses within each location. *p* values were given (n = 5). The mass recovery after fractionation for Waco and Langlands-Logie was over 91 %.

200

We then examined C fractions within the soil. The sum of four C fractions within the soil for Waco was 13.7 ± 2.3 mg C g⁻¹ bulk soil (native) and 10.4 ± 3.7 mg C g⁻¹ bulk soil (cropped) and Langlands-Logie grey Vertisol was 13.1 ± 1.1 mg C g⁻¹ bulk soil (native) and 8.9 ± 2.9 mg C g⁻¹ bulk soil (cropped). At both sites, for the native and cropped soils, the fine MAOC fraction was the dominant pool, accounting for 91 % (Waco) and 72-78 % (Langlands-Logie) of the total bulk C (Fig. 1). The oPOC fraction was the second largest pool of C, accounting for 4 % (Waco) and 15 % (Langlands-Logie) of the total bulk C. The fPOC accounted for 2.6-3.8 % of the total bulk C for Waco and 3.9-9.9 % for Langlands-Logie. The coarse MAOC was a comparatively minor proportion of total C in all soils (Fig. 1).

210

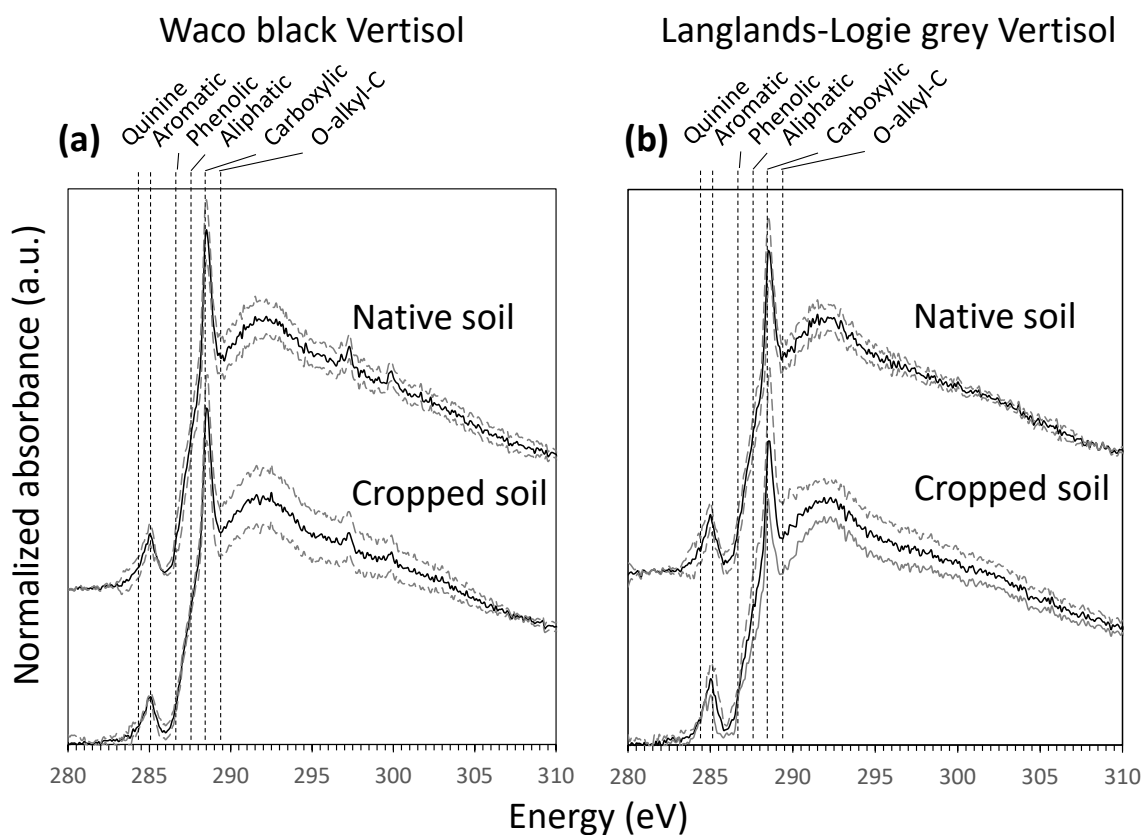

The impact of cropping on the C fractions varied depending on soils. In absolute terms, the largest decrease in C was for the MAOC fraction, with a loss of 3.0 mg MAOC g⁻¹ bulk soil for Waco and 4.7 mg MAOC g⁻¹ bulk soil

