Abstract. The subtropics are influenced by stratosphere-troposphere exchange processes through the subtropical jet streams and tropopause folding events, which are commonly identified by the opposing gradients of ozone (O₃) and carbon monoxide (CO) and thus their ratio. Here, we used airborne observations of CO and O₃, as well as the global three-dimensional ECHAM5/MESSy Atmospheric Chemistry (EMAC) model, to investigate whether there is another important mechanism that conditions the subtropics. We show that high O₃-CO ratios extend deeply into the troposphere in the subtropics, which is evident in both in situ observations and model results. Tropospheric photochemistry leads to similar O₃-CO ratios as those for stratospheric air diluted into the troposphere. In the upper tropical troposphere, frequent deep convective events produce lightning that leads to high concentrations of nitrogen oxides (NO_x ≡ NO + NO₂), which drive O₃ production and which further catalyze the recycling of hydroxyl (OH) radicals, which reduces CO. These lightning-affected air masses can be transported from the tropics into the subtropics via the Hadley circulation. We have excluded NO production through lightning in a sensitivity run of the EMAC model and see an annual relative reduction of the O₃-CO ratio of up to almost 50% in the tropics and up to 40% in the northern subtropics, with even larger seasonal variability and major effects on the vertical profiles of O₃ and CO. We therefore show that photochemistry is an additional key factor alongside stratosphere-troposphere mixing in determining O₃-rich and CO-poor air masses in the troposphere.

15 1 Introduction

Transport processes in the subtropical troposphere are dominated by the Hadley circulation and stratosphere–troposphere exchange processes (STE). These processes shape the chemistry of the subtropics. Moist tropical air masses are lifted through deep convection within the intertropical convergence zone (ITCZ), distributed polewards in the upper troposphere. During the poleward transport the air cools and sinks at approximately 30° N and S, in the subtropical high-pressure belts. This thermally driven circulation which connects the tropics and the subtropics is known as the Hadley circulation (Seinfeld and Pandis, 2016).

Rapid chemical mixing in the upper troposphere and lower stratosphere (UTLS) occurs mainly through tropopause folding (Danielsen, 1968; Holton et al., 1995; Hoor et al., 2002), adiabatic mixing along isentropes, and up- and downdrafts of convective overshoots (Frey et al., 2015). Tropopause faults mostly occur in association with Rossby wave breaking or by the zonal shift of the subtropical jet streams at 30° N and S, resulting in bending of the tropopause (Postel and Hitchman, 2001). The transport of tropical air masses into the subtropics along the Hadley circulations is thought to take around 10 to 50 days (Seinfeld and Pandis, 2016), while mixing within the tropospheric hemispheres takes 1–2 months (Singh, 1995), and between the troposphere and stratosphere up to 0.8–2 years. Overall, the subtropical troposphere plays a critical role in the Earth’s climate and atmospheric chemistry due to its unique position as a transition zone between the tropics and mid-latitudes as well as between the stratosphere and troposphere.

Ozone (O₃) and carbon monoxide (CO) are key trace gases in the troposphere and lower stratosphere. Ozone influences air quality, climate, and UV protection, while CO is an important combustion pollutant and regulates the atmosphere’s oxidative capacity. The interactions and distributions of these two trace gases are critical for understanding air quality, atmospheric chemistry, and climate dynamics. Tropospheric O₃ originates naturally from the stratosphere (Danielsen, 1968) or through photodissociation of nitrogen oxides NO_x (NO_x ≡ NO + NO₂) in the presence of UV and visible light:

where *M* indicates a third molecule which stabilizes the O₃ formed as it absorbs the excess vibrational energy from the reaction (Seinfeld and Pandis, 2016). NO_x is produced by anthropogenic burning processes such as pollution emissions through aircraft, and industry, but also from natural sources, like biomass burning, soil emissions, and through lightning. Lightning NO_x (LNO_x) has been found to dominate O₃ chemistry in the upper troposphere (Nussbaumer et al., 2023a), particularly in the tropics, where 77 % of the world’s lightning occurs. LNO_x in the upper troposphere has an approximated lifetime of 4–7 days (Schumann and Huntrieser, 2007).

In the presence of H₂O, and therefore mostly in the lower troposphere, ozone can be destroyed by photodissociation to form O(¹D) and reaction with H₂O to form hydroxyl (OH) radicals through Reactions R3 and R4:

50 These reactions are the primary source of highly reactive OH radicals, which play a crucial role in removing most natural and anthropogenic gases from the atmosphere (Lelieveld et al., 2016). They can react within 1 – 2 s with CH₄, non-methane volatile organic compounds (VOCs), and CO to form peroxy radicals (HO₂ + RO₂). In the free troposphere, the most important sink of OH radicals is through the reaction with CO (Lelieveld et al., 2016; Seinfeld and Pandis, 2016):

55 HO₂ radicals can further combine to form peroxides. Further propagation of the formed peroxides leads to higher-generation products, and reaction with NO for OH recycling, a secondary source of OH radicals. Different OH recycling mechanisms exist (e.g., O_x recycling, OVOC recycling, NO_x recycling), with NO_x recycling (Reaction R6) being the most prominent in highly NO_x-polluted regions and in the upper troposphere (Lelieveld et al., 2018):

60 In the tropics, CO emissions are mostly derived from biomass burning and anthropogenic emissions (Crutzen and Andreae, 1990). In the free and upper troposphere, CO can further be produced through oxidation of CH₄ or other hydrocarbons (Strode et al., 2018). At the same time, high concentrations of OH through primary production on the surface, and secondary production in the upper troposphere, provide a strong sink for CO in the tropics. Overall, this shortens the lifetime of CO in the tropics to about one month, while its global lifetime is approximately three months in the troposphere (Lelieveld et al., 2016).

65 The subtropical troposphere is known to be mainly influenced by STE. The purpose of this study is to investigate the effect of transport and distribution of photochemistry via the Hadley circulation in the upper troposphere of the tropics into the subtropics. To study the relevance of that mechanism, we first present the zonal distribution of CO, O₃, and the O₃ – CO ratio derived from airborne observations and further simulated by the dynamic EMAC chemistry model. Furthermore, we show with a sensitivity study of the model that internal tropospheric mixing processes along with chemical reactions make a higher-than-
70 expected contribution to the tropospheric subtropical air masses.

2 Observations and model simulations

This study uses airborne in situ measurements of CO and O₃ from 12 different aircraft research campaigns as well as numerical results of the ECHAM5/MESSy EMAC model.

2.1 Airborne observations

75 The observations used in this work are from a combined data set of 12 different aircraft research missions, carried out from 2012 to 2024, covering all seasons (Table 1). Each campaign focused on investigations of dynamic and/or chemical processes

Table 1. Overview of aircraft campaigns used for this study. Most of the campaigns have been carried out with the HALO aircraft of the DLR (German Aerospace Center, Oberpfaffenhofen, Germany). The ATom campaigns have been carried out with the NASA DC-8 aircraft (Wofsy et al., 2018).

