

Supplemental Material for ‘Seasonal Predictability of Vapor Pressure Deficit in the western United States’

a. LIM Tests

Penland and Sardeshmukh (1995) outline a series of tests to ensure the LIM that has been constructed behaves according to the underlying assumptions of a linear system forced by white noise. The noise covariance matrix should be positive and less than one, as is the case in both LIMs constructed here (Table S1), confirming the system composed by the state vector may be approximated by the LIM components, namely the deterministic operator and the noise. Another test is the behavior of the error; the error of both LIMs used in this study closely matches the error predicted from theory and is lower than that of forecasts from persistence and a first-order autoregressive process (Fig. S1).

In a perfectly linear system, the LIM would be independent of its training lag τ_o , while in reality this is not the case due to imperfect observations and nonlinearities (discussed further in Penland and Sardeshmukh 1995). One assessment of how linear a system represented by a LIM is, is to test how well the LIM, trained on a lag τ_o can reproduce the lagged covariance at lags longer than τ_o (Newman et al. 2011; example of LIM-predicted covariance for a 12-month lag: $C(12)=G(3)^4*C(0)$). For VPD, the observed lagged covariance decreases markedly at a lead time of 6 months and longer, but persists even out to a 36-month lag in the western US (Fig. S2). The lagged covariance expected from the 3-month G produces a very similar evolution, although the amplitude of the covariance is lower than observations. However, this is the case even for the equal-time covariance C_0 -LIM, implying the variance truncation of VPD also affects the lagged covariance which is not surprising. Nonetheless, overall the evolution and pattern produced by the LIM is generally in good agreement with observations even lags that are 12 times longer than the 3-month training lag, so we conclude the LIM approximation of linearity holds suitably well. This is bolstered by the high forecast skill the LIM is able to produce at longer lead times (Figs. 2-3).

b. LIM Trend Removal

The least damped eigenmode of the LIM that includes the trend displays a temporal evolution reflecting the trend (Fig. S3a). However, it is possible that some variability in the least damped eigenmode is a convolution with other modes of the system. For these reasons, the Gram-Schmidt orthogonalization procedure (Lankham et al. 2024) is used to remove any projection of other modes onto the least damped eigenmode, resulting in a time series with lower variability and behavior more indicative of the long-term warming trend (Fig. S3b). The pattern associated with this modified time series is determined by regressing the time series onto the full-field VPD/SST/SM anomalies, and the combination of the time series and pattern are used to create trend-related anomalies for each timestep and variable in the record. To detrend each variable, these trend-related anomalies are subtracted from the full field anomalies. A new LIM is constructed using the detrended VPD and SST anomalies as described in the Methods section. Time series of area-averaged VPD and SSTs with and without the trend thus defined confirm that this method of detrending has the desired effect (Fig. S4).

LIM with Trend: eig(Q)	LIM without Trend: eig(Q)
