Abstract. Rivers play a critical role in the global carbon cycle. However, the environmental and hydro-climatic factors that control the direction and magnitude of river CO₂ fluxes across seasons and multidecadal periods are poorly constrained. The origin of excess river CO₂—delivered by soils, wetlands and groundwater or produced by aquatic respiration of organic matter—remains an important unknown in linking terrestrial and aquatic carbon budgets. To address these knowledge gaps, we report on a 32-year high-frequency dataset (1990–2021) from the Loire River, a large, temperate river that underwent a shift from a phytoplankton-dominated regime to a macrophyte-dominated regime around 2005. We estimated daily river-atmosphere CO₂ flux (FCO₂) and river net ecosystem productivity (NEP) from hourly pH, alkalinity, dissolved oxygen, water temperature and solar radiation. We demonstrate that: i) annual FCO₂ varied an order of magnitude among years (range = 200–2600 g C m² yr⁻¹) with a long-term decrease trend, mainly linked to decreased groundwater contribution; ii) the mean annual contribution of internal CO₂ production from net ecosystem respiration to total FCO₂ was 40%, increasing from 37 ± 27% in phytoplankton-dominated regime to 57 ± 10% in macrophyte-dominated regime; iii) while the river predominantly acted as a CO₂ source, it occasionally functioned as a CO₂ sink (FCO₂ < 0) during summer, though this sink behavior constituted a minor component (-0.6%) of the FCO₂ budget; and iv) FCO₂ exhibited strong seasonality linked to discharge, exhibiting hysteresis

Formatted: Subscript

where FCO₂ levels at equivalent discharge were 1.5 to 2 times higher during the rising limb (autumn) compared to the falling limb (spring). The magnitude of this hysteresis diminished in the later macrophyte-dominated regime, indicating ~~a reduced seasonal control by discharge on FCO₂~~. This study ~~demonstrates~~ that river FCO₂ ~~and its source are~~ dynamic within and across years, driven by hydro-climatic variations and biological activity. Catchment-scale hydrogeological changes ~~(including groundwater and surface water interactions)~~ can be a more dominant driver of long-term riverine CO₂ evasion than in-stream ecological regime shifts ~~(transitions from phytoplankton-dominated to macrophyte-dominated communities)~~, controlling the balance between internal and external CO₂ production.

Keywords: internal contribution, autotrophic, heterotrophic, long-term trend, metabolic shift, Loire River

1. Introduction

Streams and rivers are a major component of inland water CO₂ evasion, with the most recent estimates for this flux at $2.0 \pm 0.2 \text{ Pg C yr}^{-1}$ (Liu et al., 2022). Earlier foundational work suggested this riverine flux accounted for approximately 60% of all inland waters (Raymond et al., 2013). Most CO₂ flux (FCO₂) is often assumed to come from "external" sources, delivered to streams via groundwater inputs, ~~surface and subsurface runoff~~, and via temporary hydrologic connectivity with riparian wetlands (Abril & Borges, 2019; Hotchkiss et al., 2015). Additionally, geochemical weathering and photochemical processes are also considered external sources to river FCO₂ (Hotchkiss et al., 2015). While geochemical weathering primarily affects river alkalinity and indirectly influences CO₂ dynamics through changes in water chemistry (J. B. Jones et al., 2003), photochemical processes make a relatively minor contribution to CO₂ production when compared to biological processes (Amaral et al., 2013; Koehler et al., 2014). The remainder of FCO₂ from rivers originates from in-stream respiration of organic matter (Cole et al., 2001), termed the "internal" source of CO₂. While the balance between internal versus external CO₂ sources is spatially predictable (Hotchkiss et al., 2015), its temporal variation is less clear. Most analyses on the origin of stream FCO₂ occur over one season (e.g., Bernal et al., 2022; Rocher-Ros et al., 2020) or rely on discrete samplings (e.g., Hotchkiss et al., 2015). Consequently, while progress has been made, a comprehensive understanding of the full spectrum of temporal variability (seasonal to multidecadal) in FCO₂ and its sources remains limited, particularly for

Deleted: a changing seasonal discharge control

Deleted: makes clear

Deleted: —

Deleted: —is

69 large river systems. Recent work by Young et al. (2025) highlighted this complexity by documenting
70 strong seasonal variability driven by hydrological events, temperature fluctuations, and biological
71 productivity in a temperate river. Their four-year study emphasized the need for longer-term datasets to
72 capture interannual variability, particularly in the context of ongoing climate and ecological changes.
73 The seasonal hydrology plays an important role in determining the magnitude and timing of CO₂
74 emissions from rivers, as changes in flow rates affect the transport of nutrient, organic carbon from
75 surrounding land as input for stream metabolism and the exchange of CO₂ between the river and the
76 atmosphere (Cole et al., 2007; Hotchkiss et al., 2015). There is thus a lack of understanding of the
77 temporal variability of FCO₂ and its sources, which are [becoming](#) increasingly crucial under a changing
78 climate that increases water temperature and modifies river flow (Floury et al., 2012; Van Vliet et al.,
79 2013). This knowledge gap is most prominent in large rivers, leading to significant uncertainty in global
80 FCO₂ assessment from inland waters (Battin et al., 2023; Hotchkiss et al., 2015).

81 The relative contribution of internal CO₂ sources can be quantified as the ratio between net ecosystem
82 productivity (NEP) and FCO₂. NEP is the balance between gross primary production (GPP) and
83 ecosystem respiration (ER) ($NEP = GPP - ER$). When NEP is negative ($GPP < ER$), the river is in a
84 "heterotrophic" state, and CO₂ is added to the water column by net organic matter respiration. Assuming
85 the river is a CO₂ source ($FCO_2 > 0$) and in a heterotrophic state, the $-NEP/FCO_2$ ratio yields the ratio
86 of internal source contribution to total emissions, and by difference, the ratio of external CO₂ source
87 contribution ($=1 + NEP/FCO_2$). This ratio can be evaluated in response to environmental drivers such as
88 hydrology (Hotchkiss et al., 2015), light (Rocher-Ros et al., 2021), water temperature (Lynch et al.,
89 2010; Wallin et al., 2020), and organic matter source (Bernal et al., 2022; Reed et al., 2021). However,
90 rivers are not always CO₂ sources and can seasonally function as CO₂ sinks when high rates of GPP
91 deplete CO₂, leading to CO₂ undersaturation (Aho et al., 2021; Zhang et al., 2017). In this "autotrophic"
92 state ($GPP > ER$), positive NEP means a net production of organic matter within the reach, leading to
93 increases in biomass (e.g., algal, macrophyte) and potentially contributing to particulate and dissolved
94 organic matter pools. Such [an](#) autotrophic state, sometimes leading to CO₂ undersaturation, can be more
95 prevalent or sustained in larger rivers due to factors like greater water residence times, increased light

96 availability across wider channels, and potentially a greater buffering capacity against rapid changes in
97 external CO₂ inputs compared to smaller streams (Hotchkiss et al., 2015). However, these periods,
98 especially if transient or occurring outside of typical low-flow summer conditions, can be missed FCO₂
99 by sampling campaigns that are often infrequent or biased towards specific seasons, thus
100 underestimating their occurrence and impact.

101 The eutrophic state was common in large rivers across Europe throughout the 1980s and 1990s,
102 characterized by high nutrient concentrations and high chlorophyll-*a*, leading to a net autotrophic state
103 (Dodds & Smith, 2016). The Loire River (France) was one of the most eutrophic rivers in Europe at that
104 time with total phosphorus (TP) concentrations frequently exceeding 0.2 mg P L⁻¹ and chlorophyll-*a*
105 concentrations often surpassing 100 µg L⁻¹, with summer peaks reaching over 200 µg L⁻¹ (Minaudo et
106 al., 2015; Moatar & Meybeck, 2005). Despite potential autotrophic dominance, the CO₂ dynamics
107 during these periods remain poorly documented due to the lack of comprehensive CO₂ data, leaving a
108 gap in our understanding of whether the river predominantly acted as a CO₂ source or sink.