CAMPAIGN	START	END	AIRCRAFT

CAFE Pacific (The Chemistry of the Atmosphere Field Experiment in the Pacific)	09-01-2024	01-03-2024	HALO

of the troposphere and lower stratosphere based each in a different location around the world. The flight tracks of each campaign are shown in Figure 1 and provide zonal and meridional coverage of the Earth, except for large parts of Asia. However, due to the long lifetimes of CO and O₃ in the troposphere, the Asian emissions are covered by long-distance transport processes, which also have been among the research goals of some of the campaigns (e.g., the Asian Summer Monsoon by OMO, WISE, PHILEAS). Specific research goals, and accordingly the flight planning, have been selected with consideration of specific weather or extreme events (e.g., deep convection, biomass burning events) and therefore can be biased to some extent. To minimize these biases, the medians of the averaged distributions are used in this study. Furthermore, the statistical representativeness of the selected observations has been tested with a model comparison of a full climatology and data just along the flight tracks. This comparison can be found in the Supplementary Material. In particular, the modeled O₃ – CO ratios along the flight tracks in the northern hemisphere and tropics have been found to agree well with the model climatology.

Two aircraft's were used throughout these campaigns: the High Altitude Long-range (HALO) Gulfstream G550 research aircraft, run by the German Aerospace Center (DLR) and the NASA DC-8 aircraft, owned by the NASA Armstrong (Dryden) Flight Research Center. For CO measurements, four different instruments (UMAQs, QCLS, TRISTAR, ATTILA) and for O₃, two different instruments (FAIRO (Obersteiner, 2024b), NO_yO₃) collected the data sets used in the scope of this work. The total measurement uncertainties for CO vary in a range of 0.94 – 1.8 ppbv and for O₃ from 2 to 2.5 %. More detailed information on the uncertainties and equipment used during the campaigns can be found in Table 2 and in the Supplementary Material.

Figure 1. Overview of the flight tracks of the aircraft campaigns used in this study.

The measurement techniques for each tracer were similar. CO was measured by infrared absorption spectroscopy (Fried and Richter, 2006) with quantum cascade lasers (QCLS) (Faist et al., 1994; Pal and Pradhan, 2021) and multipass circulations of the types of White and Herriott (White, 1957; Herriott and Schulte, 1965; McManus et al., 1995; Wienhold et al., 1998) throughout all campaigns. The O₃ measurements were taken using UV absorption and chemiluminescence (CL) techniques (e.g., Toby (1984); Ridley et al. (1992); Zahn et al. (2012)). Frequent calibrations against primary and secondary standards during the research flights ensured comparability of the CO observations. For O₃, simultaneous UV absorption measurements alongside CL detection are provide for high accuracy and continuous in-flight calibrations.

From 2012 to 2024 there was no significant trend in the global average atmospheric mixing ratios of CO and O₃ in remote regions according to the measurements from the Carbon Cycle Cooperative Air Sampling Network (Laboratories, 1988) and the TOAR network data sets (Tarasick et al., 2019). Nevertheless, studies have shown annual variations, especially in more polluted and more densely populated regions. Field et al. (2016) has shown that in 2015 strong open biomass burning events caused by the global climate phenomenon El Niño resulted in the peaking of CO emissions in Indonesia which then spread into the upper troposphere over East Africa to the western Pacific Ocean. Furthermore, continuous control measures targeting industrial and transportation emissions in developed countries are leading to a moderate reduction of pollutants. For example, in China, from 2010 to 2017, a 16 % decrease in CO emissions could be achieved by replacing pollutant fuels (e.g., biofuel, coal) with cleaner fuels (e.g., natural gas, electricity) (Li et al., 2024).

Besides annual trends, there are seasonal and local variations in source regions (Hoor et al., 2002; Li et al., 2024). Emission

¹Thompson et al. (2022), ²Riese and Hoor (2017)

rates in general depend on the amount of biomass burning and anthropogenic activity (e.g., heating, combustion), which are strongly season-dependent. In the tropics, the strongest seasonal differences are due to shifts of the zonal positioning of the ITCZ (Waliser and Somerville, 1994), in particular above land surface. The CAFE Brazil and CAFE Pacific campaigns col-

lected a larger data set for continental areas in the tropics; these were run from December 2022 to January 2023 above the
115 Amazon rainforest, and January to February 2024 above Australia, respectively. During CAFE Brazil, the seasonal shift of
the ITCZ influences the contribution of air masses from the southern or northern hemispheres, affecting the Amazon basin. In
January, the ITCZ is slightly south of the Amazon region, which leads to a stronger influence of air masses originating from
the northern hemisphere in this region. The seasonal variation slightly shifts the deep convection activity zonally, and hence
results in a broadening strong uptake of surface emissions in the vertical profile of the tropics. Note that meridional variations
120 will also be averaged for this study.

However, zonal and annual averages, and the long lifetimes of O_3 and CO which ensure globally well transported and mixed
distributions, tend to weaken the effects of those local and temporal emission variations. Nevertheless, these will be taken into
account and further discussed in Section 3.

Overall, the twelve campaigns listed in Table 2 above provide a good global coverage of in situ measurements from the
125 boundary layer up to the lower stratosphere. In particular, statistically relevant data can be found in the northern hemisphere,
especially in the northern subtropical region. As the data sets have been measured using various time resolutions, all sets were
averaged to 60 s before they were combined. Furthermore, the measurements were transferred into the same grid resolution as
the modeled data, with a sufficient number of data points for each grid box.

130 2.2 EMAC model

The numerical results used for this study were simulated with the ECHAM5/MESSy Atmospheric Chemistry (EMAC) model
(Jöckel et al. (2006); Jöckel et al. (2016) and publications therein). EMAC is a three-dimensional numerical chemistry and
climate model which includes several sub-models describing lower and middle atmospheric processes and their interactions
with the ocean, land, biosphere, human factors, and many other parameters. The simulation of atmospheric dynamics and
135 transport processes is based on the fifth-generation of the European Centre Hamburg general circulation model (version 2.54.0;
ECHAM5; Roeckner et al. (2006)). Fully coupled chemistry and miscirculationaneous processes are provided by a set of
submodels controlled by the second-generation Modular Earth Submodel System (version 2.54.0; MESSy; Jöckel et al. (2005);
Jöckel et al. (2010)).

Numerous experimental evaluations of the EMAC model have revealed it to be reliable (e.g., Jöckel et al. (2016); Tomsche
140 et al. (2019); Lelieveld et al. (2018); Tadic et al. (2021); Nussbaumer et al. (2023b); Nussbaumer et al. (2024)). In Lelieveld
et al. (2018) a variety of atmospheric gases measured during the OMO aircraft campaign have been compared to the EMAC
model, revealing a slight overestimation of tropospheric column O_3 , and CO. O_3 overestimation by the model could account for
the reduced LNO_x emissions in South Asia. Difficulties in representing the intermittent nature of convection and lightning has
been shown in the study of Lelieveld et al. (2018) and are generally known to be a challenge for climate models. Comparisons
145 of the CAFE Africa campaign measurements with the EMAC model show a weak correlation between measured and modeled
NO in the upper troposphere (Nussbaumer et al., 2024). Nevertheless, this seems to be a regional issue, as, in general, measured
 NO_x , O_3 , and HO_2 values are found to correlate well with the EMAC model (correlation coefficients of 0.5 and larger) in the

OMO, CAFE Africa, CAFE Brazil, and ATom campaigns (Nussbaumer et al., 2024). More details on the EMAC model and its evaluation with measurements can be found in Righi et al. (2014) and Jöckel et al. (2016) and citations within.

