## Abstract

Understanding aquatic ecosystem metabolism involves the study of two key processes: carbon fixation via primary production and organic C mineralization as total ecosystem respiration (ERtot). In streams and rivers, ERtot includes respiration in the water column (ERwc) and in the sediments (ERsed). While literature surveys suggest that ERsed is often a dominant contributor to ERtot, recent studies indicate that the relative influence of sediment-associated processes versus water column processes can fluctuate along the river continuum. Still, a comprehensive understanding of the factors contributing to these shifts within basins and across stream orders is needed. Here we contribute to this need by measuring ER<sub>we</sub> and aqueous chemistry across 47 sites in the Yakima River 25 basin, Washington, USA. We found that ER<sub>wc</sub> rates varied throughout the basin during baseflow conditions, ranging from -7.38 to 0.36 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>, and encompassed the entire range of ER<sub>wc</sub> rates from previous work. Additionally, by comparing to ER<sub>tot</sub> estimates for rivers across the contiguous United States, we suggest that the contribution of ERwc rates to reach-scale ERtot rates across the Yakima River basin are likely highly variable, but we did not test this directly. We did not observe clear increases in ER<sub>wc</sub> moving down the stream network, and instead observed that ER<sub>wc</sub> is locally controlled by temperature, dissolved organic 30 carbon, total dissolved nitrogen, and total suspended solids, which explained 40% of ERwc variability across the basin. Our findings highlight the potential relevance of water column processes in aquatic ecosystem metabolism across the entire stream network and that these influences are likely not predictable simply via position in the stream network. Our results are generally congruent with previous work in terms of locally-influential variables, suggesting that the observed variability and suite of associated environmental factors influencing ERwc are potentially transferable across basins.

# 35 1 Introduction

Metabolism in streams and rivers includes both gross primary production (GPP) and ecosystem respiration (ER<sub>tot</sub>) as fundamental processes that shape energy dynamics and nutrient cycling in riverine systems (Bernhardt et al., 2018). GPP and ER<sub>tot</sub> impact

biogeochemical cycling through the fixation and subsequent breakdown and processing of carbon (*C*) in aquatic ecosystems (Allan et al., 2021; Genzoli & Hall, 2016; Hall, 2016; Hall & Hotchkiss, 2017; Reisinger et al., 2016). Riverine metabolism is modulated by various environmental features, including physical and biogeochemical factors. Physical parameters include discharge, flow regimes, flow extremes, light availability, and temperature (Bernhardt et al., 2022; Hensley et al., 2019; Jankowski & Schindler, 2019; Nakano et al., 2022). Biogeochemical influences include the availability, amount, and composition of *C* and other nutrients (Bertuzzo et al., 2022; Garayburu-Caruso et al., 2020; Mulholland et al., 2008; Reisinger et al., 2021). Additionally, watershed characteristics such as stream size or drainage area, hydrologic connectivity, watershed geomorphology, and land use and land cover further affect these metabolic processes (Bernot et al., 2010; Demars, 2019; Finlay, 2011; Jankowski & Schindler, 2019).

Reach scale ecosystem metabolism encompasses biogeochemical processes that occur in both the water column and in benthic and hyporheic sediments (Hall & Hotchkiss, 2017). Historically, metabolism studies focused on headwater streams which are characterized by relatively large contact areas between surface water and the benthic sediments (Alexander et al., 2007; Battin et al., 2008; Findlay, 1995; Gomez-Velez et al., 2015; Mulholland et al., 2008; Peterson et al., 2001). Recent advances in computing power and the increased availability of high-resolution sensor data (e.g., dissolved oxygen, temperature, and river depth) have expanded the scope of metabolism studies beyond single small streams enabling researchers to investigate the relative contributions of ER<sub>sed</sub> and water column respiration (ER<sub>wc</sub>) to ER<sub>tot</sub> across diverse stream networks and orders. These efforts show that the proportion of ER<sub>tot</sub> derived from ER<sub>sed</sub> varies greatly across different sites, contributing from 3% to 95% of ER<sub>tot</sub> (Battin et al., 2003; Fuss & Smock, 1996; Gagne-Maynard et al., 2017; Jones Jr, 1995; Kaplan & Newbold, 2000; Naegeli & Uehlinger, 1997). This observed variability in the fraction of ER<sub>tot</sub> derived from ER<sub>sed</sub> indicates that ER<sub>wc</sub> may be important in certain places and times.

Water column processes, including nutrient cycling, occur at considerable rates and become increasingly important as rivers grow in size, marking a transition from benthic-dominated to water column-dominated processing (del Giorgio & Williams, 2005; Gardner & Doyle, 2018; Reisinger et al., 2015, 2016). However, even as rivers increase in size, the relative contribution of ER<sub>wc</sub> to ER<sub>tot</sub> remains variable, likely in response to changing environmental conditions (Genzoli & Hall, 2016; Reisinger et al., 2021; Ward et al., 2018). This highlights a key knowledge gap that while the role of the water column in reach-scale processes such as GPP and ER<sub>tot</sub> likely fluctuates along the river network, this relationship remains poorly understood. We contribute to addressing this knowledge gap by investigating the spatial variation of ERwc in the Yakima River basin, Washington, USA. The Yakima River basin is representative of the Columbia River basin, one of the largest river basins in the contiguous United States (CONUS), that spans the northwest region of CONUS. The Yakima River basin encompasses climatic regimes, biomes, physical settings, and land use conditions commonly found throughout the Columbia River basin and the western CONUS. Using the environmental diversity of the Yakima River basin, our goal was to generate knowledge of ERwc that could be transferable across the Columbia River basin and potentially beyond. We focus on ERwc during summer baseflow conditions and specifically 1) compare ERwc from the Yakima River basin to published ER<sub>wc</sub> and ER<sub>tot</sub> from other systems; 2) test the hypothesis that ER<sub>wc</sub> will increase moving down the stream network; and 3) compare variables that explain variation in ER<sub>wc</sub> to those found as explanatory in previous studies. To address these objectives, we estimated ER<sub>we</sub> and measured surface water chemistry at 47 sites across the Yakima River basin during the summer of 2021. Our estimates of ERwc span all previously reported rates and while we did not observe clear increases in ERwc moving down the stream network, the most important explanatory variables did align with previous studies.