109 Following efforts to reduce nutrient inputs between the early 1990s and the mid-2000s, TP
110 concentrations declined by approximately 50-70%, and mean summer chlorophyll-*a* concentrations
111 decreased to <30 µg L⁻¹ (Minaudo et al., 2015). The Loire River underwent ecological shifts from
112 planktonic autotrophic communities dominated by phytoplankton to benthic communities dominated by
113 rooted macrophytes (Minaudo et al., 2015), which is termed "re-oligotrophication" (Ibáñez et al., 2022).
114 The ecosystem transition was followed by a delayed shift in the river's metabolic regime around 2012–
115 2014, with GPP declining and NEP decreasing by roughly 10% during the growing season from spring
116 to summer (Diamond et al., 2022). As re-oligotrophication may become increasingly common in
117 developed countries, its effects on FCO₂ and CO₂ source variation remain unknown.

118 In this study, we used a 32-year daily dataset of coupled stream metabolism (NEP) and FCO₂ to assess
119 the temporal internal/external CO₂ source contributions in the Loire River. We hypothesized that the
120 FCO₂ and its internal source contribution would increase following the re-oligotrophication ecosystem
121 shift. Specifically, we predicted that these increases would manifest coincidentally with the shifts in
122 phytoplankton to macrophyte-dominated regime in 2005 and stream metabolism regime in 2012.

Deleted: spring–summer

Finally, discharge influences FCO_2 through multiple mechanisms, including gas transfer velocity, delivery of external CO_2 , and inhibition of in-stream primary production. Phytoplankton GPP can be sensitive to discharge (e.g., washout, turbidity), while macrophyte GPP may be less directly flow-dependent (Diamond et al., 2022). We therefore predicted that the overall control of discharge (Q) on FCO_2 would change with the shift to macrophyte dominance. Specifically, we anticipated that the seasonal hysteresis patterns observed in the FCO_2 -Q relationship (where FCO_2 differs between rising and falling limbs of the hydrograph at similar Q) would be altered, potentially becoming less pronounced or showing a different shape if macrophyte GPP imparts a more stable baseline of CO_2 uptake across varying flow conditions compared to phytoplankton. Besides, this study is complementary to a concurrent study by Diamond et al. (2025), which focuses on the river's internal biogeochemical mechanisms, including inorganic carbon uptake pathways and changes in the ecosystem quotient.

2. Methods

2.1. Study site

The study site (47.6°N, 2.6°E) is located in the middle Loire River, France, 564 km from the source, with a mean discharge of $300 \text{ m}^3 \text{ s}^{-1}$ (Supplementary Figure S1). Its 36,000 km^2 catchment is home to over two million residents. The land cover consists of forests (42%), pasture (35%), and agriculture (21%) (Moatar & Meybeck, 2005). The Loire River and its tributaries, upstream Dampierre drains volcanic, granitic area and sedimentary basins characterized by extensive limestone and marl formations (Figure S1). After the confluence with Allier River (100 km upstream of the study site), the carbonate-rich catchment and its interaction with the Loire River significantly contribute to river alkalinity primarily through the dissolution of carbonate minerals (Binet et al., 2022). Soil types within the Loire catchment are heterogeneous and their nature is closely linked to the underlying lithology. In addition, the catchment includes significant areas of alluvial deposits, which feature more fertile and productive soils for extensive agriculture in the region (Moatar et al., 2022; Moatar & Meybeck, 2005). This river is an 8th-order river with an anabranching fluvial pattern resulting from a gentle slope (0.4 m km^{-1}). During summer, low flows ($<150 \text{ m}^3 \text{ s}^{-1}$), the study site is typically shallow (around 1 m deep) and wide (330 m); during winter, with higher discharges (e.g., $>500 \text{ m}^3 \text{ s}^{-1}$), depths can increase significantly,

Deleted: ,

typically ranging from 2 to 3 m. The anabranching fluvial pattern leads to a broad range of lateral hydrologic connectivity between the main channel and secondary channels colonized by semi-terrestrial vegetation (Janssen et al., 2023). These vegetated side channels may behave like floodplains by acting as seasonal sources of organic carbon (Abril & Borges, 2019).

2.2. Data acquisition and processing

Hourly data of pH, temperature, electrical conductivity (EC) at 25°C, and dissolved oxygen (DO) from 1990 to 2021 were extracted from the monitoring program conducted by Électricité de France (EDF) upstream and downstream of the nuclear power plant Dampierre (47.6°N, 2.6°E) (Figure S2). Total alkalinity (TA) was obtained from grab samples collected by both EDF and the Loire-Brittany Water Agency (AELB), with measurement frequency ranging from daily to monthly. We reconstructed a continuous daily TA time series from the relationship between EC and TA (Appendix A, Figure A2). This study used the upstream data to calculate daily FCO₂ and NEP, while the downstream data were used to support the data cleaning procedure. A full description of the data acquisition, quality control framework, and data processing is available in **Appendix A**.

We obtained daily global radiation data (W m⁻²) from a nearby meteorological station (donneespubliques.meteofrance.fr). Mean daily discharge (m³ s⁻¹) was obtained from www.hydro.eaufrance.fr. We then estimated average river depth (m) using a local rating curve (Depth (m)=0.0716×√(Q (m³ s⁻¹) + 0.6171), which was established based on the hydraulic model for the Loire River (Camenen et al., 2016).

2.3. NEP and FCO₂ estimation

2.3.1. Metabolism estimation

We estimated daily GPP, ER (g O₂ m⁻² d⁻¹), and the gas transfer velocity coefficient (K₆₀₀, d⁻¹) by using a single-station, open-channel inverse modeling approach implemented with the streamMetabolizer R package (Appling et al., 2018). This Bayesian state-space modeling framework simultaneously estimates daily metabolism parameters (GPP, ER, and K₆₀₀) by fitting modeled diel dissolved oxygen (DO) patterns to observed hourly DO concentrations based on inputs of hourly DO, solar radiation, and water temperature while explicitly accounting for both process and observation errors. To avoid unrealistic estimates and address the common issue of equifinality, where multiple combinations of ER and K₆₀₀ can produce similar DO curves, the model constrains daily K₆₀₀ estimates. The K₆₀₀ is constrained by daily river discharge and river depth with the formulations proposed by Raymond et al.

Deleted: –

Deleted: was

Deleted: exchange rate

Deleted: the inverse modelling approach that yields the best fit between modeled and observed DO. To avoid the unrealistic estimates, the K₆₀₀ is constrained by daily river discharge and river depth with the formulations proposed by Raymond et al., 2012, while the hourly DO, solar radiation and daily water temperature data are required to further reduce equifinality of GPP, ER and K₆₀₀. These estimates are supported by the *streamMetabolizer*, a R package

(2012). Model priors for K_{600} were derived from floating-dome and eddy-covariance measurements, and priors for GPP and ER were informed by previous metabolic studies in rivers (Diamond et al., 2021). The covariance between estimated ER and K_{600} was low ($R^2 = 0.09$), demonstrating reduced influence of equifinality problem (Appling et al., 2018). The detailed model setup for the Loire River was described by Diamond et al. (2021) and Diamond et al. (2025).

GPP and ER were then converted to carbon units ($\text{g C m}^{-2} \text{d}^{-1}$) using a fixed molar $\text{O}_2\text{:C}$ ratio of 1:1. This assumption is widely used in river metabolism studies and reflects the stoichiometry of aerobic metabolism (Trentman et al., 2023). Although photosynthetic and respiratory quotients (PQ and RQ) can vary with autotrophic community composition, recent long-term analysis of the Loire River by Diamond et al. (2025) showed that such variability does not lead to cumulative bias in net ecosystem production or CO_2 budgets when integrated over decadal timescales. Therefore, we adopt this approach as a reasonable and conservative approximation for estimating long-term carbon dynamics, while acknowledging it as a source of short-term uncertainty.