for Langlands-Logie (Fig. 1). The contribution of fPOC to the total bulk C for the Waco black Vertisol was similar for both native (0.36 mg C g⁻¹ bulk soil) and cropped soil (0.39 mg C g⁻¹ bulk soil) (Fig. 1a). For the Langlands-
215 Logie grey Vertisol, the fPOC fraction also accounted for only a small proportion of the total bulk C, being 0.55 mg C g⁻¹ bulk soil for the native and 0.86 mg C g⁻¹ bulk soil for cropped soil (Fig. 1a). In relative terms, in the Waco black Vertisol, the oPOC decreased from 4.2 (native) to 3.5 % (cropped), with a decrease in the coarse MAOC from 2.3 to 1.2 % and the fine MAOC remained at 91 %. In the Langlands-Logie grey Vertisol, oPOC varied between 14-15 % and 3.3-3.8 % in the coarse MAOC and a decrease in the fine MAOC from 78 to 72 %.
220 A similar pattern was observed for N in the various fractions as described for the C fractions (Supplementary Fig. S1). Indeed, for N in both the native and cropped soils, the fine MAON fraction was the dominant pool, accounting for 95-96 % (Waco) and 85-89 % (Langlands-Logie) of the total bulk N (Supplementary Fig. S1). Despite low N concentrations, cropping significantly decreased the total N concentration of bulk topsoils ($P < 0.05$): Waco black Vertisol (0.06 ± 0.01 vs. 0.04 ± 0.01 %, being a 33 % decrease) and Langlands-Logie grey Vertisol (0.09 ± 0.01 vs. 0.07 ± 0.01 %, being a 22 % decrease) (Supplementary Fig. S1).

3.2 Changes in C and N functional groups under long-term cropping examined using NEXAFS

Given the marked loss of SOC in bulk soils and their fractions with cropping (Fig. 1), we examined whether there was also a change in C speciation associated with this loss. For this, changes in C and N functional groups of bulk soils were examined using NEXAFS. In general, six C peaks dominated the NEXAFS spectra across two soil
230 types: (1) quinone (284.4 eV), (2) aromatic C (285.2 eV), (3) phenolic C–OH (286.6), (4) aliphatic C (287.6 eV), (5) carboxyl C–OOH (288.5 eV), and (6) O-alkyl-C (289.3 eV) (Fig. 2) (Lehmann and Solomon, 2010). In the Waco black Vertisol, the sharp resonance at 297.4 eV and 300 eV corresponded to L₂ and L₃ edges of potassium (Fig. 2a).

235 **Figure 2. Synchrotron-based NEXAFS analyses of the Waco black Vertisol and Langlands-Logie grey Vertisol under the native vegetation and cropping.** NEXAFS C K-edge spectra of bulk soil for the Waco soil (a) and the Langlands-Logie soil (b) ($n=3$, $CV\% < 3\%$), featuring: (1) quinine (284.4 eV), (2) aromatic C (285.2 eV), (3) phenolic C–OH (286.6 eV), (4) aliphatic C (287.6 eV), (5) carboxyl C–OOH (288.5 eV), and (6) O-alkyl C (289.3 eV). 95 % confidence intervals were plotted in dashed lines.

240 Next, we assessed changes in the NEXAFS C K-edge spectra of soils with long-term cropping. The number of C forms
observed using NEXAFS did not change with cropping, with spectra indicating the presence of aromatic C (285.2 eV), aliphatic
C/phenolic C–OH (287.6 eV), and carboxyl C–OOH (288.5 eV). Importantly, we observed no pronounced differences in the
intensities of these peaks with cropping compared to native vegetation. Indeed, in the Waco black Vertisol, when comparing
cropping with native vegetation, carboxylic-C (45 to 35 %), aliphatic-C (10 to 7 %), and aromatic (12 to 17 %; Fig. 2a and
245 Supplementary Table S1) were all similar in the native soil and cropped soil. In a similar manner, in the Langlands-Logie grey
Vertisol, O-alkyl C varied from 39 to 23% while the intensity of the rest of the C functional groups remained unchanged.
We also examined changes in the N K-edge spectra using NEXAFS (Supplementary Fig. S2), with two main features observed
across all soils, being: (1) amide (protein, 401.2 eV), and (2) alkyl-N (amino acids, 406 eV). However, long-term cropping
depleted both amide and alkyl N in the topsoils of the Waco black Vertisol and Langlands-Logie grey Vertisol (Supplementary
250 Fig. S2).

3.3 Distribution of C forms under long-term cropping examined using IRM

To complement the C and N K-edge NEXAFS analyses of bulk soils, the lateral (two dimensional) distribution of OC was
analysed using IRM from the cross sections taken from intact microaggregates (53-250 μm) (Fig. 3 and 4). Firstly, across all
soils, the distribution of C forms was highly heterogenous. Secondly, there was no apparent consistent pattern in the distribution
255 of C forms within the microaggregate sections, as might be expected if organic C had been occluded in a central core by clay
minerals.