150 The model resolution is T63L47MA, i.e., with a quadratic Gaussian grid resolution of $1.875^\circ \times 1.875^\circ$ and a vertical resolution up to 0.1 Pa, so as to include the stratosphere. The model has been weakly nudged by Jeuken et al. (1996) towards the European Center for Medium-Range Weather Forecasts (ECMWF) ERA5-interim data (Hersbach et al., 2020). The simulations cover a period of 20 years (i.e., 2000–2019). In this work, the hybrid pressure coordinates of the numerical simulations have been interpolated to an altitude of 1 km vertically; additionally, only monthly climatology of the data set has been used. In addition
155 to the reference numerical simulation, a sensitivity numerical integration has been performed, binary identical to the reference simulation but with the lightning emissions of NO_x deactivated. In the following, we will refer to those two simulations as “REF” to the standard simulation and “without LNO_x ” to the sensitivity run excluding LNO_x emissions globally. Other sources of NO_x in the troposphere, such as surface and aviation emissions and mixing from the stratosphere, are included in both simulations. These simulations have been used before in Nussbaumer et al. (2023a) to investigate O_3 production from
160 LNO_x in the upper tropical troposphere. In that study, the authors concluded that the only source of NO_x in the upper tropical troposphere is lightning, which is hence crucial for ozone production in that region.

A comparison along the flight tracks with the observations has shown good agreement of the climatology with the single point data (Supplementary Material). Therefore, the full model is used for the investigation of the importance of LNO_x for the northern subtropics.

165 3 Results and discussion

3.1 Trace gas distributions based on observations

Figure 2 (a) and (b) show the annual median zonal distributions of CO and O_3 mixing ratios, respectively, derived from all airborne in situ observations listed in Table 1. The data points are averaged over 1 km of altitude, 1.875° of latitude and over all longitudes. Their scales have been adjusted to emphasize tropospheric values. The black lines represent the lines of constant
170 potential temperatures (Θ), which are calculated via Equation 1, including the measured air temperature T and static pressure p , the surface pressure $p_0 = 1000$ hPa, and $\kappa = 0.286$.

$$\Theta = T \left(\frac{p_0}{p} \right)^\kappa \quad (1)$$

Both zonal distributions show a good coverage of the troposphere, despite some data gaps in the polar high latitudes and in the
175 upper troposphere of the southern subtropical region. The observations show the highest CO mixing ratios near the surface in the tropics and northern mid- to high latitudes, peaking with median mixing ratios of 120–140 ppbv, due to the close proximity to combustion sources (anthropogenic or natural). In the tropics, large amounts of CO can be released from biomass burning events mainly during the dry seasons (Galanter et al., 2000), and in the northern mid- to high latitudes, industrial combustion and other anthropogenic emissions are the main sources of CO (Tomsche et al., 2019). The tropospheric background value of

Figure 2. Zonal median distribution of CO (a) and O₃ (b) from the campaigns listed in Table 1. All airborne measurements have been averaged over 1 km of altitude, and 1.875° of latitude. The scale has been adjusted to focus on tropospheric values for both tracers. White lines indicate layers of constant potential temperature, calculated using Equation 1, and averaged over 5° and 1 km.

CO is approximately 60 ppbv in the southern hemisphere and 70–100 ppbv in the northern hemisphere, generally decreasing with increasing altitude. In the vicinity of deep convection or warm conveyor belts, close to a source region, CO shows instead a C-shaped vertical profile, which can be observed especially in the tropics in the ITCZ and the northern extra tropics. In the ITCZ, the level of main convective outflow is 10–12 km (potential temperature of 350–360 K), where the CO mixing ratio nearly achieves boundary layer mixing ratios. In the northern hemisphere, a local minimum of tropospheric CO mixing ratios can be identified in the subtropics. This minimum has been already observed during previous aircraft measurements, e.g., in 1997 and 1998, where surface CO mixing ratios in the northern subtropics varied from 60 to 140 ppbv and from 80 to 200 ppbv in the northern extra tropics (Hoor et al., 2002). With the increasing distance from the source regions towards higher altitudes, CO decreases to values below 40 ppbv. In the polar UTLS region, we record CO values of below 20 ppbv, which is due to the downward transport of stratospheric low-CO air. Close to the isentropic surfaces of 360 K, the tropopause can be expected in the tropics (Holton et al., 1995), while towards higher latitudes cross-tropopause exchange can happen at lower isentropic lines of 300 K–330 K (Sprenger and Wernli, 2003).

The O₃ zonal distribution in Figure 2 (b), shows similar but inverted behavior compared to the CO zonal distribution. Low O₃ mixing ratios in the boundary layer are linked to dry deposition (Wesely and Hicks, 2000; Sumner et al., 2001), photodissociation (Reaction R3 and R4), and NO titration. These losses outweigh O₃ production through NO₂ photolysis (Reactions R1 and R2) especially in areas of low combustion NO_x emissions, e.g., remote places, forests, oceans. In the vicinity of strong NO_x combustion sources (biomass burning or industrial emissions), O₃ can be produced also at the surface. Nevertheless, low ozone values are prominent close to the surface, with minimum values in the tropics, where the median surface mixing ratios

Figure 3. Same as Figure 2, for the O_3 – CO ratio.

are lower than 20 ppbv. In the free troposphere, O_3 gradually increases with slightly higher values in the northern compared to southern hemisphere up to the O_3 -rich stratosphere. In the ITCZ, through deep convection, low surface O_3 can be vertically mixed towards higher altitudes. Together with strong uptake, convective activity is a source of lightning, which produces O_3 via LNO_x , particularly in the convective outflow region in the ITCZ (Nussbaumer et al., 2023a). In contrast to the O_3 values in the tropics, a slight increase in O_3 mixing ratios can be noted in the vertical column of the northern subtropics around $30^\circ N$. While O_3 mixing ratios range from a few ppbv up to ~ 100 ppbv (Prather et al., 2011) in the troposphere, in the stratosphere, O_3 increases dramatically up to several thousands of ppmv due to photochemical production through higher energetic UV radiation and oxygen photolysis with a typical residence time of 1 – 2 years. In the stratospheric mid-latitudes and polar regions, the downward motion of the Brewer–Dobson circulation (Brewer, 1949; Dobson, 1956) transports stratospheric O_3 -rich air closer to the tropopause. Here, ppbv values in the low hundreds could already be observed.