#### 2 Methods

## 2.1 Methods Overview

Field sites in the Yakima River basin were selected to be representative of biophysical attributes of the larger Columbia River basin. For this, we grouped all catchments in the Columbia River basin into six classes sharing similar landscape characteristics using key biophysical attributes and selected sites in the Yakima River basin from each of the six classes. Final field locations spanned six Strahler stream orders and a wide range of land cover types and physical settings. We used dark bottle incubations and collected surface water chemistry samples to study the spatial variability of ER<sub>wc</sub> at a basin scale with respect to environmental conditions during summer baseflow conditions in 2021. We also compared ER<sub>wc</sub> observed in the Yakima River basin against literature ER<sub>wc</sub> and ER<sub>tot</sub> values to understand how the Yakima River basin relates to streams and rivers across the world. We used Least Absolute Shrinkage and Selection Operator (LASSO) regression to evaluate the relationship between ER<sub>wc</sub> and drainage area, stream temperature, surface water chemistry, and organic matter putative biochemical transformations as a proxy for the diversity of reactions occurring in upstream reaches to determine the primary factors influencing ER<sub>wc</sub> throughout the Yakima River basin. All analyses were performed using R Statistical Software (v4.2.0). All data generated from the sampling study, including data not evaluated in this manuscript, are publicly available.

#### 90 2.2 Watershed characterization and site selection

The Yakima River basin is the fifth-largest basin in the Columbia River basin and is located entirely within the state of Washington, USA. The basin is roughly 16,000 km<sup>2</sup> and spans forested mountainous regions in the west to arid valleys and plains in the east. The basin has a diversity of land covers and land uses dominated by shrubland, forest, and agriculture. Annual precipitation ranges from up to 350 cm in the west to 25 cm in the east (Vano et al., 2010).

95

To enable further testing of the transferability of study results to catchments throughout the Columbia River basin, we strategically selected sampling sites in the Yakima River basin based on their biophysical (e.g. hydrology, topography, vegetation type) characteristics. This was done by first grouping all National Hydrography Dataset Plus Version 2.1 (NHDPlusV2.1) catchments (McKay et al., 2012) in the Columbia River basin (n = 181,531) into six classes sharing similar landscape characteristics using cluster analysis. To capture the variability in biophysical settings found across the Columbia River basin, we selected 16 key attributes as input variables to the cluster analysis, including climate, vegetation structure and function, topography, and wildfire potential (Table S1). We then selected multiple sites within each of the six Columbia River basin classes. Existing, readily available geospatial data came from multiple sources including NASA Moderate Resolution Imaging Spectroradiometer (eMODIS) Remote Sensing Phenological (RSP) data (U. S. Geological Survey, 2019); NASA MODIS land cover type (Friedl & Sulla-Menashe, 105 2019); NASA MODIS normalized difference vegetation index (NDVI), fraction of photosynthetically active radiation (FPAR, %), and leaf area index (LAI, m<sup>2</sup> m<sup>-2</sup>) (Myneni et al., 2015); NASA MODIS total evapotranspiration (ET, kg H<sub>2</sub>O m<sup>-2</sup> d<sup>-1</sup>) (Running et al., 2017); NASA MODIS terrestrial net primary productivity (NPP, kg C m<sup>-2</sup> y<sup>-1</sup>) and terrestrial net ecosystem productivity data (NEP, kg C m<sup>-2</sup> y<sup>-1</sup>) (Running & Zhao, 2019); PRISM precipitation data (PRISM Climate Group, Oregon State University, 2023); NHDPlusV2.1 stream length and catchment boundaries (McKay et al., 2012); USGS National Elevation Dataset (NED) 1/3 110 Arc-Second Digital Elevation Model topography data (U.S Geological Survey, 2023); USFS Wildfire Hazard Potential (WHP) data (Dillon, 2018); and Landscape Fire and Resource Management Planning Tools (LANDFIRE) existing vegetation percent cover (%) and height (m) data (Dillon & Gilbertson-Day, 2020).

We used a k-means clustering algorithm using the kmeans function within the 'stats' package in base R to group NHDPlusV2.1 catchments with similar properties using the normalized, statistical moments (minimum, maximum, mean, and standard deviation (SD)) for 70 geospatial variables within each NHDPlusV2.1 catchment (Table S1) as input. To calculate statistical moments for each variable, we summarized geospatial data types at the NHDPlusV2.1 catchment level using two different methods: zonal statistics for continuous raster data and tabulation for vector data. Zonal statistics calculate statistical moments by individual catchment polygon. Tabulation calculates total length or area of a particular vector feature within each individual catchment polygons. We evaluated 13 different sets of variable-statistical moment combinations for use in the cluster analysis and selected variable set 8, which included the zonal mean and zonal standard deviation for 70 variables (n = 140) (Table S2). Once the data for variable set 8 were summarized at the NHDPlusV2.1 catchment level, we calculated z-scores (z) for each geospatial variable. Resultant z-scores for variable set 8 were fed into the k-means classifier, which iteratively adds each catchment to one of n clusters, with n being set by the user (n = 15, this study), using Euclidean distance to minimize within-cluster distance and maximize 125 between-cluster distance. We ran multiple iterations of the cluster analysis using 2-15 clusters using the mean and standard deviation of all variables. To visualize the reduction in within-cluster variation between iterations 1–15, we generated elbow plots by plotting the Within Cluster Sum of Squares (WCSS) value against the total number of catchments in a cluster and selected six clusters as the suitable number of clusters that minimized map visual complexity enough to guide manual site selection while maintaining a level of variation in key biophysical characteristics representative of the Columbia River basin. Clusters 1 and 3-6 were categorized according to tree height, precipitation, and elevation (Table 1 and Table S3). Cluster 2 was categorized as "Water dominated" and was not used for selecting sites. Cluster analysis results were then used to guide the selection of 47 field sites distributed across Strahler stream orders 2-7 (the highest order stream in the Yakima River basin) that spanned the basin and captured the variation in biophysical characteristics represented by clusters 1 and 3-6 (Fig. S1). First order and other non-perennial streams were not sampled due to the lack of flow during summer baseflow or baseflows were too low to support sampling. We attempted to include logistical considerations in model-based site selection, but this task proved impractical and field-scouting trips were needed to refine site selections. Day-of-sampling changes to the sampling plan were made on-the-fly when the Schneider Springs Fire started on the Okanogan-Wenatchee National Forest. Fire activity and road closures restricted access to a large portion of the Yakima River basin, primarily in the Tieton River and American River watersheds located in the midwestern portion of the basin.