We examined microaggregate sections taken from soils under native vegetation to establish a baseline. Despite there being no
apparent consistent pattern to the overall distribution of C forms within the microaggregate sections, the aliphatic-C appeared
closely associated with clay, whilst polysaccharide-C was least correlated. This was confirmed by linear regression (Fig. 3b-d
and 4b-d), with aliphatic-C being strongly related with clay O-H minerals in the native Waco black Vertisol ($R^2 = 0.89$) and
260 the native Langlands-Logie grey Vertisol ($R^2 = 0.88$) (Fig. 3b and 4b). The clay association with aromatic- and polysaccharide-
C varied across soil types.

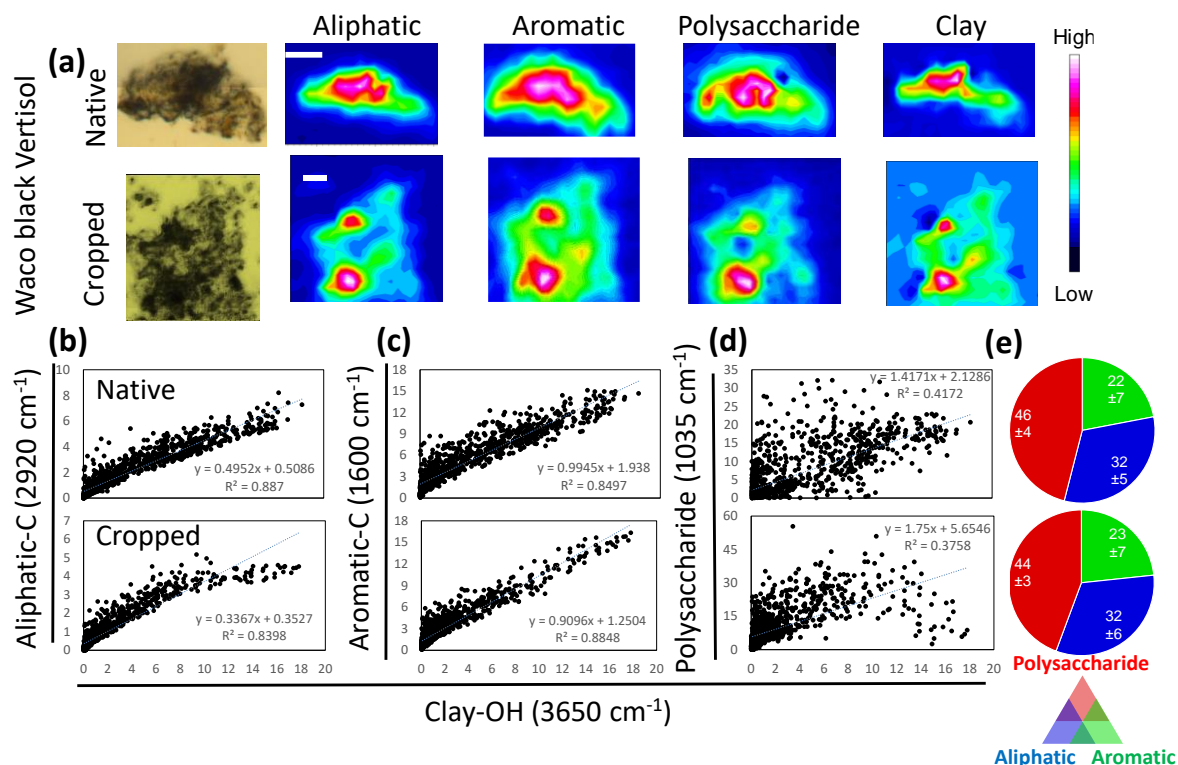

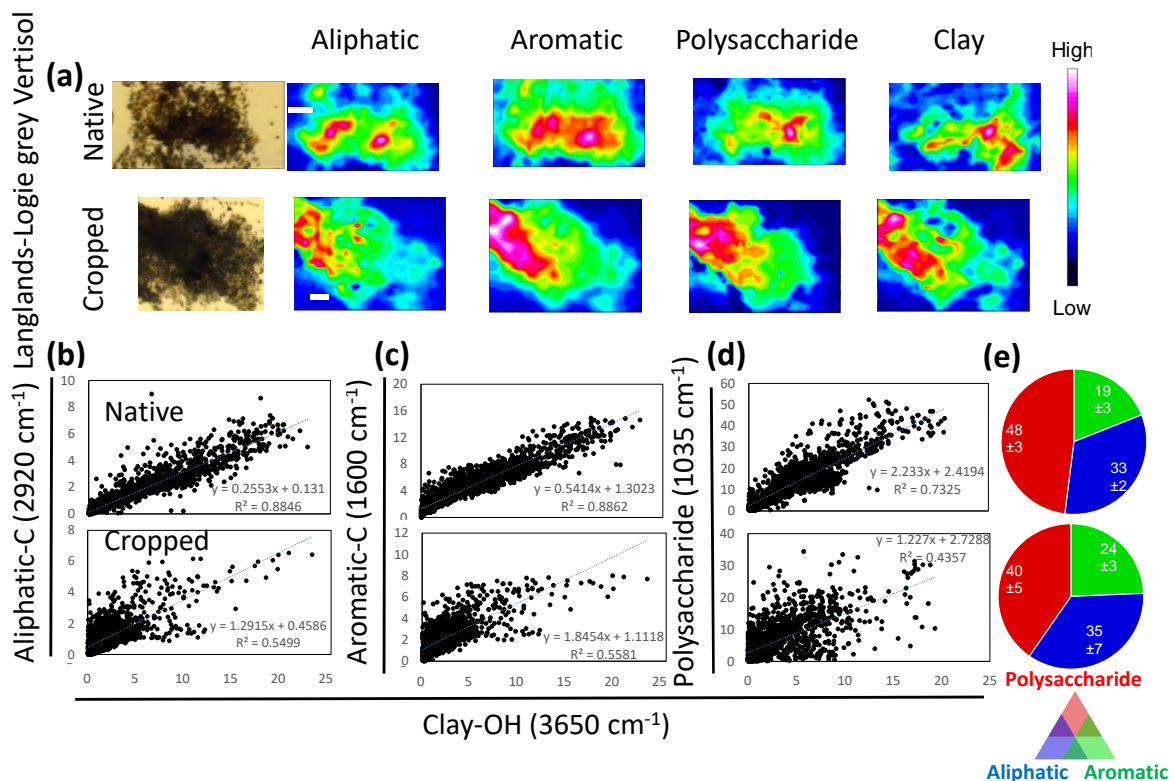

Figure 3. Synchrotron-based microspectroscopic analysis of microaggregates of the Waco black Vertisol under the native vegetation and cropping. Semi-thin (200 nm) sections of water-stable microaggregates (53-250 μm) isolated from two land uses analysed using synchrotron-based IR-microspectroscopy. **(a)** Combined RBG maps showing the distribution of polysaccharides-C (1035 cm⁻¹), aromatic-C (1600 cm⁻¹), and aliphatic-C (2920 cm⁻¹), were obtained from 64 coadded scans (4 cm⁻¹ resolution), lateral resolution 5 μm. Two replicates are shown. White scale bars are 25 μm. Correlation between **(b)** aliphatic-C, **(c)** aromatic-C, and **(d)** polysaccharides-C with clay mineral. Regression analyses were performed using the collection of spectra obtained for both maps (*i.e.*, one spectrum per pixel). Only pixels where the selected absorption peak could be detected about baseline noise were included in the regressions. **(e)** Pie charts display normalized optical proportions of the four features analysed by an image processing pipeline.