About 12% of samples ($n=1391$) were discarded due to physically impossible results in metabolism estimation (i.e., negative values). Missing mean daily GPP and ER were then replaced by their daily 75th estimated percentile values provided by *streamMetabolizer*, as detailed in **Appendix B, Section B1**. We imputed the remaining 1.7% of missing data using the rolling 7-day average. The K_{600} values derived from the model were validated against established empirical equations and found to be of the same order of magnitude, as detailed in **Appendix B, Section B2**.

2.3.2. pCO_2 and FCO_2 estimation

Daily concentrations of partial pressure of CO_2 (pCO_2 , μatm) were estimated by *pyCO2SYS*, a Python package for the *CO2SYS* model (Humphreys et al., 2022), using mean daily pH, water temperature, and TA. Carbonate dissociation constants K_1 and K_2 were chosen based on freshwater estimates (Millero, 1979). *CO2SYS* freshwater pCO_2 estimates are valid for water with $\text{TA} > 1000 \mu\text{mol L}^{-1}$, and results have been previously validated for the Loire River (2–9% bias) (Abril et al., 2015). The daily TA data in this study were estimated from daily EC with an average error of $190 \mu\text{mol L}^{-1}$, leading to an uncertainty in pCO_2 estimation. *PyCO2SYS* can estimate pCO_2 uncertainty by propagating the TA uncertainty (Humphreys et al., 2022). The uncertainty of estimated TA leads to $\pm 11\%$ uncertainty in pCO_2 estimation; however, there was no significant difference in the river's CO_2 state over 32 years, as detailed in the uncertainty analysis in **Appendix B, Section B3**.

Moved (insertion) [1]

Deleted: K_{600}

Moved up [1]: The covariance between estimated ER and K_{600} was low ($R^2 = 0.09$), demonstrating reduced influence of equifinality problem (Appling et al., 2018).

Deleted: ,

230 FCO₂ (mmol C m⁻² d⁻¹) between the water and the atmosphere was calculated based on Fick's law, using
 231 the CO₂ transfer velocity (k_{CO₂}, m d⁻¹) and the air-water CO₂ gradient (mmol m⁻³) (Eq. 1). We obtained
 232 k_{CO₂} (Eq. 2) using Schmidt number (Sc) at given water temperature (Eq. 3) scaling from the gas transfer
 233 velocity k₆₀₀ (m d⁻¹) (Raymond et al., 2012). The k₆₀₀ was calculated by multiplying river depth (m) by
 234 gas transfer velocity coefficient K₆₀₀ (d⁻¹). The k₆₀₀ estimates derived from K₆₀₀ values output by the
 235 StreamMetabolizer model were selected for FCO₂ calculations to ensure consistency with the NEP
 236 calculations.

$$FCO_2 = k_{CO_2} \times (CO_{2\text{ water}} - CO_{2\text{ air}}) \quad \text{Eq. 1}$$

$$k_{CO_2} = depth \times K_{600} / (600 / Sc_{CO_2})^{-0.5} \quad \text{Eq. 2}$$

$$Sc_{CO_2} = 1911.1 - (118.1 \times T) + (3.45 \times T^2) - (0.0413 \times T^3) \quad \text{Eq. 3}$$

237 CO_{2,water} is aqueous CO₂ (mmol m⁻³) estimated by pyCO2SYS, and CO_{2,air} is CO₂ in equilibrium with
 238 the atmosphere using global monthly atmospheric CO₂ from 1990–2021 from the National Oceanic and
 239 Atmospheric Administration Global Monitoring Laboratory (<https://gml.noaa.gov/ccgg>). Sc_{CO₂} is the
 240 Schmidt number for CO₂ (unitless), T is the water temperature in degrees Celsius (°C). We used Henry's
 241 law to convert pCO₂ in µatm into CO₂ in mmol m⁻³ using temperature-dependent solubility constants.

242 2.3.3. Categorizing NEP-FCO₂ states by autotrophic/heterotrophic and source/sink states

243 We categorized the river into four trophic-flux states (or "trophlux" states) based on daily NEP and
 244 FCO₂ (Diamond et al., 2025). Following Odum (1956), if NEP is positive (GPP > ER), the river is
 245 autotrophic, while if NEP is negative (GPP < ER), the river is heterotrophic. Likewise, if FCO₂ is
 246 positive, the river is a CO₂ source, while if FCO₂ is negative, the river is a CO₂ sink, relative to the
 247 atmosphere. The river could thus be in four possible trophlux states: 1) autotrophic-sink, 2) autotrophic-
 248 source, 3) heterotrophic-sink, and 4) heterotrophic-source. The autotrophic-sink and heterotrophic-
 249 source states imply that NEP and FCO₂ vectors are moving CO₂ in the same direction, into water column
 250 biomass or out of the water column, respectively (Bogard & Del Giorgio, 2016). The remaining two
 251 states imply opposite directions between NEP and FCO₂. The autotrophic-source state implies that
 252 although there is a net conversion of CO₂ into biomass, there is a surplus of water column CO₂ relative

Deleted: using

Deleted: (Raymond et al., 2012a)

Deleted:

Deleted: from

Deleted: K₆₀₀ is the gas exchange rate coefficient normalized to a Schmidt number of 600 (d⁻¹) from *streamMetabolizer*, ...

263 to autotrophic needs, leading to continued positive FCO₂. The heterotrophic-sink, a temporary condition
264 likely caused by temporal lags in the carbonate system's buffering capacity during the shift between
265 autotrophic and heterotrophic states, indicates net conversion of biomass into water column CO₂, even
266 CO₂ remains undersaturated relative to the atmosphere, likely due to prior autotrophic uptake. Recent
267 work using this dataset has provided strong evidence for this mechanism, showing that these events are
268 temporary and typically follow periods of intense autotrophic activity (Diamond et al., 2025). A more
269 detailed discussion of methodological considerations for this state is provided in **Appendix B, Section**
270 **B4**.

271 Conventionally, the aquatic metabolism contribution to river CO₂ emissions (i.e., the internal CO₂
272 source) is calculated as -NEP/FCO₂ in the heterotrophic-source state (Bernal et al., 2022; Hotchkiss et
273 al., 2015; Kirk & Cohen, 2023).

274 **2.4. Change points and long-term trend analysis**

275 To test our hypothesis that FCO₂ would vary as a function of ecosystem state and metabolism shifts in
276 the Loire River, we compared change points in FCO₂ with previously estimated change points in
277 ecosystem regime (ca. 2005) and metabolic regime (ca. 2012) (Diamond et al., 2022; Minaudo et al.,
278 2015). We used the *ruptures* Python package (Truong et al., 2020) with a five-year window interval to
279 ensure that identified changes were sustained beyond year-to-year variation. The change point detection
280 was also applied to the daily NEP and related variables (pH, alkalinity, pCO₂, k₆₀₀, GPP, and ER). We
281 also conducted change point detection on the seasonal decomposed time series of daily FCO₂ and NEP.
282 This decomposition, performed using the *statsmodels* Python package (Seabold & Perktold, 2010),
283 separates a time series into trend, seasonal, and residual components, allowing us to specifically identify
284 change points in the characteristics of the seasonal cycle (e.g., amplitude changes) independently of the
285 long-term trend (**Appendix C, Section C1**). To quantitatively assess differences between change point
286 periods, we performed non-parametric Kruskal-Wallis tests followed by post-hoc Mann-Whitney U tests
287 (**Appendix C, Section C2**).

Deleted:

Deleted: state implies that despite the

Deleted: , there is still a

Deleted: undersaturation

Deleted: We expect the heterotrophic-sink state to be a temporary occurrence, reflecting temporal lags within the carbonate system buffering capacity during the short transition between autotrophic and heterotrophic states.

Formatted: Subscript

296 We further estimated long-term trends of FCO₂ and NEP as functions of hydroclimatic conditions
297 (discharge, water temperature) in each trophlux state by using the Mann-Kendall test (*pyMannKendall*
298 Python package) (Hussain & Mahmud, 2019).