Table 1. Cluster analysis results characterizing NHDPlusV2.1 catchments across the Columbia River basin and Yakima River basin with similar biophysical and hydrologic characteristics and the number and percentage of sites in each basin.

Cluster	Name	CRB Drainage Area	YRB Drainage Area	YRB Sites Per Cluster	Percent YRB Sites Per Cluster
mesic					
2	Water dominated	3%	2%	0	0%
3	Tree dominated high elevation	7%	2%	2	4%
	hydric				
4	Shrub-steppe middle elevation	25%	28%	10	21%
	xeric				
5	Tree dominated middle elevation	17%	17%	13	28%
	mesic				
6	Tree dominated middle elevation	24%	23%	13	28%
	xeric				

"CRB Drainage Area" is the percentage of the total drainage area of the Columbia River basin that was classified in each cluster. "YRB Drainage Area" is the percentage of the total drainage area of the Yakima River basin that was classified in each cluster. "YRB Sites Per Cluster" is the total number of field sites in the Yakima River basin (n = 47) located in each cluster. "Percent YRB Sites Per Cluster" is the percentage of the total number of sampling sites in the Yakima River basin located in each cluster.

## 2.3 Water column respiration data collection

We measured ER<sub>wc</sub> (g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>) in triplicate for 2 h at each site between 30 August and 15 September 2021 using a modified "semi-*in situ*" dark bottle incubation (Genzoli & Hall, 2016) (Fig. 1a). Calibrated DO sensors (miniDOT Logger; Precision Measurement Engineering, Inc.; Vista, CA, USA) recorded DO concentration (mg L<sup>-1</sup>) and temperature (°C) at 1 min intervals in 2-L dark bottles (Nalgene<sup>TM</sup> Rectangular Amber HDPE bottles; ThermoFisher Scientific; Waltham, Massachusetts, USA) (Fulton et al., 2022). Bottle necks were slightly widened (1 to 2 mm) to accommodate the diameter of the DO sensor.

At the start of each sampling day, DO sensors and all sampling equipment were placed in a cooler with blue ice packs to keep them cool and minimize the time needed at each site for the sensors to equilibrate with the similarly cool river water temperatures. Upon arrival at each site, bottles were rinsed three times with river water and then filled by wading as close to the thalweg as possible, submerging the bottles below the river surface, and rolling them 360 degrees while held upright underwater to ensure no air bubbles were present in the bottles (Fig. 1a). Bottles were secured upright in a cooler filled with river water, placed in the shade on the streambank, and allowed to equilibrate for 20 min. Following the 20 min equilibration period, the bottles were emptied and refilled with fresh river water and a small, battery-powered mixing device (Underwater Motor, Item Number 7350; Playmobil; Shanghai, China; rechargeable AA NiMH battery; Amazon; Seattle, Washington, USA) and the DO sensor was gently inserted (sensor face-up) in the bottles to minimize trapping air bubbles in the bottles. The bottles were capped underwater and returned to the water-filled cooler. The bottles were incubated for 2 h, and river water surrounding the bottles in the cooler was replenished every 20 min to maintain *in situ* temperature.

Figure 1. Modified semi-in situ dark bottle incubation method and example study sites. (a) Underwater photograph of DO sensor being inserted into incubation bottle filled with river water and mixing device. Right panels emphasize the diversity of environmental settings covered in this study. (b) North Fork Teanaway River (site S19E), Kittitas County, Washington, September 2021. Site S19E is classified as a mesic, high elevation site dominated by tree canopy (Cluster 1; see Table 1, Table S3, Fig. S1). (c) Yakima River at Mabton (site T02), Yakima County, Washington, September 2021. Site T02 is classified as a mesic, middle elevation site dominated by tree canopy (Cluster 5; see Table 1, Table S3, Fig. S1).