Next, we examined the impact of cropping on the distribution of various C forms within the microaggregate sections. From visual observation of the maps, there were no clear differences between the cropped and native soils, with this perhaps not unexpected given the somewhat subtle differences observed in bulk C speciation from NEXAFS. Linear regressions confirmed that, with long-term cropping, aliphatic C remained closely correlated with clay for the cropped Waco Black Vertisol whilst the aliphatic C-clay correlation weakened in the cropped Langlands-Logie grey Vertisol. The R² values were substantially greater for polysaccharide C under native vegetation than cropping in the Langlands-Logie grey Vertisol from 0.73 to 0.44, whilst the correlation remained unchanged in the topsoil of Waco black Vertisol (0.38-0.42).

280

Figure 4. Synchrotron-based microspectroscopic analysis of microaggregates of the Langlands-Logie grey Vertisol under the native vegetation and cropping. Semi-thin (200 nm) sections of water-stable microaggregates (53-250 μm) isolated from two land uses analysed using synchrotron-based IR-microspectroscopy. **(a)** Combined RGB maps showing the distribution of polysaccharides-C (1035 cm⁻¹), aromatic-C (1600 cm⁻¹), and aliphatic-C (2920 cm⁻¹), were obtained from 64 coadded scans (4 cm⁻¹ resolution), lateral resolution 5 μm. Two replicates are shown. White scale bars are 25 μm. Correlation between **(b)** aliphatic-C, **(c)** aromatic-C, and **(d)** polysaccharides-C with clay mineral. Regression analyses were performed using the collection of spectra obtained for both maps (*i.e.*, one spectrum per pixel). Only pixels where the selected absorption peak could be detected about baseline noise were included in the regressions. **(e)** Pie charts display normalized optical proportions of the four features analysed by an image processing pipeline.