The ratio of O_3 to CO is shown in Figure 3. In the absence of strong vertical transport, O_3 shows an increasing gradient towards higher altitudes, while CO decreases with altitude. This would result in low O_3 – CO ratios near the surface and increasing ratios with altitude. This behavior is particularly observed in the southern extra tropics. Low O_3 – CO ratios (< 0.6 ppbv/ppbv) up to 12.5 km in the ITCZ and up to 7.5 km in the northern mid-latitudes indicate transport of surface air masses with high CO and

low O_3 mixing ratios. Higher O_3 – CO ratios (> 0.6 ppbv/ppbv) represent air masses with lower CO and higher O_3 , which can be observed closer to the stratosphere but also in the subtropics, which we will further define from $23.3^\circ - 40^\circ$. This O_3 – CO ratio is more pronounced in the northern compared to southern hemispheric subtropics. In the following, we will focus on the northern subtropical region. Although values are similar in the southern subtropics, the zonal gradient to higher latitudes is less pronounced than in the northern hemisphere, probably due to less data coverage, flight tracks that mostly traverse the ocean, and in general a lower CO background (no significant CO source in the southern high latitudes).

3.1.1 Observed northern hemispheric gradient

In the zonal distribution in Figure 3, an increase in the O_3 – CO ratio was observed in the northern subtropics around $23.3 - 40^\circ N$. For further analysis, we have calculated the zonal 10° , 2 km altitude-binned medians of the airborne measurements for CO, O_3 , and their ratio for the northern hemisphere and shown in Fig. 4 (a), (b), and (c), respectively. The global gradients for the zonal medians, including the southern hemisphere, can be found in the Supplementary Material. Only tropospheric values have been used based on O_3 mixing ratios lower than 100 ppbv, according to Prather et al. (2011).

The subtropics are dominated by relatively low CO and high O_3 mixing ratios, resulting in a median O_3 – CO ratio of 0.7 ppbv/ppbv in the upper troposphere. Towards the tropics and the mid- to high latitudes, the O_3 – CO ratios decrease to 0.4 – 0.45 ppbv/ppbv and 0.55 – 0.6 ppbv/ppbv, respectively, in the upper troposphere. This tendency is evident throughout all altitudes from 0 to 12 km. From the boundary layer to the upper troposphere, in the northern subtropics, CO mixing ratios range from 120 ppbv to 80 ppbv, and O_3 mixing ratios range from 35 to 65 ppbv, resulting in ratios of 0.35 – 0.7 ppbv/ppbv. Closer to the pole, we observe an enhancement of O_3 at higher altitudes (above 6 km), which could be due to the proximity of the tropopause and exchange processes with stratospheric O_3 -rich air (Hoor et al., 2002, 2004).

Assuming that cross-tropopause exchange takes place mostly in the vicinity of the subtropical and polar jet streams and along isentropic layers, as has been shown in numerous studies (e.g., Lelieveld et al. (1997); Fischer et al. (2000); Krasauskas et al. (2020)), enhanced O_3 – CO ratios are expected in the subtropics and at the poles. Finding a negative correlation between O_3 and CO, several studies have identified air masses to originate from either the stratosphere or troposphere (Fischer et al., 2000; Hoor et al., 2002, 2004; Joppe et al., 2024). Here, we observe enhanced O_3 – CO ratios covering the whole tropospheric column down to the boundary layer in the subtropics. This deep intrusion raises the question of whether cross-tropopause exchange, which transports high O_3 and low CO downward from the stratosphere into the troposphere, is the predominant mechanism affecting the troposphere subtropical column. To address this question, we investigated another possible mechanism that can lead to similar changes in the O_3 – CO ratios in the subtropics. In the upper tropical troposphere, LNO_x emissions can lead to significant O_3 production, and simultaneously, catalyze OH recycling, which decreases CO in the atmosphere. Those emissions can be distributed via the Hadley circulation from the tropics into the subtropics. In the following, this hypothesis will be investigated using sensitivity simulations with the EMAC model (Sec. 2.2).

Figure 4. Northern hemispheric zonal gradients of CO (a), O_3 (b), and their ratio (c) based on all aircraft measurements, which are listed in Table 1, averaged over 10° of latitude, and 2 km of altitude. Displayed are the medians as dots and the 25th and 75th percentiles as shaded areas. Before the calculations, stratospheric values have been filtered out through excluding all measurements with O_3 values lower than 100 ppbv, according to the chemical troposphere definition of Prather et al. (2011).

3.2 EMAC model simulations

245 To investigate whether a chemical mechanism contributes to the O_3 enhancement and CO decline in the subtropical troposphere, we use the three-dimensional chemistry and dynamic EMAC model. The model results cover 20 years of simulation (2000–2019) with monthly values and a spacial resolution of $1.875^\circ \times 1.875^\circ \times 1$ km. This climatology has proven to be comparable to empirical observations (see Supplementary Material). In the following, we test, whether the model reproduces the same subtropical O_3 – CO ratio enhancement in its standard simulation (REF) which could be identified in the observations.

250 As for the empirical observations, an annual zonal distribution of the modeled O_3 – CO ratio has been calculated from this data set, shown in Figure 5. An overview of the monthly zonal distributions can be found in the Supplementary Material.

The ratio plotted in Figure 5 shows similar features as identified in the zonal distribution of the airborne observations (Fig. 2 and 3). Low O_3 – CO ratios are generally found in the lower troposphere and extend into higher altitudes in the mid- and high latitudes and in the tropics. Closer to the tropopause, O_3 – CO ratios increase. Here, the model shows a slight overestimation of O_3 and CO, and hence of the O_3 – CO ratio in the upper troposphere. A further difference can be noted in the tropical troposphere. The tropical “belt” of low O_3 – CO ratio representing the ITCZ with strong uptake of surface mixing ratios through frequent convection seems to be less pronounced in the model than in the observations. This difference remains when looking at the model data extracted from the flight track (not shown here), which means that the representation of convection in the model is likely to cause this difference (Lelieveld et al., 2018; Nussbaumer et al., 2024). However, in the subtropical regions, high O_3 and low CO values, indicated by high O_3 – CO ratios, are found immediately above the boundary layer, which is visible in the subtropics of both hemispheres but more pronounced in the northern subtropics. This enhancement results in similar

Figure 5. The median annual zonal distribution of the O_3 –CO ratio calculated from the EMAC model data (REF). All data points are averaged over 1 km of altitude and 1.875° of latitude. The scale has been adjusted to display tropospheric values. The white dashed lines indicate the tropopause layer height with its standard deviation shaded in white.

values than those from the empirical observations, and hence we conclude that the model can well capture the features of zonal O_3 –CO ratios.

3.2.1 Modeled northern hemispheric gradient

265 For a better comparison with the observations, we will focus on the northern hemispheric gradients in the following; however, we present the global zonal gradients, including the southern hemisphere, in the Supplementary Material. In Figure 6 the northern hemispheric gradients of the modeled CO, O_3 , and the O_3 –CO ratio for different altitude ranges are shown in (a), (b), and (c), respectively. Similar to the observations, the modeled data was averaged over 2 km and 10° of latitude over all longitudes for tropospheric values only, excluding data points with O_3 values higher than 100 ppbv, according to Prather et al.
270 (2011).