## 2.4 Surface water chemistry sample collection and analysis

Filtered surface water samples were collected at each site for dissolved inorganic C (DIC, mg L<sup>-1</sup>); dissolved organic C (DOC, mg L-1); total dissolved N (TDN, mg L-1); anions, including nitrate (NO<sub>3</sub>-, mg L-1), chloride (Cl-, mg L-1), and sulfate (SO<sub>4</sub>-, mg L-1); and DOM chemistry using a 50-mL syringe and 0.22 µm sterivex filter (MilliporeSigma™ Sterivex™ Sterile Pressure-Driven Devices; MilliporeSigma<sup>TM</sup>; Burlington, Massachusetts, USA) (Grieger et al., 2022). Samples were collected in triplicate from 50% of the water column depth. Prior to sample collection, filter assemblies were rinsed once by pushing 5 mL of river water through the filter. DIC, DOC and TDN samples were filtered into 40 mL amber glass vials (Amber Clean Snap Vials; Thermo Fisher Scientific; Waltham, Massachusetts, USA). DIC samples were collected by attaching a sterile 18 g needle (BD General Use and PrecisionGlide Hypodermic Needles; Becton, Dickinson and Company; Franklin Lakes, NJ, USA) to the sterivex filter and pushing three vial-volumes of river water (~150 mL) slowly through the syringe to prevent the introduction of air bubbles to the sample, allowing the vials to overflow continuously. When the final 50 mL of river water was pushed through the syringe, the vials were capped with a surface tension dome of water to ensure no headspace. Samples collected for ion analysis were filtered into a 15 mL conical tube (Olympus<sup>TM</sup> Plastics; Genesee Scientific; Morrisville, NC, USA). Samples collected for DOM chemistry were filtered into pre-acidified (85 % phosphoric acid, H<sub>3</sub>PO<sub>4</sub>) 40 mL amber vials (Amber Clean Snap Vials; Thermo Fisher Scientific; Waltham, Massachusetts, USA) (Grieger et al., 2022). One unfiltered grab sample for total suspended solids (TSS, mg L<sup>-1</sup>) was collected using a pre-washed 2-L amber bottle (Nalgene<sup>TM</sup> Rectangular Amber HDPE Bottles; ThermoFisher Scientific; Waltham, Massachusetts, USA). TSS bottles were rinsed three times with river water prior to sample collection. All samples were stored on ice in the field and then refrigerated at 4° C before shipping for analysis to the Pacific Northwest National Laboratory (PNNL) Marine and Coastal Research Laboratory in Sequim, Washington (DOC and DIC) and PNNL Biological Sciences Facility 190 Laboratory in Richland, Washington (TSS, ions, and DOM). TSS samples were analyzed within one week of collection, DOC and TDN were measured within two weeks of collection, DIC was measured within one month of collection, and ion and DOM samples were frozen (-20 °C) upon receiving until analysis.

DOC, TDN, and DIC were measured on a Shimadzu TOC-L Total Organic Carbon Analyzer. DOC was measured as non-purgeable organic C (NPOC). Anion concentrations were determined quantitatively on a Dionex ICS-2000 anion chromatograph with AS40 auto sampler using one replicate. An isocratic method was used with 23 mM KOH eluent at 1 mL/minute at 30°C. The analytical column was an IonPac AS18 (4 x 250 mm, Dionex catalog # 060549). The suppressor was a ADRS 600 set at 57 mA (4 mm, self regenerating, Dionex catalog # 088666). Concentrations below the limit of detection (LOD) of the instrument, or below the standard curve, were flagged (Grieger et al., 2022). Replicates with a coefficient of variation greater than 30 % were flagged and the outlier sample was identified and removed from analysis by calculating the distance between each of the replicate samples. For samples below the lowest standard value (TDN: 0.1 mg L<sup>-1</sup>, NO<sub>3</sub><sup>-</sup>: 0.07 mg L<sup>-1</sup>), one half of the lowest standard value was used (TDN: 0.05 mg L-1, NO<sub>3</sub>: 0.035 mg L-1) for statistical analysis. For samples below the limit of detection (TDN LOD: 0.07 mg L-1; NO<sub>3</sub>: LOD: 0.07 mg L<sup>-1</sup>), but above the lowest standard, one half of the LOD value (TDN: 0.035 mg L<sup>-1</sup>; NO<sub>3</sub>: 0.035 mg L<sup>-1</sup>) was used for analysis. Parameter mean values for each site were then calculated from the remaining replicates.

TSS samples were filtered in the laboratory through a pre-weighed and pre-combusted 4.7 cm, 0.7 µm GF/F glass microfiber filter (Whatman<sup>TM</sup> glass microfiber filters, Grade 934-AH®; MilliporeSigma; Burlington, Massachusetts, USA). After water filtration, the filter and filtration apparatus were rinsed with 30 mL of ultrapure Milli-Q water (Milli-Q® IQ Water Purification System; MilliporeSigma; Burlington, Massachusetts, USA) to ensure that all residue was captured by the filter. The filter was placed in foil and oven dried overnight at  $45^{\circ}$  C. TSS (mg  $L^{-1}$ ) was calculated as the difference between the weight (mg) of the filter before and

240

after filtration of the water sample divided by the volume of water filtered (L). For samples below the LOD, one half of the LOD value (LOD:  $0.24 \text{ mg L}^{-1}$ ) was used for analysis.

## 2.5 DOM chemistry via ultra-high resolution mass spectrometry and biochemical transformations

Organic matter chemistry was characterized via ultra-high resolution mass spectrometry using a 12 Tesla (12T) Bruker SolariX 215 Fourier transform ion cyclotron resonance mass spectrometer (FTICR-MS) at the PNNL Environmental Molecular Sciences Laboratory in Richland, Washington, following methods described in . Measured DOC concentrations were used to normalize the DOC concentration of the sample to 1.5 mg C L<sup>-1</sup> prior to further processing. Samples were thawed in the dark at 4°C overnight before acidifying to pH 2 using 85 % H<sub>3</sub>PO<sub>4</sub>. Samples were then subjected to solid phase extraction (SPE) using Bond Elut PPL cartridges (Agilent; Santa Clara, CA, USA) following protocols employed by Dittmar et al. (2008). Extracted samples were run in 220 the FTICR-MS with a standard electrospray ionization source in negative mode. Data were collected with an ion accumulation time of 0.08 seconds. BrukerDaltonik Data Analysis version 4.2 was used to convert raw spectra to a list of molecular compound mass-to-charge ratios (m/z) with a signal-to-noise ratio (S/N) threshold set to 7 and absolute intensity threshold to the default value of 100. Peaks were aligned (0.5 ppm threshold) and molecular formula were assigned using the Formularity software with S/N > 7 and mass measurement error < 0.5 ppm (Tolić et al., 2017). The Compound Identification algorithm takes into consideration the 225 presence of C, H, O, N, S, and P and excludes other elements. Aligned and calibrated data was further processed using ftmsRanalysis (Bramer et al., 2020). Replicate samples were merged into one site where peaks in a sample were retained if they were present in at least one of the replicates. DOM biochemical transformations were inferred following methods previously employed by Ryan et al., (2024); Danczak et al., (2023); Fudyma et al., (2021); Garayburu-Caruso et al., (2020); Stegen et al., (2018). In summary, we calculated pairwise mass differences between every peak in a sample regardless of molecular formula 230 assigned and compared that mass difference to a list of 1,255 molecular masses associated with commonly observed biochemical transformations (Table S4). Biochemical transformations allow you to infer the number of times the mass that corresponds to a specific molecule is gained or lost. For example, if a mass difference between two peaks corresponded to 128.095, that would correlate to the loss or gain of the amino acid lysine (see Table S4). We further calculated the total number of DOM transformations per site and the total number of DOM transformations normalized by the number of peaks present in the site (i.e., "normalized DOM transformations").