To quantify these observations from IRM, we developed an image processing pipeline to quantify the mean area proportion of polysaccharide-C, aliphatic-C, and aromatic-C (all pixels comprising the samples divided by the sum images across the intact section). For the Waco soil, the proportion of polysaccharide-C (44-48 %), aliphatic-C (27-33 %), and aromatic-C (20-29 %) was similar in the native vegetation and cropped soil (Fig. 3e). For the Langlands-Logie soil, long-term cropping slightly decreased polysaccharide-C (40 %) compared with the native vegetation (48 %) in the topsoil (Fig. 4e). Principal component analysis indicated that the distribution of C forms associated with clay mineral was less affected by cropping in the Waco soil

295

whereas the aliphatic C-clay association was weakened with cropping in the Langlands-Logie soil and the polysaccharide C-clay association was most vulnerable towards SOC loss (Supplementary Fig. S3 and S4).

A hierarchical clustering dendrogram (Fig. 5) indicated the similarity in relationships between the first derivatives of NEXAFS spectra (Fig. 2) and changes in C distribution (Fig. 3-4) and soil properties across land uses and soil types. Heavy fraction, polysaccharide, clay- and silt-C were in the same cluster, which were positively correlated with aromatic-C, phenolic-C, and aliphatic-C. Total organic C, total N, light fraction, and sand-C were in the same cluster which were positively correlated with carboxyl C-OOH and O-alkyl C that were vulnerable to SOC loss.

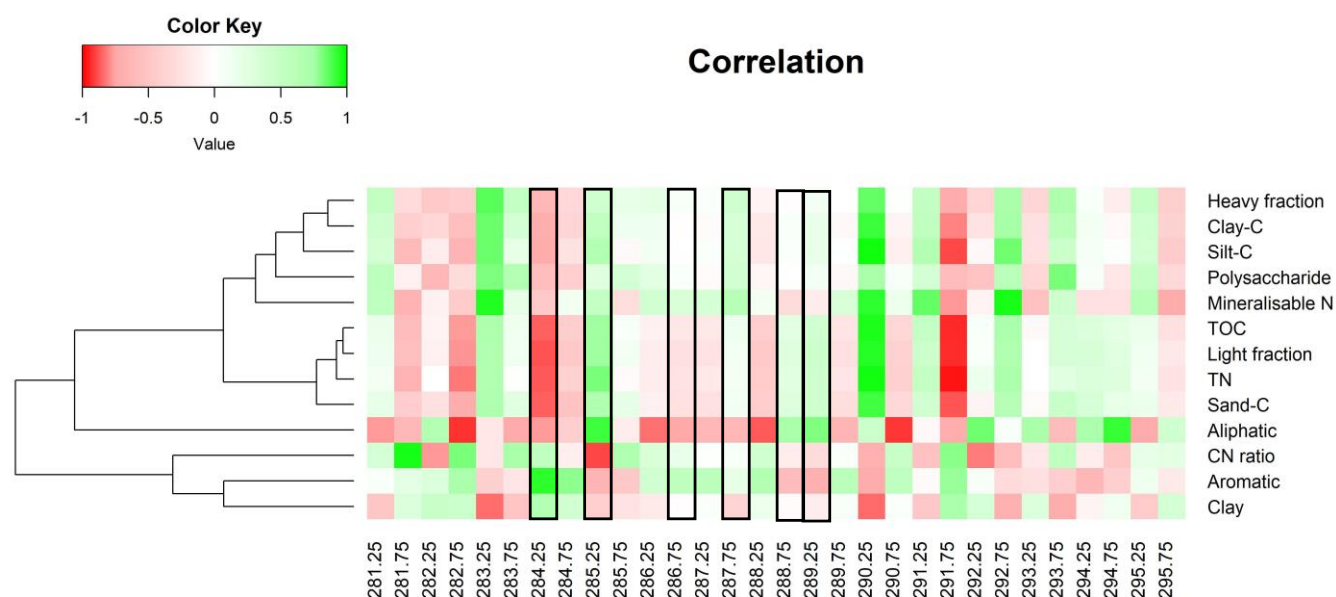

Figure 5. A hierarchical clustering dendrogram indicate the similarity relationships between the first derivatives of near edge X-ray absorption fine structure (NEXAFS) spectra (Fig. 2) and changes in soil properties across land uses and soil types. The first derivative of the NEXAFS spectra, 281-296 eV for C K-edge across all land uses and soil types were divided into 30 bins and pairwise correlations between each energy segment and distribution of aromatic C, aliphatic C, polysaccharide C, clay OH from IRM (Fig. 3 and 4) and other soil properties were assessed to explore relationships between C-speciation and C-distribution. The heatmap presents the colour-coded correlation co-efficient.