In comparison to the observations, the modeled gradients for CO and O_3 mixing ratios are slightly higher except for the CO mixing ratios in the tropics, where the observations show higher CO mixing ratios throughout all altitudes. Furthermore, the decrease of CO in the northern subtropics is much more pronounced in the observations than in the model. Nevertheless, the difference between the model and the observations lies mostly within the range of the 25th and 75th percentiles and the gradients

Figure 6. Northern hemispheric zonal gradients of CO (a), O₃ (b), and the O₃ – CO ratio (c) from the EMAC model data (REF), averaged over 10° of latitude and 2 km of altitude. Dots represent medians and shaded areas denote the 25th and 75th percentiles. Before the calculations, only tropospheric data was selected based on the chemical definition of the tropopause by Prather et al. (2011) at 100 ppbv of O₃.

show a similar pattern: smaller CO and higher O₃ mixing ratios in the subtropics compared to the northern extra tropics and tropics. The underestimation of CO in the tropics results from applying global climatology, which results in the smoothing of emission regions with more remote regions. The flight track extraction tends to overestimate surface CO mixing ratios in the tropics, due to the complexity of modeling occasional biomass burning events and their exact emission rates.

Overall, the gradients of the O₃ – CO ratio in Figure 6 (c) show a similar enhancement in the subtropics as has been observed (Fig. 4 (c)), with modeled O₃ – CO ratios ranging from 0.45 to 0.8 ppbv/ppbv in the northern subtropics with highest values close to the tropopause. The slight overestimation of the modeled median mixing ratios of CO and O₃ leads to ~0.1 ppbv/ppbv higher O₃ – CO ratios than in the observations. Nevertheless, the decreasing gradients towards the tropics and mid- to high latitudes are reproduced by the model.

3.3 Modeled sensitivity study: without LNO_x

The measured and modeled zonal distributions of the O₃ – CO ratio, shown in Figures 3 and 5, as well as the northern hemispheric gradients in Figures 4 and 6, all indicate a strong enhancement in the O₃ – CO ratio in the northern subtropics. It is to be expected that STE at the subtropical jet has a pronounced effect on the composition of the subtropical troposphere. This results in high O₃ and low CO mixing ratios in the troposphere of the subtropics. This process might be responsible for the O₃ – CO ratio enhancement identified in the in situ observations and the model results. However, chemical processes in the upper troposphere driven by LNO_x emissions lead in principle to similar conditions, according to Reactions R1, R2, R5, and R6. Tropical convection associated with the ITCZ transports surface emissions into the upper troposphere. Lightning associated with deep convection produces significant amounts of NO, which catalyze a series of chemical reactions that yield O₃. In addition, NO

is an important secondary OH source via recycling of peroxy radicals, leading to higher OH concentrations in the convective outflow (Lelieveld et al., 2018). This potentially shortens the lifetime of CO and other hydrocarbons (Lelieveld et al., 2016).
295 The secondary production of highly reactive OH radicals results in reduced CO levels in the tropics. Overall, lightning is expected to yield enhanced O₃ and low CO mixing ratios. These air masses are transported within the troposphere following the Hadley circulation that transports tropical air masses into the subtropics. Thus, we hypothesise that high O₃ – CO ratios in the subtropical troposphere are not only due to exchange processes with the stratosphere but result also through photochemistry within the troposphere. To test this hypothesis, we used a model sensitivity study without lightning NO_x production. By excluding LNO_x, the effect of high O₃ production and, indirectly, the loss of CO in the upper troposphere is excluded from the simulations, while all other mechanisms are kept as usual. Note that other reactions linked to NO_x chemistry, like the depletion of CH₄ and other hydrocarbons through OH, are also affected by the absence of LNO_x. However, dynamic processes, like STE, transport through tropospheric mesoscale circulations, surface emissions, and other chemical reactions which are not effected by LNO_x are unchanged. The difference between the “REF” and the “without LNO_x” simulations of the EMAC model can
300 thus be interpreted as the effect of LNO_x on tropospheric chemistry (including, e.g., Reactions R1, R2, R5, R6). This effect we study on the basis of the absolute and relative differences of the zonal distribution, the change of the northern hemispheric gradients, and the vertical profile of the northern subtropics in the following sections.

3.3.1 Relative and absolute differences due to LNO_x emissions

In Figure 7 the absolute and relative differences for CO ((a), (b)) and O₃ ((c), (d)) between the standard model run and the
310 sensitivity run without lightning are shown for the annual average, respectively. The absolute difference (D_{absolute}), calculated in Equation 2, represents the total change of mixing ratios (MR) caused by LNO_x, and the relative difference (D_{relative}, Eq. 3) represents changes relative to the local mixing ratios provided by the standard simulation (REF) in percent.

$$D_{\text{absolute}} = \text{MR}_{\text{without LNO}_x} - \text{MR}_{\text{REF}} \quad (2)$$

315

$$D_{\text{relative}} = \frac{\text{MR}_{\text{without LNO}_x} - \text{MR}_{\text{REF}}}{\text{MR}_{\text{REF}}} \times 100 \quad (3)$$

As expected, we found in general an increase in CO and a decrease in O₃ by excluding LNO_x from the EMAC model simulations. The largest impact is found in the tropics where the largest emissions of LNO_x are found (Schumann and Huntrieser, 2007; Nussbaumer et al., 2023b). Here, absolute CO mixing ratios increase by 15–25 ppbv south and north of the ITCZ. This
320 is a difference of over 30 % compared to values measured for CO in the upper tropical troposphere by excluding LNO_x. The ITCZ can be identified as a vertical band with slightly less enhancement north of the equator, lifting surface emissions, which are only affected by the exclusion of LNO_x in the outflow at high altitudes. In the same region where CO increases, O₃ is reduced by up to 40 %. Average O₃ mixing ratios in the tropical upper troposphere are in the range of 50 ppbv. Inhibiting production through LNO_x decreases O₃ by 15–20 ppbv in that region. Especially in the upper tropical troposphere, LNO_x is

Figure 7. Relative and absolute differences of CO and O₃ caused by excluding LNO_x emissions in the global 3D model EMAC (without LNO_x), shown on annual averaged zonal distributions. In a) and c) the absolute differences (Eq. 2) of the gas concentration are shown and in b) and d) the relative difference (Eq. 3) in percentage normalized to the background concentration in the particular area are displayed for CO (a, b) and O₃ (c, d). The black dashed lines and shaded area indicate the mean height of the tropopause layer and its standard deviation, respectively, by taking the zonal and annual average.