#### 2.6 DO sensor data cleaning, processing, and analysis

We extracted the raw DO concentration (mg  $O_2$   $L^{-1}$ ) and temperature (°C) sensor data for each site and plotted DO and temperature against incubation time for each set of triplicate incubations (n = 141). The plots were visually inspected to a) confirm that temperature sensors were at equilibrium with the river temperature when the 2 h incubation test period began and b) identify data gaps, outliers, and other data anomalies. Following the visual inspection of plots, the first 5 min of the time series was removed, then the data was trimmed to 90 min to account for anomalies due to emptying and refreshing river water in the bottles, and to ensure all sites had the same incubation time. Sensor data distributions were also evaluated using violin plots for each site.

 $ER_{wc}$  rates for individual triplicate incubation samples were calculated as the slope of the linear regression between the DO sensor data and the incubation time, which was converted to  $(g O_2 m^{-3} d^{-1})$  units. All samples met the normalized root mean square error (NRMSE) criteria of  $\leq 0.01$  (Shcherbakov et al., 2013). Mean  $ER_{wc}$  for each site and the global mean and variance were then calculated from the samples (n = 141). Nearly one-fifth of  $ER_{wc}$  values were slightly positive. Positive respiration rates are biologically unrealistic, however positive values less than  $0.5 g O_2 m^{-3} d^{-1}$  are difficult to distinguish from zero (Appling et al.,

2018b). Thus, we retained positive ER<sub>wc</sub> values less than 0.5 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup> and removed values greater than 0.5 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup> (n = 2). ER<sub>wc</sub> values greater than 0.5 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup> were observed when the DO concentration in the bottle started near 5 mg O<sub>2</sub> L<sup>-1</sup> and increased over the 2-hour incubation period. The increase in concentration and the high, positive respiration rate is likely due to diffusion of DO through the bottle walls.

# 2.7 Relationship of water column respiration rates to watershed characteristics and surface water chemistry

We evaluated the relationship between ERwc, watershed characteristics, physical parameters, and surface water chemistry using 255 LASSO regression models, which performs variable selection and model regularization, to establish the suite of explanatory variables that most influence variation in ER<sub>wc</sub> across the Yakima River basin. We observed that several model input variables had skewed distributions, thus a cube root transformation was applied to all variables to reduce the impact of high leverage points in the regression analysis. Further, all data was standardized as z-scores before analysis to ensure all data was in the same quantitative range. β coefficients reported for each variable were calculated by performing LASSO regression using the glmnet function in R 260 (Friedman et al., 2010) over 100 random seeds, normalizing to the maximum β coefficient in each regression, and averaging the normalized  $\beta$  coefficients across the 100 iterations. The minimum penalty parameter ( $\lambda$ ) determined by cross validation was used in each regression. Because LASSO regression was used for exploratory analysis, not prediction, data was not split into training and testing sets. Drainage area (km<sup>2</sup>) was defined as the total upstream drainage area from each site and was extracted for each site from the NHDPlusV2.1 stream database using site latitude and longitude. Stream order for each site was extracted as the reach 265 attribute "StreamOrde" from the NHDPlusV2.1 stream database, which is a modified version of Strahler stream order (Blodgett & Johnson, 2022; McKay et al., 2012; Willi & Ross, 2023). To evaluate whether the directionality of relationships observed in the LASSO regression were consistent with univariate relationships, we used Pearson correlations between ERwc, drainage area, water chemistry, and environmental factors; these correlations were calculated using the cor function in R.

# 2.8 Comparison to published water column respiration rates

270 To contextualize the magnitude of observed ERwc rates in the Yakima River basin, we compared our results to published literature values of ER<sub>wc</sub> (n = 118) (Table S5) and ER<sub>tot</sub> (n = 208). Published ER<sub>wc</sub> values were converted to volumetric units (g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>) using standard unit conversions. For example, molar values (µmol O<sub>2</sub> L<sup>-1</sup> H<sup>-1</sup>) as in Devol et al. (1995) and Quay et al. (1995) were corrected using the molar mass of oxygen and standard time conversions. When ERwc was reported with respect to C or carbon dioxide (CO<sub>2</sub>), as in Ellis et al. (2012) and Ward et al. (2018), conversions provided in the text were used to convert to an 275 O<sub>2</sub> basis. Areal estimates of ER<sub>wc</sub> (g O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>), as in Genzoli and Hall (2016) and Reisinger et al. (2021), were converted to volumetric units by multiplying by 1/depth (m<sup>-1</sup>) using same-day depth data for each reach studied. We also compared our ER<sub>wc</sub> values to daily reach-averaged estimates of ERtot (n = 490,907) for 356 rivers and streams across the CONUS by using the datasets published in Appling et al., (2018b) and Bernhardt et al., (2022) where ERtot was estimated by a single-station, open channel approach using the streamMetabolizer package in R (Appling et al., 2018b, 2018a). For our comparative analysis, we used the cleaned, gap-filled data from Bernhardt et al. (2022) (n = 208). The Bernhardt et al. (2022) sites are a subset from the Appling et al. (2018a, 2018b) dataset generated through a robust data quality analysis to remove sites potentially affected by process or observation error. For comparison with our ER<sub>wc</sub> values, we first averaged Bernhardt et al. (2022) ER<sub>tot</sub> areal units (g O<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>) at each site. Then, average ERtot values were converted to volumetric units by calculating average river depth per site from the Appling et al. (2018a, 2018b) dataset and multiplying average ER<sub>tot</sub> by 1/depth.