299 **2.5. Seasonal hysteresis of NEP and FCO₂ in response to discharge changes**

300 To test the influence of discharge on CO₂ emissions, we evaluated the hysteresis of mean daily FCO₂
301 and NEP against mean daily discharge across the periods delineated by the change point analysis. We
302 predicted that for the same discharge, FCO₂ would exhibit a range of magnitudes depending on the
303 season but that this range would decrease systematically as a function of decreasing phytoplankton
304 coverage in the Loire River. We evaluated the hysteresis loops by the direction of hysteresis (clockwise
305 or counterclockwise) and the magnitude (i.e., difference of FCO₂ at the same discharge but in the rising
306 and falling flow stage). We anticipated that the shift to a macrophyte-dominated regime, with potentially
307 more stable GPP across flow conditions, might lead to a flattening or a reduction in the magnitude of
308 these hysteresis loops for FCO₂ and NEP. We additionally calculated hysteresis magnitude for -NEP,
309 external source contribution (FCO₂ + NEP), and -NEP/FCO₂ at the mean discharge (300 m³ s⁻¹, Table
310 2) during the rising (autumn) and falling stage (spring).

311 **3. Results**

312 **3.1. Daily, seasonal, inter-annual FCO₂ emissions and NEP contribution for 32 years**

313 FCO₂ and NEP exhibited strong daily, seasonal, and inter-annual variations (Figure 1). The pronounced
314 seasonal variability drove successive transitions among different trophlux states. Typically, the river
315 would shift from being heterotrophic and a CO₂ source in winter, towards becoming more autotrophic
316 in spring and potentially a CO₂ sink in summer during low flows, before returning to heterotrophic
317 source conditions in autumn with rising flows. This general seasonal pattern, involving changes in both
318 NEP (autotrophic/heterotrophic) and FCO₂ (sink/source), recurred each year, though its specific timing
319 and intensity varied (Figure 1c). The corresponding hydro-climatic context, including mean annual
320 discharge for each year, is provided in the Supplementary Information (Figure S3) for a detailed
321 comparison.

Figure 1. Evolution of FCO_2 and $-\text{NEP}$ during 1990-2021. (a) Daily values ($\text{g C m}^{-2} \text{d}^{-1}$), (b) Cumulative annual fluxes (calendar year, $\text{g C m}^{-2} \text{y}^{-1}$), (c) Seasonal fluxes during hydrological year in each decade 1990-2000, 2001-2010, 2011-2021. In Figure 1c, the solid line and shaded area are the average and the 95% confidence interval of the daily fluxes each decade, calculated by 10 daily fluxes in the same day-year.

The daily average FCO_2 was $3 \text{ g C m}^{-2} \text{d}^{-1}$, with high peaks reaching $20 - 60 \text{ g C m}^{-2} \text{d}^{-1}$ during high flow in winter ($1000-2000 \text{ m}^3 \text{s}^{-1}$) and low peaks with negative FCO_2 of $-0.8 \text{ g C m}^{-2} \text{d}^{-1}$ during the low flow in summer ($<150 \text{ m}^3 \text{s}^{-1}$) (Figure 1). The daily NEP was $-0.45 \text{ g C m}^{-2} \text{d}^{-1}$, with average peaks from $-4.0 \text{ g C m}^{-2} \text{d}^{-1}$ in winter to $3.6 \text{ g C m}^{-2} \text{d}^{-1}$ in summer (Figure 1a).

Cumulative annual FCO_2 ranged from 221 to $2633 \text{ g C m}^{-2} \text{y}^{-1}$ and NEP from -383 to $584 \text{ g C m}^{-2} \text{yr}^{-1}$.

Notably, the Loire River experienced several years of net autotrophic state (Figure 1b, green bars), mainly in 1990-2000. Even during these years, the Loire River was a net source of CO_2 to the atmosphere (Figure 1b, grey bars). The contribution of external CO_2 sources ($\text{FCO}_2 + \text{NEP}$) ranged from $800-2400 \text{ g C m}^{-2} \text{y}^{-1}$ in 1990-2010. However, the contribution of external CO_2 sources has significantly decreased to ca. $400 \text{ g C m}^{-2} \text{y}^{-1}$ since 2011 (Figure 1b).

Figure 2. Change point detection in the daily time series of (a) FCO₂, pCO₂, pH, alkalinity and (b) –NEP, K₆₀₀, GPP, ER during 1990-2021. The vertical red lines indicate the year of the change point.

The change point analysis on daily time series detected that the FCO₂ experienced two change points in 2000 and 2008 (Figure 2a), while the change points of –NEP were detected in 1995 and 2011 (Figure 2b). While change points in –NEP described a gradual increase, change points in FCO₂ indicated more abrupt fluctuations, with abnormal decreases in 2000 and 2008. The daily time series of pCO₂, pH, and alkalinity had similar change points to FCO₂. The change points of –NEP were mainly dependent on GPP, while there was no significant change in the ER time series (Figure 2b). In addition, the seasonal decomposition analysis detected the same change point in 2008 for the seasonal amplitude in both FCO₂ and NEP, indicating a significant decrease in the seasonal variations (Figure C1).

The periods of change in both FCO₂ and NEP spanned roughly three decades: (i) 1990–2000, (ii) 2001–2010, and (iii) 2011–2021. These time frames were selected based on changepoint analysis, which identified shifts in FCO₂ around 2000 and 2008, in NEP around 1995 and 2011, and GPP around 1997

and 2015 (Figure 2). Despite some discrepancies in the exact timing of these changepoints between FCO₂ and NEP, grouping the data by decades allowed for a coherent comparison of long-term trends in ecosystem behavior. These periods corresponded to distinct phases in river metabolism and CO₂ emissions: (i) high primary productivity (cumulative annual GPP= 1113 ± 225 g C m⁻² y⁻¹, ER= 1136 ± 241 g C m⁻² y⁻¹) and low CO₂ emission (FCO₂ = 1031 ± 531 g C m⁻² y⁻¹) ; (ii) reduced primary productivity (GPP= 973 ± 292 g C m⁻² y⁻¹, ER= 1136 ± 128 g C m⁻² y⁻¹) and high CO₂ emission (FCO₂ = 1534 ± 620 g C m⁻² y⁻¹), and (iii) low primary productivity (GPP= 867± 212 gC m⁻² y⁻¹, ER= 1167 ± 163 g C m⁻² y⁻¹) and low CO₂ emission (FCO₂ = 773 ± 272 g C m⁻² y⁻¹).

3.2. Occurrence and contribution of trophlux states to CO₂ emissions

At the seasonal time scale, the Loire River varied among trophlux states, with the heterotrophic-source state predominating. The source state occurred the least (64% of time) in the first decade delineated by change points (1990–2000) and occurred the most (92% of time) in the most recent decade (2011–2021). Likewise, the heterotrophic state occurred at a minimum of 54% and a maximum of 67% of time during those decades, respectively. The joint occurrence of the heterotrophic-source state each year thus ranged from 47.3 ± 9.4% in 1990-2000 to 66.8 ± 11.3% in 2011-2021 (Table 1), coinciding with low water temperature and high discharge (Figure C2). This state contributed more than 90% of the total annual CO₂ emissions. Within this heterotrophic-source state, the contribution of internal sources (–NEP/FCO₂) to total CO₂ emissions varied across the decades: it was 37 ± 27% in 1990-2000, 28 ± 9% in 2001-2010, and increased to 57 ± 10% in 2011-2021 (Table 1). This implies that external CO₂ sources, accounting for the remaining proportion in each period, have declined over time.