325 expected to be the predominant driver of photochemically formed O₃, which we confirm with these results. More broadly, the
 absence of NO also reduces the secondary production of OH radicals (Reaction R6), which are highly reactive with CO in
 the upper troposphere (Lelieveld et al., 2016). Overall, the sensitivity run indicates that without LNO_x, O₃ and OH production
 decreases. This yields lower O₃ and higher CO mixing ratios in the upper tropical troposphere. Subsequent transport in the
 Hadley circulation results in similar changes for O₃ and CO in the subtropics. Note that switching off LNO_x also affects the
 330 mixing ratios of CO and O₃ in the lowermost stratosphere, although to a lesser extent, compared to typical CO and O₃ values
 in the stratosphere. Nevertheless, these changes in the lowermost stratosphere are expected to be mainly caused by upwelling
 air transported through the tropical tropopause layer (TTL) into the stratosphere and distributed in the lowermost stratosphere.
 It can be assumed that in the upper tropical troposphere, NO_x has a lifetime of ~4–7 days (Schumann and Huntrieser, 2007),

while CO has a lifetime of approximately 38 days (Lelieveld et al., 2016). Transport through the Hadley circulation into the
 335 subtropics takes 10 to 50 days according to Seinfeld and Pandis (2016). Therefore, the photochemistry that results in higher
 O_3 and reduced CO is expected to continue during transport from the tropics to the subtropics. Note that the production of
 CO by CH_4 oxidation is also altered by the absence of LNO_x emissions. While OH acts as an important sink for CH_4 as well
 (Lelieveld et al., 2016), longer lifetimes and thus higher levels of CH_4 are also expected as a consequence of excluding LNO_x
 emissions. Through the increase in CH_4 mixing ratios, more CO can be produced by its oxidation. However, CH_4 is quite
 340 stable with a lifetime of approximately 9 years (Szopa et al., 2021) and with mixing ratios an order of magnitude higher than
 CO (approx. 1770–1870 ppbv in the annual global mean at marine surfaces in the years from 2000 to 2019 according to the
 NOAA background stations network, Lan and Dlugokencky (2025)). Therefore, we expect the contribution to the increase of
 CO resulting from enhanced CH_4 to be rather small.

Overall, upper tropical LNO_x emissions can exert a profound influence all the way down to the lower troposphere of the sub-
 345 tropics (approximately 3 km). Therefore, the resulting changes in the subtropics are linked directly to LNO_x production in the
 upper tropical troposphere affecting the chemistry there, and along the path ways of the Hadley circulation.

3.3.2 Modeled northern hemispheric gradient without LNO_x

In Figure 8, the modeled annual zonal northern hemispheric gradients of the CO (a), O_3 (b), and O_3 – CO ratio (c) are shown
 for the “without LNO_x ” simulation. The corresponding gradients for all latitudes can be found in the Supplementary Material.
 350 There are three main differences to the standard simulation, in addition to the above-mentioned generally higher CO and lower
 O_3 mixing ratios: lower O_3 – CO ratios over the whole northern hemisphere; less vertical variation in the tropics and subtropics;
 and, a partially smaller meridional variability indicated by the 25th and 75th percentiles.

First, we focus on the generally lower O_3 – CO ratios. Excluding LNO_x emissions causes an increase in tropospheric CO and

Figure 8. Same as Figure 6, for the model simulation without LNO_x .

a reduction in tropospheric O_3 , as shown before, resulting in a smaller ratio. This reduction is most pronounced in the upper
355 troposphere and continues into the free troposphere and lower troposphere with decreasing influence. Hence, the annual average of the $O_3 - CO$ ratio is nearly constant at 0.4 ppbv/ppbv throughout the whole subtropical troposphere and is even lower in the tropics at 0.3 ppbv/ppbv. Nevertheless, the local high of the $O_3 - CO$ ratio in the subtropics is still present, albeit weaker. Secondly, vertical changes of the mixing ratios seem to be smaller, yielding similar $O_3 - CO$ ratios from the boundary to the upper troposphere. Only towards the pole, where the tropopause is much lower and the influence from the tropics much weaker,
360 the vertical gradient is still visible.

Finally, the percentiles provide an indication of meridional variations over the zonal-vertical averages, showing reduced variability for the sensitivity run without lightning relative to the base run. This indicates enhanced homogeneity not only vertically but also meridionally.

The absolute and relative differences between the base run and the sensitivity run for the northern hemispheric gradients of the
365 $O_3 - CO$ ratios are shown in Figure 9 (a) and (b), respectively. Again, the corresponding gradients for the global distribution can be found in the Supplementary Material.

Focusing on the absolute differences (Fig. 9, (a)), calculated in Eq. 2, we find the largest change in the upper troposphere in the subtropics with $O_3 - CO$ ratios smaller by -0.4 ppbv/ppbv than for REF. The least impact is found at the lowest altitude range (0–2 km) and towards the higher latitudes.

The relative differences, which are calculated with Eq. 3, show the normalized influences, which are strongest in the tropics

Figure 9. Same as Figure 6, but for the absolute differences (a) and relative differences (b) of the $O_3 - CO$ ratio between the base run and the sensitivity run without LNO_x .

370 slightly south of the equator extending into the subtropics. The relative effect is smallest again towards higher latitudes and lower altitudes but results in a change in the O_3 –CO ratio of 50 % in the tropical upper troposphere and over 40 % in the subtropics.

3.3.3 Vertical distribution of the northern subtropics

The vertical distribution of the mean relative differences between the base run and the sensitivity run without LNO_x of CO, O_3 and the O_3 –CO ratio for the northern subtropics, ranging from $23.3^\circ N$ – $40^\circ N$, are shown in Figure 10. The main effect of switching off LNO_x is found in the upper troposphere, mainly around 12 km. We can assume that deep convection, and

Figure 10. The mean relative differences in O_3 (blue bars), CO (orange bars), and their ratio (green bars) averaged over all longitudes, the northern subtropics ranging from $23.3^\circ N$ – $40^\circ N$, and for each kilometer, with exclusion of stratospheric values selected by O_3 values higher than 100 ppbv. This mean includes an average over all months. The error bars show the standard deviation and represent the meridional variability of the relative differences. Calculated using Eq. 3.

hence local LNO_x emissions, are rare in the subtropical regions due to a general downward motion via the Hadley circulation. Nussbaumer et al. (2023a), who used a similar simulation with EMAC, concluded that lightning occurs and is observed mainly

over land in the upper tropical troposphere.

380 As has already been seen in the zonal gradients, LNO_x emissions cause a strong impact on the subtropical mixing ratios of O₃ and CO, yielding enhanced O₃ and diminished CO. For zonal and annual averages, excluding LNO_x emissions increase CO by ~30 % and decrease O₃ by ~20 % in the upper subtropical troposphere (orange and blue bars in Fig. 10). This results in a change of the subtropical ratio of these two gases by over 30 % in the mean value of the upper subtropical troposphere. In general, the effect of LNO_x on O₃, CO, and the O₃ – CO ratio decreases towards the surface in the subtropics. Nevertheless, 385 there are still changes in the O₃ – CO ratio of over 10 % attributable to the effect of LNO_x in altitudes lower than 1 km. Overall, the LNO_x effect on CO removal by OH recycling is one-third of the northern subtropical CO mixing ratio. Taking into account that seasonality and spacial differences have been averaged, the impact of tropical LNO_x on the subtropics is not expected to be equally distributed, and therefore stronger and lesser for each region and time.

3.3.4 Seasonal variability

390 The annual zonal distributions, shown and discussed in the previous sections, provided an average over all seasons. Therefore, seasonal variability has been smoothed out. To show the effect of excluding global LNO_x emissions on the seasonality, we first show zonal distributions of the O₃ – CO ratio of both simulations for the two most contrasting months, January and July, in Figure 11. Below, all monthly medians are shown for CO, O₃, and their ratio separately, as well as the fraction of different mechanisms of O₃ generation contributing to the northern subtropical troposphere. A selection of all monthly means of CO, 395 O₃, and their ratio of the standard and the sensitivity run of the model can be found in the Supplementary Material.