#### 285 3 Results and discussion

# 3.1 Yakima River basin ERwc rates spanned literature values

At baseflow conditions,  $ER_{wc}$  varied widely across the Yakima River basin. The linear regression models for each triplicate set of DO sensor measurements were well-fit to the data and all sites met the criteria for NRMSE  $\leq$  0.01 (Fig. S2; Fig. S3). After removing positive respiration rates > 0.5 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup> which are associated with diffusion effects on DO,  $ER_{wc}$  rates ranged from -7.38 to 0.36 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>, with a median value of -0.58 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup> (mean: -0.82 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>, standard deviation = 1.25 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>) (Fig. 2a). Thirteen sites had at least one replicate incubation where  $ER_{wc} > 0.0$  g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>, indicating that at those sites, true  $ER_{wc}$  values were too small to overcome instrument noise. Data from these seven sites were retained to avoid biasing the results of this study by including only high respiration rates. Overall, the consistent data between triplicate measurements illustrates that the method was effective in providing repeatable estimates of  $ER_{wc}$  rates throughout the Yakima River basin (Fig. S2; Fig. S3).

The values of ERwc observed in our study spanned the range of published literature values (Fig. 2; Table S5). From 118 published measurements of ERwe across the CONUS and the Amazon River basin, ERwe ranged from -4.63 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup> to -0.07 g O<sub>2</sub> m<sup>-3</sup> d-1. We compared median values, rather than means, across studies as medians are more appropriate for skewed distributions and are less sensitive to outliers in the data. The median  $ER_{wc}$  from this study (-0.58 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>) is slower than the median of literaturereported ER<sub>wc</sub> values (-0.96 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>). However, the fastest ER<sub>wc</sub> rate in the Yakima River basin (-7.38 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>), exceeded the fastest reported literature value (-4.63 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>)(Reisinger et al., 2021). Reisinger et al. (2021) measured ER<sub>wc</sub> in 15 midsized rivers across basins with differing turbidity levels and nutrient concentrations, finding a similar median ER<sub>wc</sub> (-0.60 g O<sub>2</sub> m<sup>-3</sup> d-1) to this study. In the Klamath River, median ER<sub>wc</sub> (-0.51 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>) was also similar to the Yakima River basin. However, ER<sub>wc</sub> doubled following summer cyanobacteria blooms, emphasizing the temporal variability in water column processes with changing environmental conditions (Genzoli & Hall, 2016). In the Amazon basin, literature comparisons varied, with median ER<sub>wc</sub> measurements similar to those found in the Yakima River basin in some studies (i.e., Devol et al., 1995; Ellis et al., 2012; Quay et al., 1995) and faster than the Yakima River basin in others (i.e., Ward et al., 2018). Ward et al. (2018) highlighted the importance of mixing in large rivers, noting that previous measurements of aquatic respiration in large tropical rivers, such as those measured in Quay et al. (1995) and Devol et al. (1995), may underestimate microbial respiration contribution due to lack of mixing during rate measurements. While comparisons across study medians are variable, the observation that ER<sub>wc</sub> in the Yakima River basin spans — and exceeds — reported literature values highlights the potential for using it as a test basin for understanding and uncovering transferable principles linked to stream metabolism.

While ER<sub>tot</sub> estimates are not available across the Yakima River basin at the time of ER<sub>wc</sub> estimation for this manuscript, measured ER<sub>tot</sub> rates spanned a large fraction of CONUS-scale ER<sub>tot</sub> rates estimated by Appling et al., (2018a, 2018b) and Bernhardt et al. (2022). ER<sub>tot</sub> rates are reach-scale estimates of stream metabolism derived from time series measurements of DO. This method assumes well-mixed conditions such that sensor measurements represent homogenous reach observations. Under well-mixed conditions, ER<sub>wc</sub> measurements from dark bottle incubations are also representative of reach-scale processes. The median ER<sub>tot</sub> for 208 CONUS measurements was -5.25 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup> with a range from -36.55 to -3.73 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>. The median ER<sub>wc</sub> rate (-0.58 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>) observed in the Yakima River basin was 11% of median ER<sub>tot</sub> (Fig. 2). The fastest ER<sub>wc</sub> rate in the Yakima River basin (-7.38 g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>), was faster than the median ER<sub>tot</sub> (Fig. 2). Given the overlap of ER<sub>wc</sub> from the Yakima River basin with CONUS-scale ER<sub>tot</sub>, we suggest that ER<sub>wc</sub> typically represents a small fraction of ER<sub>tot</sub> but may occasionally have larger contributions across the Yakima River basin. In comparison, Genzoli and Hall (2016) observed that before summer cyanobacteria blooms, ER<sub>wc</sub> contributed around 10% of ER<sub>tot</sub> in sites along the Klamath River, with the contribution of ER<sub>wc</sub> to ER<sub>tot</sub> increasing following

330

340

345

350

cyanobacteria blooms. Additionally, Reisinger et al. (2021) found that  $ER_{wc}$  was not the dominant contributor to  $ER_{tot}$  in mid-sized rivers, except at sites with low  $ER_{tot}$  (mean  $ER_{wc}$  contributions to  $ER_{tot}$ : 35%, range 2 – 81%). While these studies have shown spatiotemporal variability of the contributions of  $ER_{wc}$  to  $ER_{tot}$ , exploring these relationships in the Yakima River basin requires further research where  $ER_{tot}$  is measured in conjunction with  $ER_{wc}$ .