310 4 Discussion

4.1 Impact of long-term cropping on bulk C content and fractions

In the current study, land use change from native vegetation to cropping caused significant SOC loss in the bulk soils (17-23 %). This is consistent with values reported previously in global meta-analyses, such as the 20-60 % reduction reported after

315 long-term cropping by Kopittke et al. (2017) and the value of 42 % reported by Guo and Gifford (2002). In global tropical systems, SOC decline due to conversion of primary forests to cropland and perennial crops has been reported to be between 25 and 30 % (Don et al., 2011). Indeed, land use change from native tropical vegetation to continuous cropping up to 82 years was found to decrease SOC stocks by 43 % in subtropical Australia (Barnard et al., 2024). In the current study, the net losses in SOC in cropped soils in comparison to their native counterparts, can be the result of that the formation of new SOC from lower C inputs in cropped soils cannot counterbalance the loss of native SOC, and destruction of organo-mineral associations with cultivation (Even and Cotrufo, 2024). The land use change from native vegetation to cropping may have altered the C flows and inputs in both locations.

When further examining the SOC fractions, our findings that the MAOC is the dominant fraction in heavy clay soils are consistent with previous studies showing that fine MAOC contributes the majority of C with oPOC making a smaller but still important contribution (Traore et al., 2020; Kleber et al., 2015). These results highlight the importance of organo-mineral interactions (*i.e.*, fine MAOC) and physical occlusion of particulate organic matter through aggregation (*i.e.*, oPOC) in building SOC stocks (Angst et al., 2017). Silt- and clay-rich Vertisols in the current study, consist of montmorillonites with a high permanent negative charge and surface area, can further enhance OC sorption (Traore et al., 2020).

Overall, SOC loss as a result of long-term cropping was predominantly from the two largest fractions, being the fine MAOC and oPOC fractions (Fig. 1). Although the fine MAOC fraction is generally considered the most persistent fraction (Dungait et al., 2012), we showed that losses were greatest from this fraction given that it accounted for 72-91% of the total SOC. Indeed, decreases in fine MAOC accounted for 88 % of the total decrease in SOC. These observations are in accordance with previous findings that have shown that the mineral-associated fractions can be sensitive to land use changes (Yeasmin et al., 2023; Hondroudakis et al., 2024; Barnard et al., 2024). The factors that influencing MAOC following land use changes can be driven by tillage, root exudates, and microbial processes (Even and Cotrufo, 2024).

335 We also examined the impact of cropping on other fractions. The fPOC fraction is often more accessible to biodegradation hence rapid turnover can occur even in the native vegetation systems. Although the fPOC fraction is often more sensitive to land use changes (Hondroudakis et al., 2024; Barnard et al., 2024), we found this fraction made only small contributions to the total bulk C for these subtropical semi-arid Vertisols and was not subject to land use change (Fig. 1a and b). In a similar manner, the coarse MAOC contributed the smallest proportion of total C in all soils (Fig. 1).

340 **4.2 Impact of long-term cropping on preservation of C forms**

Given the marked loss of SOC with cropping (Fig. 1), we examined whether there was also a change in C speciation associated with this loss. NEXAFS analyses revealed that conversion to cropping did not cause a marked change in the C forms (Fig. 2 and Supplementary Table S1). Therefore, our first hypothesis that subsequent cropping can affect functional composition of SOC with preservation of complex C forms after SOC loss is not supported.

345 These findings provide important information regarding the underlying mechanisms driving SOC preservation. Specifically, we have shown that the SOC loss (Fig. 1) was not due to preferential consumption of particular forms of C and the concomitant accumulation of complex or highly diverse forms of C, but rather, an overall depletion of all C forms. These observations are important in understanding the mechanisms that higher complexity and diversity could result in preservation of complex C forms (De Nobili et al., 2020). Rather, we show here in a long-term cropping system that the most persistent SOC (*i.e.*, the
350 SOC remaining after long-term land use change and disruption) was similar in form to that from the undisturbed native soil (Fig. 2). Thus, our data do not support the hypothesis that increasing SOC storage is driven by preservation of complex C forms. Our findings here are somewhat similar to those of Jones et al. (2023) who reported that persistent soil organic matter in a podzol chronosequence was not compositionally complex or diverse. In a similar manner, the study of Leifeld and Leifeld and Kögel-Knabner (2005) used ¹³C nuclear magnetic resonance (NMR) analyses and showed that there was no change in the
355 composition in response to land use change.