The strongest seasonal difference can be perceived in the standard run in the northern subtropics reaching a ratio difference of 0.5 ppbv/ppbv (Fig. 11, (a), (c)). Generally, the tropospheric O₃ – CO ratio is strongest in the subtropics in summer in both hemispheres, and weakest in winter. By excluding LNO_x emissions in (b) and (d), the seasonal difference becomes even more pronounced, as the O₃ – CO ratio is nearly constant throughout the whole troposphere in the northern subtropics in 400 January (Fig. 11, (b)). In the southern hemisphere the seasonality is much weaker, but the O₃ – CO ratio is still shifted to higher values by excluding LNO_x. Many studies have linked this hemispheric difference to tropopause height changes resulting in net mass transfer between the stratosphere and troposphere (Staley, 1962; Robinson, 1980; Murgatroyd et al., 1980; Sprenger and Wernli, 2003), with a more pronounced seasonal cycle in the northern than southern hemisphere (Appenzeller et al., 1996), also coupled to the amount of land cover. However, as the sensitivity run still shows strong seasonality, LNO_x is not expected 405 to be the mechanism controlling the seasonal variation.

NO_x emissions from lightning have distinct spatial and temporal variations in the extra tropics, being highest in summer and lowest in winter, and pronounced in the northern hemisphere due to the larger land cover (Collier and Hughes, 2011b). Yet, 77 % of the world's lightning activity occurs in the tropics, between 30° S and 30° N (Schumann and Huntrieser, 2007), and mainly over land (Ricciardulli and Sardeshmukh, 2002; Williams and Stanfill, 2002). The occurrence of lightning in the tropics 410 is to be expected to show no significant seasonal variation, as it moves along the ITCZ, even though lightning activity is highly complex and depends on thunderstorm activity and the properties of the aerosols, which have stronger spatial variations than temporal ones (Williams, 1985; Rycroft et al., 2000; Williams et al., 2002; Zipser et al., 2006; Collier and Hughes, 2011b, a).

Figure 11. Monthly medians of the zonal distribution of the modeled O_3 – CO ratio from January (a, b) and July (c, d), with (a, c) and without (b, d) LNO_x . All monthly medians can be found in the Supplementary Material.

Tropical LNO_x , and its distribution of chemical successors seem to have a global impact over all seasons, as can be seen in the comparison of the standard and sensitivity simulation in Figure 11. This is consistent with the findings of Mickley et al. (2001), who modeled an overestimation of 50 % of preindustrial O_3 during winter in the northern mid-latitudes compared to measurements and linked it to tropical LNO_x emissions.

When excluding LNO_x from the model simulations, seasonality is still strong. The remaining effects, controlling O_3 production and CO loss are therefore expected to depend on other mechanism, like stratosphere–troposphere exchange, other NO_x sources, and changing background emissions.

In Figure 12 (a), the monthly medians of CO , O_3 , and their ratio are shown, averaged over the whole troposphere in the northern subtropics, from 23.3 – 40°N . Anthropogenic emissions peak during the winter and spring, especially in the northern hemisphere, with the background CO mixing ratios increasing up to 125 ppbv in the zonal median. Biomass burning also contributes to the background CO but is more common in the tropics, and at higher latitudes. O_3 is at a maximum in May at approximately 80 ppbv, with a gradually decreasing gradient up until winter. In winter, photolysis rates are lowest, hence the O_3 lifetime is longer and more O_3 accumulates (Mickley et al., 2001). During the summer, O_3 depletion is strongest due to higher photochemical activity.

For a clearer identification of seasonality in the model simulation we introduce the O_3S tracer, provided by the model, which

identifies all O₃ originating from the stratosphere and propagating into the troposphere. With this tracer and the sensitivity run, by excluding the chemical production of O₃ by lightning emissions, we can identify different O₃ origins that contribute to the O₃ – CO ratio. These are shown in Figure 12 (b).

First, the O₃S tracer reveals the amount of O₃ coming from the stratosphere, which can be linked directly to STE. O₃S changes marginally between the two model simulations (not shown here). Therefore, we conclude that O₃ produced in the tropics and distributed from the TTL through the stratosphere seems to have a minor influence on O₃ transported into subtropical regions. The contribution of STE to the total tropospheric column O₃ budget in the northern subtropics comes to about 25 – 50 %, peaking in February and having its minimum in August. This contrasts with the seasonality of the O₃ – CO ratio, which has its maximum in July and its minimum in January. However, storm tracks and mountain chains in the subtropics are preferred regions for STE (Škerlak et al., 2014), being strongest in summer, particularly over continents (Sprenger and Wernli, 2003). STE is highly affected by the movements of the jet streams, due to their role in the formation of tropopause folds. The location and strength of jet streams are strongly influenced by temperature differences between high and low latitudes and the rotation of the Earth. More homogeneous temperatures are expected to weaken the jet streams and make them more wavy zonally (Stendel et al., 2021). Such north-south propagations through alternating low- and high-pressure regions are known as Rossby waves. These planetary waves influence the zonal position of the jet streams, moving polewards in summer and equatorwards in winter. Jing and Banerjee (2018) have found that anticyclonic wave-breaking events became more frequent especially in summer, and can be associated with stronger isentropic STE. Overall, STE seems to have a strong impact on the mixing ratios in the UTLS region; however, in a vertical average over the whole troposphere, this influence on O₃ seems to have a minor effect in summer in the northern subtropics. Škerlak et al. (2014) showed in a climatological study based on ERA-Interim reanalysis data that high O₃ can be found all the way down to the planetary boundary layer (PLB) throughout all seasons with global hot spots along mountain chains mainly in the subtropics in summer. However, they identified an accumulation of O₃ below the tropopause as being transported downwards, rather than coming from the stratosphere directly. Similar seasonality can be found in the southern hemispheric subtropics, but this peaks in summer and has its lowest value in winter (not shown here).

The contribution of O₃ produced by LNO_x has been calculated by subtracting total O₃ from the “without LNO_x” run from total O₃ from the “REF” simulation of the model (tr. LNO_x, Fig. 12 (b)). As most LNO_x is expected to be in the tropics (Schumann and Huntrieser, 2007), we conclude that this O₃ is mostly produced by tropical LNO_x emissions, transported via the Hadley circulation into the subtropics. The median contribution of photochemically produced O₃ to the northern subtropical tropospheric column varies between 5 and 15 % throughout the year, with slightly higher contributions in summer than in winter. This modest seasonality indicates a minor contribution of local induced LNO_x emissions in summer and autumn. However, strong convective activity would transport upward surface emissions, with high CO and low O₃, which is not the case based on the monthly medians of CO and O₃ in Fig. 12 (a). In highly polluted regions, however, high NO_x emissions can result in a higher O₃ – CO ratios, which is taken up by convection (e.g., Asian Summer Monsoon, Mickley et al. (2001)). Furthermore, deep convection is also linked to stratospheric–tropospheric mixing through overshoots and corresponding downdrafts (Frey et al., 2015).