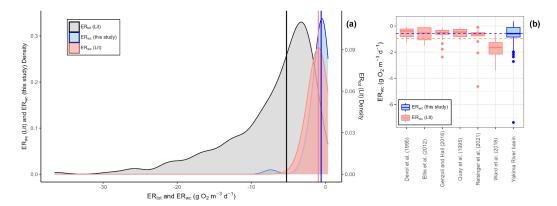

Figure 2. Water column respiration data from the Yakima River basin (ER<sub>wc</sub> (this study); n = 45), published water column respiration rates (ER<sub>wc</sub> (Lit); n = 118), and reach-scale estimates of ecosystem respiration by Appling et al., (2018a, 2018b) and Bernhardt et al. (2022) (ER<sub>tot</sub>; n = 208). (a) Kernel density plots of ER<sub>wc</sub> from the Yakima River basin (this study), published ER<sub>wc</sub> rates (Lit) that have been converted to the same units as this study (g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>), and published reach-scale ER<sub>tot</sub> (Lit) from Bernhardt et al. (2022) that have been converted to volumetric units using depth data from Appling et al. (2018a). The left y-axis is for ER<sub>wc</sub> values. The right y-axis is for ER<sub>tot</sub> values. The vertical blue line is the median ER<sub>wc</sub> observed in the Yakima River basin (-0.58 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>). The vertical red line is the median ER<sub>wc</sub> values from studies in rivers across the CONUS and the Amazon River basin (-0.96 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>). The vertical black line is the median ER<sub>tot</sub> value (-5.25 g  $O_2$  m<sup>-3</sup> d<sup>-1</sup>). (b) Boxplots of published ER<sub>wc</sub> and ER<sub>wc</sub> from the Yakima River basin. The blue horizontal dashed line represents median ER<sub>wc</sub> in the Yakima River basin. The red horizontal dashed line represents median ER<sub>wc</sub> from literature values.

# 3.2 Water column respiration rates varied weakly with drainage area and stream order

We observed a correlation between  $ER_{wc}$  and drainage area across the Yakima River basin that was weak enough that we consider it to effectively reject the hypothesis that  $ER_{wc}$  is faster moving down the stream network (Fig. 3). The lack of a strong connection between  $ER_{wc}$  and drainage area is somewhat surprising as such a relationship could emerge from downstream C transport as well as increasing autochthonous C inputs due to increasing temperature and light availability, providing additional substrate for microbial respiration (Finlay, 2011; Webster, 2007). The fastest observed  $ER_{wc}$  rate in the Yakima River basin occurred in an agriculturally influenced, low gradient,  $5^{th}$  order stream, as opposed to a higher order river (Fig. 3). The conditions at this sampling location were not representative of the whole drainage area, as areas upstream of this site are mountainous with little human influence. This finding suggests that localized factors, not upstream conditions or drainage area, provide primary controls over  $ER_{wc}$ . Anthropogenic impacts, such as from agriculture and urbanization, can alter nutrient dynamics and flow regimes in these areas, influencing biogeochemical processes such as  $ER_{wc}$  (Bernot et al., 2010). The weak correlation between  $ER_{wc}$  and drainage area in the Yakima River basin likely reflects the interplay of multiple factors, including spatially variable local conditions, underscoring the complex controls on ecosystem processes in this region.

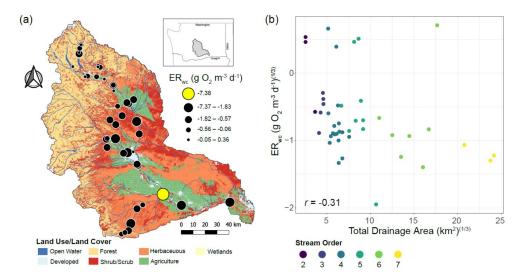

Figure 3. ER<sub>wc</sub> across the Yakima River basin and its relationship with drainage area. (a) Map of land use/land cover classes in the Yakima River basin with ER<sub>wc</sub> values (g O<sub>2</sub> m<sup>-3</sup> d<sup>-1</sup>) overlaid. Faster rates are indicated by larger circle diameters. The fastest rate is indicated by the yellow circle. The map was generated using the Free and Open Source QGIS (v. 3.16.1 and v. 3.26.0). Map data include catchment boundaries and hydrography from the National Hydrography Dataset Plus (NHDPlusV2.1) (McKay et al., 2012) and 2016 land use/land cover data from the National Land Cover Dataset (Brown, 2024). (b) Scatter plot of cube root transformed ER<sub>wc</sub> related to cube root transformed total drainage area with points colored by stream order. The Pearson correlation coefficient (r) is provided on the panel.

## 3.3 Higher temperatures and nutrient concentrations are associated with faster ERwc.

Regression analyses show that  $ER_{wc}$  in the Yakima River basin varied with chemical and physical water quality parameters. TDN, temperature, DOC, and TSS emerged as key variables in the LASSO regression, whereby  $ER_{wc}$  was faster with higher values of all these variables (Table 2). The LASSO regression explained 40% of the variation in  $ER_{wc}$  (Table 2). LASSO results are similar to univariate relationships, whereby DOC, TDN, temperature, and TSS had the strongest correlations with  $ER_{wc}$  (r = -0.44 to -0.53) (Fig. 4, Fig. S4) and all correlations were qualitatively in the same direction as indicated by the LASSO  $\beta$  coefficients. Collectively, the relative importance of these variables suggests that  $ER_{wc}$  is not controlled by a single variable, and instead multiple factors (i.e., nutrient concentrations, suspended particles, and temperature) are simultaneously linked to  $ER_{wc}$ .

Table 2.  $\beta$  coefficients from LASSO analyses for explaining ER<sub>wc</sub> across the Yakima River Basin. ER<sub>wc</sub> and all explanatory variables were cube root transformed and standardized as z-scores. LASSO was performed over 100 seeds, and  $\beta$  coefficients for each variable were normalized to the maximum  $\beta$  coefficient in each seed and averaged across all seeds for the reported values. Values of zero indicate that while the variable was included in the model, it was deemed not influential in predicting model outcomes and thus was not assigned a  $\beta$  coefficient.