The remaining three trophlux states (autotrophic-source, autotrophic-sink, and heterotrophic-sink) had a combined net impact of less than 10% on total FCO₂ despite their regular occurrence (e.g., up to 50% of time) during the 1990-2000 decade. The autotrophic-sink state, driven by high GPP, typically occurred for 1–3 months during the summer growing season, coinciding with the highest water temperatures and the lowest discharge (Table 1). The autotrophic-sink reduced annual FCO₂ by -3.0 ± 4.2% during 1990–2000 and by -0.4 ± 0.3% in 2011–2021. In spring and autumn, the Loire River was regularly in an autotrophic state (17% to 28% of time) but remained a CO₂ source, presumably attributed

Deleted: cd

to external CO₂ sources. This autotrophic-source state contributed 8.2–9.2% to annual FCO₂ across years. The heterotrophic-sink state occurred rarely (1–7% of time) and had a small influence on the annual FCO₂ budget (reducing it by 0.1% to 0.8% across the decades). This state typically occurred as relatively short events of 1–14 days from June to August during the transition from autotrophic-sink state or heterotrophic-source state.

Table 1. Summary of the occurrence, fluxes, and related hydroclimatic conditions of each trophlux state in three decades, 1990-2021. The values within the table are depicted as the mean annual value ± standard deviation, calculated for each decade (N=10 or 11).

Variable	Period	CO ₂ source		CO ₂ sink		All states
		Heterotrophic	Autotrophic	Heterotrophic	Autotrophic	
Occurrence (% of days)	1990-2000	47.3 ± 9.4	16.7 ± 9.2	7.3 ± 5.4	28.7 ± 7.0	100

* Not applicable. In these cases, the –NEP/FCO₂ ratio does not represent a simple contribution of internal respiration to CO₂ evasion and is therefore not reported. The mass balance for these states is presented in Figure 5.

** Not Applicable. Internal metabolism consumes both external CO₂ and the CO₂ supplied from the atmosphere through the gas exchange at the air-water interface.

The external CO₂ (gC m⁻² y⁻¹) = FCO₂ + NEP

3.3. The inter-annual trend of FCO₂ depending on trophlux states

The occurrence of heterotrophic-source and autotrophic-sink and their contribution to FCO₂ gradually changed from 1990 to 2021 (Figure 3). The occurrence of the heterotrophic-source state increased from 140 days in 1990 to 250 days in 2021 (Figure 3a). However, the annual flux of -NEP within this state remained relatively stable (Figure 3b), while FCO₂ decreased with an average rate of 0.16 g C m² d⁻¹ per year, resulting in a 62% reduction of FCO₂ in the heterotrophic-source state over the 32 years (Figure 3d). The annual decline in FCO₂ was uncorrelated ($R^2 = 0.09$) with the increase in annual water temperature (+5.7 °C/32 years), but it was positively correlated ($R^2 = 0.36$) with the decrease in annual discharge (-13%/32 years) (Table D1). Since the annual -NEP remained stable and FCO₂ decreased, the ratio of -NEP/FCO₂ thus increased from 20–40% in the 1990s to 60–75% in recent years, +1.25% per year (Figure 3f). There were some abnormal increases of -NEP/FCO₂ observed in 1995–2000, with the ratio reaching 100% in 1997 and 90% in 1996 and 2000. These peaks were associated with a significant drop in FCO₂ (Figure 3d) and, thus, in external CO₂ sources (Figure 3b).

The autotrophic-sink state occurrence decreased from 140 days in 1990–2000 to 30 days in recent years (Figure 3a), following a reduction in +NEP from about 2 to 1.5 gC m⁻² d⁻¹ (-25%/32 years), corresponding to -0.015 g C m² d⁻¹ per year (Figure 3b). In this state, annual discharge and temperature did not show significant changes ($p > 0.05$) (Figure 3c, e). The decrease in +NEP was not significantly correlated with either annual discharge ($R^2 = 0.03$) or annual temperature ($R^2 = 0.00$) (Table D2).

Regarding the other two trophlux states, the autotrophic-source state showed a significant increasing trend in occurrence, similar to the heterotrophic-source state (Figure 3a). This state was also associated with increasing annual temperatures and decreasing annual discharge over time (Figure 3c,e). However, unlike the heterotrophic-source state, there was no significant long-term trend in FCO₂. In contrast, the heterotrophic-sink state existed rarely over the study period and showed no significant long-term trends due to its very infrequent occurrence.

Figure 3. Long-term trends over 32 years of CO₂ fluxes, aquatic metabolism contribution, and hydroclimatic conditions on each trophic state: a) occurrence per year, b) annual aquatic metabolism flux (–NEP), c) annual discharge, d) annual FCO₂, e) annual water temperature, f) –NEP/FCO₂. The points depicted on the graph were the annual averages. The regression lines were the Theil-Sen slopes with significant trends (p-value < 0.05).

3.4. Seasonal hysteresis of NEP and FCO₂ in relation to discharge

FCO₂ and NEP exhibited a similar clockwise hysteresis pattern in response to seasonal variations of discharge, i.e., higher fluxes in the rising discharge stage compared to the falling stage (Figure 4). Typically, hysteresis cycles started with FCO₂ minima and NEP maxima in July and August (mean discharge <150 m³ s⁻¹, mean temperature 23 °C), with opposite peaks in January and February (mean discharge >500 m³ s⁻¹, mean temperature 5 °C) (Figure 4a). As river discharge gradually increased from summer to winter, the river transitioned from an autotrophic to a heterotrophic state and from CO₂ sink to source. Subsequently, but along a different trajectory, the river shifted back to an autotrophic state during the spring-summer falling discharge stage (150–300 m³ s⁻¹). During this time, however, the river continued to act as a CO₂ source, lasting two to three months (April–June) before returning to the FCO₂

436 minimum again in summer. The contribution of external CO₂ sources (FCO₂ + NEP) also exhibited a
 437 clockwise hysteresis loop with discharge, with higher external contributions during the rising limb
 438 (autumn/winter) and lower contributions during the falling limb (spring) at equivalent discharge rates,
 439 generally mirroring the patterns observed for FCO₂ and -NEP (Figure 4, bottom row).

441 Figure 4. Hysteresis loops of -NEP, FCO₂, and external sources (FCO₂ + NEP) during the hydrological
 442 cycle in each decade 1990-2000, 2001-2010, and 2011-2021. The color lines are the daily average fluxes
 443 in each decade. The circle shape with numbers is the monthly average and standard deviation fluxes in
 444 each decade.

445 The discharge trajectories of -NEP, FCO₂, and external sources varied across the three decades
 446 delineated by the change point analysis. In three decades, all hysteresis loops exhibited positive
 447 relationships with discharge, except the external CO₂ sources in 2011–2021. FCO₂ hysteresis magnitude
 448 at 300 m³ s⁻¹ (autumn–spring) decreased from 3.2 g C m⁻² d⁻¹ in 1990–2000 to -0.09 g C m⁻² d⁻¹ in 2011–
 449 2021. The near-zero FCO₂ hysteresis magnitude at 300 m³ s⁻¹ in 2011–2021 (Table 2) indicates that
 450 FCO₂ values at this discharge were very similar during both the rising (autumn) and falling (spring)

limbs of the hydrograph. This reduction in the hysteresis loop area suggests that the relationship between FCO₂ and discharge became less dependent on the seasonal progression of the hydrograph in recent years, making FCO₂ at a given moderate discharge more predictable regardless of season. Likewise, the magnitude of –NEP hysteresis at 300 m³ s⁻¹ was weakest in recent years (0.68 g C m⁻² d⁻¹), but unlike FCO₂, it exhibited a peak (2.12 g C m⁻² d⁻¹) in 2001–2010 (Table 2).

The internal source contribution of FCO₂ (–NEP/FCO₂) at 300 m³ s⁻¹ between spring and autumn had contrasting ratios, with a positive CO₂ contribution in autumn (14 – 34%) but a negative contribution in spring (-26%, i.e., CO₂ consumption) in 1990-2000 and 2001-2010 (Table 2). In 2011-2021, internal source contributions of FCO₂ in autumn and spring were both positive, 64% and 34%, respectively.