360 Closer examination of the NEXAFS analyses revealed carboxylic-C functional group as the most prominent feature in the two agroecosystems, followed by O-alkyl-C and aromatic-C (Fig. 2; Supplementary Table S1). The phenolic-C represents a tracer for lignin in the form of O-substituted aryl-C and potentially ketonic-C and phenyl-C attached to amide group (Urquhart and Ade, 2002). The O-alkyl-C component represents mostly polysaccharides and fractions of alcohol and ether-C (Lehmann and Solomon, 2010). These results support the previous findings of the impact of land use change on C functional groups in
(sub)tropical forest soils dominated by carboxylic-C (34-40 %), O-alkyl C (22-24 %), and aromatic C (17-19 %) (Solomon et al. 2007).

365 Nevertheless, previous studies using NEXAFS reported that the proportion of aromatic C increased, and the phenolic-C and O-alkyl C decreased over time when converted native tropical forest and subtropical grassland to agriculture (Solomon et al. 2007). The changes in C functional groups indicated that mineralisation and depletion of O-alkyl structures, in the form of cellulose, or carbohydrates, or short chain oxidation of phenylpropane units of lignin, with continuous cropping (Solomon et al. 2007). This increased aromatic-C functional group may be resulted from accumulation of H- and C-substituted aryl-C structures and aliphatic components such as (poly)methylene during mineralisation with cropping. However, such increased aromaticity was not evident in this current study. It is likely that reduced return of organic matter to the soil (fPOC in Fig. 1)
370 and rapid organic matter mineralisation in both cropped and native vegetated systems depleted carboxylic-C group in these two agroecosystems. This is supported by NEXAFS analyses that showed lack of response in the composition of fPOC, oPOC, and MAOC to land use change (Barnard et al., 2024; Hondroudakis et al., 2024).

4.3 Impact of long-term cropping on lateral heterogeneity of C forms

375 We further investigated the *in-situ* distribution of C functional groups in sections taken from intact microaggregates using high resolution microspectroscopic techniques. The IRM mapping supports the fractionation results that binding of C to the mineral fraction contributes to the majority of SOC as MAOC. We showed that strong association between aliphatic- and aromatic-C

with clay OH minerals whereas polysaccharide-C was less correlated to clay. IRM analyses revealed high heterogeneity of SOC distribution as well as the consequences of land use change. Our data suggest that preservation of SOC in these Vertisols is likely regulated by the physical protection of SOC with clay minerals.

380 Several overall observations from these IRM analyses can be made to advance the understanding of how organic C behaves at the microscale that are critical to preservation of SOC. Firstly, we found that land use change did not result in a marked change in C forms within these sections from intact microaggregates. Indeed, for the Waco soil, the proportion of polysaccharide-C (44-48 %), aliphatic-C (27-33 %), and aromatic-C (20-29 %) was similar in the native vegetation and cropped soil (Fig. 3e), whilst for the Langlands-Logie soil, the proportion of polysaccharide-C (40-48 %), aliphatic-C (32-35 %), and aromatic-C

385 (19-25 %) was also similar in the native vegetation and cropped soil (Fig. 4e). Related to this observation, it was also noted that the IRM mapping supported the results of the fractionation, with strong correlations between both the aliphatic-C and the clay OH minerals and between the aromatic-C and the clay OH minerals, with this contributing to the MAOC fraction being the dominant C pool (Fig. 3b & c and 4b & c). In contrast, polysaccharide-C was less correlated to clay (Fig. 3d and 4d). Therefore, such findings supported our second hypothesis that strong correlations between the lateral distribution of C forms

390 and clay minerals can provide physical protection of SOC. Indeed, the largest proportion of organic C was found in the clay-size fractions of the native Waco black Vertisol (52 %) and the Langlands-Logie grey Vertisol (44 %) (Barnard et al., 2024). Despite most of SOC loss being MAOC upon land use change, the distribution of C forms in association with clay minerals remained less affected. Thus, these two observations (*i.e.*, the close correlation between SOC forms and clay minerals, plus the similarity of SOC forms in native soils and cropping soils) further supported the NEXAFS results that preservation of SOC

395 was not due to the formation of complex C compounds, rather the physical protection of SOC. The surfaces of clay minerals can adsorb organic molecules which is an important mechanism for preservation of SOC (Kleber et al., 2021). Soil minerals also contribute to the formation and destruction of aggregates that regulate protection of organic matter against microbial mineralisation (Lehmann et al., 2020). Indeed, a hierarchical clustering dendrogram (Fig. 5) indicated the similarity in relationships between the first derivatives of NEXAFS spectra (Fig. 2) and changes in C distribution (Fig. 3-4) and soil

400 properties across land uses and soil types. Heavy fraction, polysaccharide, clay- and silt-C were in the same cluster, which were positively correlated with aromatic-C, phenolic-C, and aliphatic-C. Total organic C, total N, light fraction, and sand-C were in the same cluster which were positively correlated with carboxyl C–OOH and O-alkyl C that were vulnerable to SOC loss.