Figure 12. Monthly medians of CO, O₃, and the O₃ – CO ratio in (a), and different O₃ sources in (b) averaged over the whole troposphere of the northern subtropics, defined from 23.3–40°N. The shaded areas display the 25th and 75th percentiles. The different O₃ sources are defined by calculations of O₃ from the two model runs and the O₃S tracer of the model, which is the O₃ originating from the stratosphere only (STE, black crosses). The background O₃ mixing ratios of the northern subtropics are derived from the difference of all O₃ minus O₃S from the “without LNO_x” run (BG, green stars), and O₃ produced and transported from tropical LNO_x (tr. LNO_x, triangles) is calculated from the difference of total O₃ minus the O₃S tracer of REF minus the background mixing ratios. Adding all three O₃ origins in (b) results in the O₃ mixing ratios shown in (a), being 100 %. Only tropospheric values have been taken for the calculations, by excluding O₃ higher than 100 ppbv according to Prather et al. (2011).

Extracting O₃S from the total O₃ from the sensitivity run excluding LNO_x results in the background O₃ mixing ratio, defining O₃ which is neither coming from the stratosphere nor from tropical photochemistry including lightning NO_x. This remaining O₃ mixing ratio (BG, Fig. 12 (b)) shows a strong seasonality, peaking in summer and having its minimum in winter. It contributes approximately 40–60 % to the total O₃ column of the northern subtropics, and mainly drives its seasonality. The seasonal variation of the background O₃ could be linked to other NO_x sources like soil, anthropogenic emissions, or biomass burning emissions (Škerlak et al., 2014), but these possibilities have not been further investigated in this study. Possible transport of PAN via the Ferrell circulation from the mid-latitudes into the subtropics and its thermal depletion in the downward branch is another potential source of NO_x.

In conclusion, STE seems to have a minor role in controlling the seasonality. Tropical LNO_x transported via the Hadley circulation consistently influences the O₃ mixing ratio in the northern subtropics, and possible also the depletion of CO, throughout the year. The strongest effects on seasonality are exerted by the remaining factors defining the background mixing ratios.

475 4 Conclusions

Tropospheric chemistry and transport processes, within the troposphere as well as STE processes are important in conditioning the background mixing ratios of greenhouse gases and trace gases in the troposphere. This study used in situ observations from 12 aircraft campaigns, from 2012 – 2024, to investigate the tropospheric zonal distribution of O_3 and CO and their ratio. Particularly in the northern subtropics, a strong enhancement in the O_3 – CO ratio almost down to the boundary layer could be identified, which is usually expected to be caused by STE processes in the vicinity of the subtropical jet stream, bringing high- O_3 and low-CO air from the stratosphere into the troposphere. In this study, we have investigated another possible mechanism contributing to the chemical composition of the tropospheric subtropics, which had not yet been considered. High O_3 – CO ratios can also be produced through photochemistry and transport within the troposphere. In the upper tropical troposphere, substantial emissions of LNO_x , especially in the ITCZ, are a major source of O_3 , and, simultaneously, catalyze the recycling of OH radicals in the upper troposphere. Those highly reactive radicals are the main sink of CO in the free and upper troposphere, shortening the lifetime of CO. Thus, through the presence of LNO_x , high O_3 – CO ratios can also be photochemically generated and distributed by the Hadley circulation into the subtropics. To test this hypothesis, we have used the general circulation and chemistry model EMAC and run a sensitivity study on the effect of LNO_x on the troposphere O_3 – CO ratio. First, we show that the modeled zonal distributions give the same enhancement of O_3 – CO ratio in the subtropics than the observations. Second, we identified a strong effect of LNO_x , which is mainly produced in the tropical troposphere, on the chemical composition of the subtropics outside the convective regions in the down-welling branch of the Hadley circulation. Photochemistry contributes by 40 % to the O_3 – CO ratio in the upper troposphere of the northern subtropics. These air masses propagate through the whole vertical column of the northern subtropics, supported by the Hadley circulation. The effect of LNO_x on O_3 and CO in the southern subtropics, tropics, extra tropics, as well as in the UTLS region were also noticed, but were not in the focus of this work. We conclude that tropical LNO_x emissions are crucial for O_3 production and subsequently for CO loss through the secondary production of OH radicals, which can be distributed in significant amounts throughout the whole troposphere. Furthermore, we see a strong inter-annual variability, mainly influenced by a complex interaction of STE and background concentrations. The highest O_3 – CO ratios have been identified in summer in the northern subtropics, corresponding with low CO and high O_3 mixing ratios. Besides contributing to the seasonality of background concentrations, STE is weakest in summer, which is in contrast to the enhancement of the O_3 – CO ratios in summer. However, more frequent Rossby wave occurrences in summer are expected to contribute to stronger mixing throughout the troposphere. Furthermore, other tropospheric sources of NO_x seem to play an important role in conditioning the troposphere as well, which needs further investigation. Meridional variations have been briefly discussed in this study. More detailed investigation could verify the impact of tropospheric photochemistry on the background concentrations of specific regions. Furthermore, LNO_x emissions are dependent on the frequency of deep convective systems as well as many other factors (e.g., ice-nucleating particles, emissions, turbulence, cloud top height), which can be hard to model. There are still major uncertainties in understanding the varying manifestations of these emissions over continental and maritime surfaces. However, we showed that lightning emissions have a strong effect

on tropospheric photochemistry and global distributions of the O_3 – CO ratio. This effect along tropospheric transport plays a key role in conditioning the troposphere and needs to be considered in future studies.

510 *Code and data availability.* The data measured during the campaigns ESMVal, OMO, WISE, CAFE Africa, SouthTRAC, CAFE Brazil, PHILEAS and CAFE Pacific are available on the HALO database platform via DLR (2012, 2015, 2017, 2018, 2019, 2023a, b, 2024), respectively. Specifically, data and code of FAIRO O_3 data processing can be accessed via Obersteiner (2024b). The ATom missions data sets can be accessed through the NASA website (Wofsy et al., 2018).

515 *Author contributions.* LO, AP and HF designed the study; LO, HF, FO, AZ provided the HALO campaign data sets; TR, JP, IB, CT, BD provided the ATom data sets; AP provided the modeling data; LO analyzed and processed the data and wrote the paper; All others proofread and edited the paper.

Competing interests. Some authors are members of the editorial board of journal ACP.

520 *Acknowledgements.* The authors gratefully acknowledge the whole HALO and NASA DC-8 team, which were present for and contributed to all campaigns used for this study. Additionally, all institutes which took place in those campaigns are hereby acknowledged, including the Max Planck Institute of Chemistry, the atmospheric department of the University of Frankfurt, Karlsruhe Institute of Technology, the institute of physics at the University of Mainz, the NASA Armstrong (Dryden) Flight Research Center, the NOAA Earth System Research Laboratories, the University of Harvard, and the Deutsches Zentrum für Luft- und Raumfahrt (DLR) in Oberpfaffenhofen. JP, IB, and CT were supported in part by NOAA cooperative agreement NA17OAR4320101. Acknowledgment is also given to ChatGPT (open AI), who helped out by coding problems now and then.