Table 2. The mean ± standard deviation fluxes of daily –NEP, FCO₂, external CO₂, and –NEP/FCO₂ in spring and autumn at the mean river discharge of 300 ± 30 (m³ s⁻¹).

	Flux*	1990–2000	2001–2010	2011–2021
River metabolism (g C m ⁻² d ⁻¹)	–NEP ₃₀₀ spring	-0.28 ± 0.41	-0.69 ± 0.11	0.83 ± 0.18
	–NEP ₃₀₀ autumn	0.66 ± 0.15	1.43 ± 0.13	1.5 ± 0.06
	–NEP ₃₀₀ hysteresis	0.94 ± 0.43	2.12 ± 0.17	0.68 ± 0.18
Total CO ₂ fluxes (g C m ⁻² d ⁻¹)	FCO _{2 300} spring	1.55 ± 0.44	2.65 ± 0.15	2.42 ± 0.12
	FCO _{2 300} autumn	4.77 ± 0.14	4.15 ± 0.25	2.34 ± 0.08
	FCO _{2 300} hysteresis	3.22 ± 0.47	1.5 ± 0.29	-0.09 ± 0.14
External CO ₂ flux (g C m ⁻² d ⁻¹)	(FCO _{2 300} +NEP ₃₀₀) spring	1.83 ± 0.2	3.34 ± 0.05	1.59 ± 0.14
	(FCO _{2 300} +NEP ₃₀₀) autumn	4.12 ± 0.05	2.72 ± 0.12	0.83 ± 0.05
	(FCO _{2 300} +NEP ₃₀₀) hysteresis	2.29 ± 0.2*	-0.62 ± 0.13**	-0.76 ± 0.15
–NEP/FCO ₂ (%)	–NEP/FCO _{2 300} spring	-26 ± 33%	-26 ± 5%	34 ± 6%
	–NEP/FCO _{2 300} autumn	14 ± 3%	34 ± 1%	64 ± 1%
	–NEP/FCO _{2 300} hysteresis	40 ± 34%	61 ± 5%	30 ± 6%

* The hysteresis flux is equal to the difference of flux in autumn and spring, i.e., 2.29 = 4.12–1.83, where the 300 subscript refers to the fact that these measurements are averages from mean discharge at 300 m³ s⁻¹.

** Negative hysteresis flux indicates lower flux in autumn (rising waters stage), i.e., -0.62 = 2.72–3.34

4. Discussion

Our data analysis reveals important long-term changes in carbon fluxes of the Loire River. Re-oligotrophication led to an increase in the contribution of internal source of FCO₂, supporting our hypothesis but for reasons that ran counter to our predictions. Indeed, under oligotrophic conditions and macrophyte dominance, –NEP/FCO₂ increased by fourfold overall under the heterotrophic-source state,

with $-NEP$ contributing up to 75% of FCO_2 at the monitoring station during the last decade (Figure 3). However, this change was largely due to decreases in total FCO_2 rather than an increase in the magnitude of $-NEP$. While the magnitude of $-NEP$ did not change notably, the CO_2 consumption by the autotrophic state has significantly decreased in magnitude and duration over the recent decade (Figure 3b), resulting in slight increases in annual cumulative $-NEP$. Instead, decreases in FCO_2 appeared to be due to an approximate halving of external CO_2 sources (Figure 5). Still, the timing of FCO_2 shifts, as detected by our change point analysis (ca. 2000 and 2010), broadly corresponded to our predictions based on previous studies (i.e., 2005 for trophic state change and 2012 for metabolism change), suggesting similar drivers of external and internal CO_2 . Finally, we observed clear support for our prediction of weaker discharge controls on FCO_2 and $-NEP/FCO_2$ based on hysteresis analysis. However, this appeared to be most strongly due to a weakened discharge-external CO_2 source link rather than a weakened discharge-internal CO_2 source link.

4.1. Trophlux states and their contribution to CO_2 emissions

Large river systems function predominately as a source of CO_2 to the atmosphere (Battin et al., 2023; Butman & Raymond, 2011; Cole et al., 2007; Raymond et al., 2013; Abril and Borges 2019), and CO_2 sink states are rarely observed, even in large eutrophic rivers (Raymond et al., 1997). However, our unique dataset revealed the commonality of CO_2 sink behavior in the Loire River and further highlighted the seasonal transitions among all four possible trophlux states and how these transitions varied annually and across decades (Figure 1, Figure 4).

This capacity for CO_2 uptake distinguishes the Loire from other comparable river systems that consistently report persistent emissions. For example, the highly urbanized Seine River (France) has remained a persistent CO_2 source since the 1970s; even during periods of intense phytoplankton blooms, in-stream respiration and high loads of organic matter from wastewater treatment plants (WWTPs) overwhelmed any photosynthetic CO_2 drawdown (Marescaux et al., 2018). Similarly, studies of the eutrophic Han River in South Korea show that while high phytoplankton biomass can reduce CO_2 concentrations, the system remains a net source due to the rapid mineralization of both algal- and wastewater-derived organic matter (Kim et al., 2021). This high rate of mineralization can even be

494 amplified by synergistic interactions, where mixing different organic matter pools leads to greater CO₂
495 production than expected (Begum et al., 2019).

496 Our finding challenges the conventional understanding of large rivers as persistent CO₂ sources and
497 demonstrates how ecosystem metabolism can fundamentally alter carbon cycling patterns. The
498 frequency of CO₂ sink conditions in the Loire River reveals an important but often overlooked aspect of
499 river carbon budgets that may be significant for other large temperate systems undergoing similar
500 environmental changes. Importantly, the transitions among these trophic states are influenced by
501 seasonal climatic drivers (temperature, solar radiation, discharge patterns, which themselves are subject
502 to long-term climate change) and broader environmental changes like nutrient loading (e.g., re-
503 oligotrophication) or external factors such as groundwater, making such long-term analyses critical for
504 systems undergoing similar pressures.

505 We found that, regardless of the long-term trophic regime, the heterotrophic/source state was the most
506 prevalent (47–66% of time), while the autotrophic-source state occurred for approximately a quarter of
507 the year (17–26% of time) (Figure 5). By contrast, the mean annual occurrence of the autotrophic-sink
508 state depended strongly on the trophic conditions of the river, decreasing from $28.7 \pm 7.0\%$ of days in
509 the eutrophic 1990–2000 period to $7.3 \pm 5.7\%$ in the oligotrophic 2011–2021 period (Table 1). This shift
510 in trophic state dominance reflects the ecosystem's response to re-oligotrophication (Diamond et al.,
511 2022). Reduced nutrient availability, particularly phosphorus, directly restrained GPP more substantially
512 than ER because ER is supported by both autochthonous organic matter (linked to GPP) and
513 allochthonous inputs from the catchment. The declining prevalence of autotrophic-sink conditions
514 indicates that the river's capacity to sequester atmospheric CO₂ has diminished with the transition from
515 phytoplankton to macrophyte dominance. This demonstrates long-term trophic shifts, such as re-
516 oligotrophication, can fundamentally alter river carbon dynamics, affecting ecosystem metabolism and
517 atmospheric CO₂ exchange beyond mere adjustments in productivity rates.

Deleted: how long-term changes in trophic status can fundamentally alter carbon dynamics beyond simple changes in productivity rates

Figure 5. Annual CO₂ budget in three main trophic states in 1990–2000, 2001–2010, and 2011–2021. All flux values are expressed in units of gC m⁻² y⁻¹. The notation [FCO₂ > 0] denotes CO₂ emissions from rivers to the atmosphere, whereas [FCO₂ < 0] signifies CO₂ ingassing. The percentages in parentheses represent the proportion of each flux component, with the percentage calculated relative to the maximum flux component (shown in black bold).