Secondly, in this study we showed that long-term continuous cropping can weaken the correlations between the distribution

405 of C forms and clay minerals. This was particularly evident in the Langlands-Logie soil with quartz (51 %) as the dominant mineral and less impacted in the smectite-dominant (60 %) Waco soil. This further explained that the majority of SOC loss occurred in the MAOC fraction. From visual observation of the IRM maps, there were no clear differences between the cropped and native soils. Linear regressions confirmed that, with long-term cropping, aliphatic C remained closely correlated with clay for the cropped Waco Black Vertisol whilst the aliphatic C-clay correlation weakened in the cropped Langlands-Logie grey

410 Vertisol. Ligand exchange may explain the strong resilience of aliphatic-clay associations against cropping-driven

mineralisation. Such organo-mineral interactions can be strengthened in the case of Waco clay through anion exchange and/or sorption between carboxylic and phenolic/aliphatic C functional groups and clay mineral-OH groups such as phyllosilicate edges and hydroxyl groups of Fe, Mn, and Al (Adhikari and Yang, 2015; Newcomb et al., 2017). Further, slower turnover of SOC in clay and fine silt fractions than sand fractions has also been reported (Marschner et al., 2008). However, the R^2 values were substantially greater for polysaccharide C under native vegetation than cropping in the Langlands-Logie grey Vertisol (0.73 to 0.44) whilst the correlation remained unchanged in the Waco black Vertisol (0.38-0.42). The strong correlations between polysaccharide-C and clay in the native Langlands-Logie soil can be explained by the high organic input from native forest whereas weaker correlations were observed in the grassland-derived native Waco soil. Furthermore, principal component analysis indicated that the distribution of C forms associated with clay mineral was less affected by cropping in the Waco soil whereas the aliphatic C-clay association was weakened with cropping in the Langlands-Logie soil and the polysaccharide C-clay association was most vulnerable towards SOC loss (Supplementary Fig. S4).

Thirdly, across all soils (both native and cropped), the distribution of C forms was highly heterogenous, with no apparent consistent pattern in the distribution of C forms within the core of microaggregates (Fig. 3-4). These findings support the growing body of microscopic evidence (Weng et al., 2022; Weng et al., 2024; Hondroudakis et al., 2024) against the hypothesis that the formation of microaggregates occurs via the occlusion of organic matter by mineral particles (Six et al., 1998; Tisdall and Oades, 1982). Indeed, our findings align with the observations from previous studies. For example, there was no gradient in the C concentration from aggregate surface to the interior for C forms for a Vertisol and a Oxisol after conversion from native vegetation to cropping (Hernandez-Soriano et al., 2018). In a similar manner, organic C was heterogeneously distributed within microaggregates with no clear pattern from three forest-derived soils (Lehmann et al., 2008). Instead, preferential localisation of organic matter in fine-scale discrete areas has been observed by numerous studies (Vogel et al., 2014; Steffens et al., 2017; Kopittke et al., 2018). It is noted that such organo-mineral associations often occur at submicron scales whereas the resolution of synchrotron-based IRM of 5 μm may limit the observations.

5 Conclusions

We have provided, for the first time, two-dimensional microscale information of C forms and their distribution in the microaggregates under long-term land use change from native forest/grassland to cropping. Long term cropping of subtropical semi-arid Vertisols depleted SOC by up to 23 %. Despite being persistent fractions, the largest C losses with cropping were in the two largest pools (fine MAOC and oPOC). This highlights the importance of organo-mineral interactions and occlusion of particulate organic matter through aggregation in maintaining SOC stocks. This was confirmed by IRM and NEXAFS analyses showing that despite the loss of fine MAOC and oPOC, there were only modest changes in C forms and distribution, with this supporting the importance of ‘spatial heterogeneity’ as an important controller of preservation of SOC as opposed to being related to the formation of recalcitrant and highly complex C compounds. Although highly heterogenous distribution of C forms within intact microaggregates, strong associations between C forms and clay were maintained under cropping in the

445 Waco black Vertisol but weakened in the Langlands-Logie grey Vertisol. The findings of this study provide new insight into protection and storage of SOC. The in-situ analyses supported observations from the fractionation analysis, demonstrating that the binding of organic C to the mineral fraction is critical in determining preservation of SOC under land use change.

Code and data availability.

The data and analyses that support these findings will be made available in response to a reasonable request but are not hosted in an online repository at this time in order to protect the privacy of growers.

Author contributions

450 ZHW, PMK, and RCD designed the experiments, and ZHW carried them out. BAM, MB, CLD, EL, and conducted analyses. BJR, YGZ, and TIM contributed to writing and revising of the manuscript. ZHW drafted the manuscript with contributions from all authors.