Predictor Variable	Mean β Coefficient	Standard Deviation	
TDN	-0.98	0.03	
Temperature	-0.95	0.08	
DOC	-0.74	0.09	
TSS	-0.48	0.09

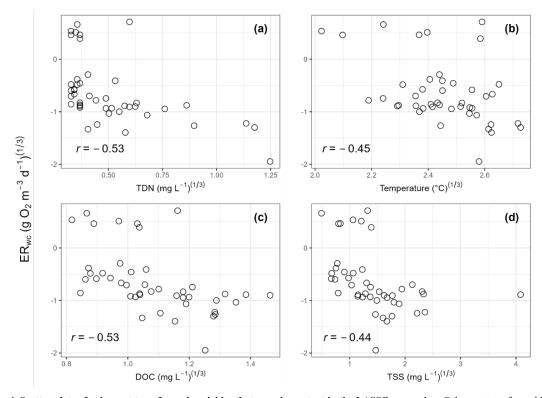

Figure 4. Scatter plots of cube root transformed variables that were important in the LASSO regression. Cube root transformed  $ER_{wc}$  is the y-axis for all panels. (a) cube root transformed total dissolved nitrogen (TDN); (b) cube root transformed temperature; (c) cube root transformed dissolved organic carbon (DOC); (d) cube root transformed total suspended solids (TSS). Pearson correlation coefficients (r) are provided on each panel.

Faster ER<sub>wc</sub> with increasing TDN, temperature, DOC, and TSS in the Yakima River basin is expected, as nutrients and temperature can impact variation in stream metabolism (Ardón et al., 2021; Bernot et al., 2010; Honious et al., 2021; Hornbach, 2021; Nakano et al., 2022). In-stream metabolism relies on terrestrially-derived and internally-fixed inputs of DOC, which supports heterotrophic metabolism that degrades and removes organic C inputs through respiration (Hall et al., 2016; Hotchkiss & Hall, 2014; Plont et al., 2022). Faster ER<sub>tot</sub> and ER<sub>wc</sub> have been reported with increases in DOC (Bernot et al., 2010; Ellis et al., 2012). However, elevated DOC does not always correspond to greater ER<sub>tot</sub>, as discharge and residence time also affect C dynamics (Ulseth et al., 2018). In addition to DOC, suspended sediment can regulate ecosystem metabolism by decoupling ecosystem respiration and GPP through limiting light availability, thereby reducing autochthonous C production, and conversely, by stimulating processing of organic matter through increased surface area (Glover et al., 2019; Honious et al., 2021). The increased surface area of suspended particles in the water column provides microsite habitats for microorganisms (Ochs et al., 2010; Liu et al., 2013), where bacterial production and enzymatic activity is concentrated, contributing substantially to material processing in the water column, particularly in rivers 5th order and higher (Gardner & Doyle, 2018; Reisinger et al., 2015). Nutrient dynamics, particularly N, also influence ecosystem respiration, where elevated N concentrations have been linked to increased ecosystem respiration across stream orders (Benstead et al., 2009; Reisinger et al., 2016, 2021; Rosemond et al., 2015). Nitrogen is a key nutrient for microbial growth and is often a limiting nutrient in freshwater rivers (Carroll, 2022). Consistent with this, we found the fastest ER<sub>we</sub> at an agriculturally-influenced stream with the greatest TDN and NO<sub>3</sub> concentrations. Elevated nutrient levels at this site likely stimulate microbial respiration, similar to Cross et al. (2022) who found an increase in heterotrophic respiration in response to N enrichment.

Moreover, respiratory processes are typically faster at higher temperatures (Pietikäinen et al., 2005), which can shift riverine ecosystems toward heterotrophy (Song et al., 2018). By stimulating microbial respiration, higher temperatures can also amplify the effects of increasing nutrients (Cross et al., 2022). Ultimately, our results emphasize the complex and dynamic roles of the physical, chemical, and biological factors that influence ER<sub>wc</sub> in the Yakima River basin and other similar freshwater ecosystems.

## 4 Conclusions, limitations, and next steps

Our study shows that ER<sub>wc</sub> rates observed in rivers and streams across the Yakima River basin span published rates from studies conducted in rivers across the CONUS and the Amazon River basin. While this study didn't measure ER<sub>tot</sub>, the observed overlap between ER<sub>wc</sub> and literature ER<sub>tot</sub> show the potential relevance of ER<sub>wc</sub> to overall stream metabolism. We pose that the high variability observed in ER<sub>wc</sub> rates across the basin will likely translate into variable contributions of ER<sub>wc</sub> to ER<sub>tot</sub>, ranging from negligible to potentially dominant. We anticipate that these influences will not vary systematically moving down the stream network as we observed a very weak association between ER<sub>wc</sub> and drainage area across the Yakima River basin. Our results point to more localized control and the LASSO regression specifically indicated that ER<sub>wc</sub> is faster with increasing TDN, stream temperature, DOC, and TSS, consistent with previous work. Overall, our findings show that the complex interactions between physical and chemical factors affect the spatial variability in ER<sub>wc</sub> across the Yakima River basin. We encourage future work to expand on our current study by collecting both ER<sub>wc</sub> and ER<sub>tot</sub> measurements at a basin scale, and to parse the contributions from both the water column and sediments to total ecosystem metabolism.

## Code and data availability

Data and scripts used to generate the main findings within this manuscript will be published at the U.S. Department of Energy's Environmental System Science Data Infrastructure for a Virtual Ecosystem (ESS-DIVE) repository (https://ess-dive.lbl.gov/about/) upon manuscript acceptance. Currently, scripts associated with this manuscript are located on GitHub (https://github.com/river-corridors-sfa/rcsfa-RC2-SPS-ERwc). Other data collected during the field efforts (i.e., sensor data; surface water chemistry data; and geospatial information, metadata, and maps for 2021 Spatial Study sampling event) can be accessed on ESS-DIVE.