4.2. Changes in CO₂ sources in relation to hydrology and re-oligotrophication

This work provides a significant long-term perspective to our understanding of the contribution of internal and external sources to FCO₂ in large rivers. Despite this decades-old research question (Cole et al., 2001), the capacity to quantify the relative strength of these two fluxes is relatively recent (Bernal et al., 2022; Hotchkiss et al., 2015; Kirk & Cohen, 2023), and data in mid-sized and large rivers are still limited. Utilizing a dataset comprising five rivers with mean discharge >100 m³ s⁻¹, Hotchkiss et al. (2015) estimated an NEP of -0.51 to -1.01 g C m⁻² d⁻¹ and -NEP/FCO₂ of 25% to 54%. More recently, Solano et al. (2023) highlighted the vast range of this contribution, with values spanning from less than

10% to over 100%. Our results in the Loire River, which show strong seasonal variability in this metric, align with this broader context. This reinforces that within a single large river system, the contribution of internal metabolism to FCO_2 can be highly dynamic, covering much of the spectrum reported across diverse global systems.

While the magnitude of discharge is a known control on CO_2 dynamics, our results highlight that the seasonal timing and the rising or falling limb of the hydrograph are equally crucial for determining CO_2 fluxes and sources, due to hysteresis effects. Depending on the season, our results caution that measurements at the same discharge may yield contrasting estimates of the internal source contribution (Table 2, Figure 4). This difference was mainly explained by the difference in NEP magnitude and not by differences in FCO_2 . For example, at the same mean discharge, NEP in autumn during the rising stage was more negative, and the river was more heterotrophic than in spring during the falling stage. This difference was only partly explained by differences in daily temperature between the two seasons ($R^2=0.29$, Figure D1). First autumn floods are known to mobilize labile organic matter in temperate rivers, whose drying river beds in summer accumulate plant litter from riparian vegetation (Coyne et al., 2005; Etcheber et al., 2007). In the Middle Loire, the emergence of large, fertile riverbanks during the summer dry season may lead to organic matter deposition that is easily remobilized in autumn. Indeed, Minaudo et al. (2015) observed that the heterotrophy in the Middle Loire in autumn was strongly stimulated by a larger availability of biodegradable organic matter compared to spring. Such a seasonal hydrology-driven variability in river heterotrophy and associated CO_2 dynamics was also recently observed by Young et al. (2025) in the Upper Clark Fork River, USA. They reported pronounced seasonal variation in FCO_2 primarily linked to snowmelt-driven hydrological events mobilizing terrestrial carbon sources, reinforcing our observations that river CO_2 dynamics are strongly shaped by seasonal hydrological connectivity and terrestrial organic matter inputs.

Notably, Figure 4 reveals decadal changes in the magnitude of these hysteresis patterns. The FCO_2 hysteresis magnitude at $300 \text{ m}^3 \text{ s}^{-1}$ decreased dramatically from $3.2 \text{ g C m}^{-2} \text{ d}^{-1}$ in 1990–2000 to $-0.09 \text{ gC m}^{-2} \text{ d}^{-1}$ in 2011–2021, indicating a weakening discharge- FCO_2 relationship in recent years. Similarly, external source hysteresis (bottom row, Figure 4) has flattened considerably in 2011–2021, suggesting

564 diminished influence of terrestrial carbon inputs on seasonal CO₂ dynamics. As these insights would
565 have been invisible without a high-frequency long-term dataset (Figure 1), we, therefore, encourage
566 future efforts to capture seasonality and varying discharges in the measurement campaigns.

567 During the 1990–2000 decade, the Loire River acted as a CO₂ sink for almost half the years due to high
568 rates of GPP. The occurrence of this state has gradually declined over the three decades (Table 1),
569 highlighting an important environmental trade-off where improved water quality from re-
570 oligotrophication has diminished the river's capacity to act as a CO₂ sink. In 1990–2000, the
571 biogeochemical dynamics of the Loire River during the summer months coincided with long water
572 residence times, shallow waters, low discharge, high water temperature, and high eutrophication (>200
573 µg chlorophyll-a L⁻¹) (Moatar et al., 1999, 2001). These conditions were similar to eutrophic lakes,
574 which regularly act as CO₂ sinks (Bogard & Del Giorgio, 2016; He et al., 2022). In addition, autotrophy
575 can exert a stronger control on CO₂ dynamics in larger rivers compared to small streams. This is due to
576 factors such as increased light penetration across wider channels supporting higher areal GPP, and a
577 larger water volume where internal metabolic signals may be less rapidly overwhelmed by the
578 proportional influence of external CO₂ inputs from groundwater or riparian zones (Hotchkiss et al.,
579 2015). Our data show that in the Loire, the long-term shift from phytoplankton to macrophyte-
580 dominance in 2005 has resulted in a reduction in the duration and magnitude of seasonal autotrophy, and
581 greater annual net heterotrophy. Diamond et al. (2021) showed that the changes in stream metabolism
582 in the Loire River in 2010–2012 were related to the shift of other state variables in 2005 (turbidity,
583 nutrient concentrations, *Corbicula fluminea* densities, and chlorophyll-a), suggesting a decade lag for
584 metabolism shift. Moreover, while annual water temperature increased (+0.18°C per decade, +5.7°C
585 over 32 years) and annual river discharge decreased (-4% per decade, -13% over 32 years) (Figure 3,
586 Table D1), these hydroclimatic trends did not show a direct, strong correlation with the timing or
587 magnitude of these decadal metabolic shifts (Figure D2), suggesting that their manifestation on the
588 magnitude of NEP is insignificant.

Deleted: decrease in NEP

Formatted: Font: Italic

4.3. Long-term changes in the external CO₂ source

Contrary to our expectations, we observed a decreasing trend of FCO₂ attributable to an over 50% reduction in external CO₂ sources in the Loire River. This conclusion is supported by the key finding that, despite the overall decline in total FCO₂, the relative contribution of internal CO₂ production (–NEP/ FCO₂ ratio) notably increased from an average of $37 \pm 27\%$ to $57 \pm 10\%$ (Table 1). The Loire River has indeed experienced dramatic reductions in anthropogenic inputs from urban wastewater treatment plants and agricultural runoff since the early 1990s. Total phosphorus inputs decreased 4-fold between 1991 and 2019 (Minaudo et al., 2015), and total organic carbon fluxes declined more than three times from the early 1990s to the 2010s (Minaudo et al., 2016). However, this decline in organic matter inputs cannot explain the observed decrease in FCO₂, as heterotrophic respiration did not significantly change over the study period (Figure 3b). Besides, a decrease in anthropogenic organic matter would theoretically lower internal CO₂ production, reducing –NEP/ FCO₂ ratio. As our observations indicate the opposite trend, the significant reduction in total FCO₂ must therefore be predominantly driven by declines in external inorganic carbon inputs from groundwater.

At first glance, the reduction in external CO₂ inputs appears to be due to overall reductions in discharge and the magnitude of lateral CO₂ transport from groundwater and wetlands to the river (Abril & Borges, 2019). While our data show a modest long-term decline in total river discharge (~13% over 32 years), this alone is insufficient to explain the large reduction in external CO₂ inputs (Figures D1 & D2). Besides, the linkage between external CO₂ and river discharge is more consistent with the seasonal variation (Figure 4, Figure D1) rather than the inter-annual variation (Figure D2). In addition, while the discharge can explain ca. 37-48% of the decay in FCO₂, it only explains ca. 19-26% of the variation in external CO₂ source magnitude (Figures D1 and D2). Similarly, in a forested sandy watershed, Deirmendjian et al. (2018) reported that the export of CO₂ flux from groundwater to the stream was independent of stream discharge and relatively constant seasonally. This can be explained by the fact that higher discharge periods in these systems are associated with low dissolved CO₂ groundwater concentrations and vice-versa. Still, to explain the $>500 \text{ g C m}^{-2} \text{ y}^{-1}$ reduction in external CO₂ between 2001-2010 and 2011-2021, it seems clear that some reduction in groundwater CO₂ is occurring. This

Deleted: this may

618 decrease in external inputs must be driven by either a decrease in the volume of contributing
619 groundwater or a decrease in the CO₂ concentration of that groundwater, or a combination of both.

620 In regions with carbonate bedrock, weathering of carbonate minerals can significantly contribute to the
621 CO₂ flux through the production of alkalinity (Vihermaa et al., 2014). Although this weathering reaction
622 does not directly release CO₂, it provides bicarbonate ions (HCO₃⁻), which can equilibrate with CO₂ and
623 subsequently degas under certain conditions, influencing the CO₂ flux observed in groundwater and
624 rivers. Additionally, the transfer of CO₂ to groundwater depends on the spatiotemporal connections
625 between zones of maximal soil respiration and their intersection with the water table (Tsypin &
626 Macpherson, 2012). If the water table remains disconnected from the topsoil where respiration is
627 strongest, the transfer of soil CO₂ to groundwater becomes limited. Trend analysis of the groundwater
628 table in France over the past 30 years shows low-frequency variations of multi-annual (~7 years) and
629 decadal (~17 years) cycles in groundwater level (Baulon et al., 2022). Further evidence from a
630 representative local borehole at Montifault (20 km from our site) shows a clearly decreasing trend in the
631 piezometric level since 2003 (Appendix D, Figure D3). This regional decrease in groundwater levels
632 supports a reduction in groundwater discharge to the river.

633 To further explore the potential drivers behind the inferred long-term decrease in external CO₂ inputs,
634 we analyzed available data of pH and TA during 1990-2021 from several groundwater monitoring
635 stations situated in aquifers hydraulically connected to our study site. This analysis revealed a long-term
636 increasing trend in groundwater pH, particularly after 2008, while groundwater TA remained relatively
637 stable (Figure D4). At stable alkalinity, an increase in pH directly corresponds to a decrease in pCO₂.
638 This inferred decline in groundwater pCO₂ provides a strong, complementary mechanism explaining the
639 observed reduction in external CO₂ inputs to the river. Given the relative stability of in-river TA over
640 the study period (Figure 2), it is likely that these shifts in the carbonate system are driven by changes in
641 CO₂ supply rather than major changes in catchment-scale weathering rates. In addition, a study at a site
642 located 20 km downstream from our study area in the Val d'Orléans fluviokarst aquifer reported that
643 dissolved inorganic carbon flux from groundwater has decreased by about 20% along with the decrease
644 of groundwater level between 2000 and 2020 (Binet et al., 2022). Binet et al. (2022) also assessed that

there was no significant change in the carbonate weathering rate at this aquifer, which is similar to the relatively stable alkalinity at the Loire River (Figure 2). Together, the evidence for both reduced groundwater discharge and lower groundwater $p\text{CO}_2$ provides a robust explanation for the observed multidecadal decline in external CO_2 sources to the Loire River.

5. Conclusions

In the middle Loire River, three main trophic states alternately occur in the hydrological year cycle, predominated by the heterotrophic-source state. The heterotrophic-source state contributes more than 90% of annual CO_2 emissions, with an average of 40% from internal contribution ($-\text{NEP}$). Besides, in the 1990s, the autotrophic-sink state was still common; however, this state has gradually disappeared in recent years with the decline of phytoplankton, replaced by the dominance of macrophytes. Our analysis of seasonal hysteresis of NEP and CO_2 fluxes in relation to discharge indicates stronger heterotrophy in autumn during rising waters than in spring during the falling waters, and this is partly explained by river temperature but more likely due to the remobilization of organic matter in floodplains and secondary channels during the first floods.

We report a strong long-term decrease in CO_2 fluxes (-62% over the 32 years) and an increase in the contribution of heterotrophy ($-\text{NEP}$) to this CO_2 outgassing flux. The Loire River's transformation from severe eutrophication to oligotrophic conditions involved dramatic reductions in anthropogenic inputs, including reductions in nutrients and organic matter in urban and agricultural runoff. However, these anthropogenic changes primarily influenced internal CO_2 production through altered organic matter processing within the river, while the observed external CO_2 source reduction appears driven by groundwater biogeochemical changes that cascaded from surface ecological shifts. While our study infers changes in external CO_2 sources, a full understanding of carbon transfer at the groundwater-river interface requires more DIC data from groundwaters and riparian zones (Deirmendjian & Abril, 2018; Duvert et al., 2018). Future work should focus on obtaining such data to quantify these fluxes better. We also suggest that developing approaches to extrapolate findings from such detailed site studies across diverse river networks, integrating them with spatial hydrological and ecological data, will be key to better understanding and predicting how global changes will influence the balance between internal and

external CO₂ production at broader scales, ultimately refining estimates of the role of rivers in the global carbon budget.

Appendix A: Dataset integrity and validation

This appendix provides detailed information on the data acquisition, quality assurance/control (QA/QC) framework, and processing procedures used to generate the 32-year high-frequency dataset.

A1. Data acquisition and QA/QC framework

The dataset combines high-frequency continuous monitoring data from Électricité de France (EDF) with lower-frequency grab sample data from both EDF and the Loire-Brittany Water Agency (AELB).

The continuous measurement system of EDF is a floating platform with a temperature sensor and sensors for pH (range 0–14), DO (range 0–20 mg L⁻¹), and conductivity (range 0–1000 µS cm⁻¹) (Campbell 1
®). The surface water at 20 cm depth is pumped (ca. 0.5 L s⁻¹) through the system and measurements
are recorded every 5 seconds, with average values saved every hour. It should be noted that data were
collected both upstream and downstream of the nuclear power plant, with the upstream station located
at the entrance of the dam and the downstream station located approximately 2-5km downstream of the
dam. The data used for data analysis in this study were from the upstream station because of its data
completeness. Grab sampling data were collected by EDF and Loire-Brittany Water Agency (AELB),
including pH, conductivity, and TA in 1990-2021, with frequency ranging from daily to monthly. Grab
sampling data exist only upstream of the nuclear power plant. While AELB provided data for the period
of 1990 to 2003 for these parameters, EDF supplied data from 2007 to 2021.

EDF's environmental monitoring operates under mandatory oversight from ASN (Autorité de Sécurité Nucléaire), France's nuclear safety authority, with QA/QC protocols documented for two main periods. Prior to 2008, measurements were made with membrane sensors and validated using a multi-level quality control methodology that included routine calibrations and automated checks (Moatar et al., 2001), achieving an accuracy of approximately ±0.3 pH units and ±8% for DO. In 2008, the sensor technology was upgraded to optical sensors, and since 2009, all procedures have complied with ISO 17025:2005 standards, requiring documented calibration with certified reference standards and regular external audits.

We cross-validate the pH data from EDF with independent Water Agency grab samples (www.naiades.eaufrance.fr). The cross-validation confirms measurement continuity across the sensor transition, showing improved post-2008 agreement (pH residuals: -0.17±0.35 to -0.10±0.32 pH units) while preserving statistically significant long-term trends (**Figure A1**). Post-2008 optical sensors indicate fewer differences with the grab samples, but both continuous sensor data from EDF and grab sample data from the water agency are well consistent with the long-term trend. This demonstrates that

the sensor upgrade enhanced data quality rather than creating systematic artifacts, with the step change in 2008 contributing to but not solely explaining the multidecadal trends.

Figure A1. Comparison of continuous sensor (EDF) vs. independent grab samples from the water agency for pH and estimated pCO₂ in 1990-2021. Bottom panels show residuals (Sensor - Grab) with points colored pre/post sensor change in 2008, a LOWESS trend, and mean residual ± SD.

A2. Data Processing and Reconstruction

Data Cleaning: Although the sensors for pH and DO measurements were periodically calibrated by EDF, the dataset still exhibited a notable number of anomalous values prior to 2008, which prompted the implementation of comprehensive data control procedures. These procedures addressed sensor drift and outlier removal, which were proposed by (Moatar et al., 2001). Data cleaning was conducted for the hourly pH and dissolved oxygen data in this study, while the daily conductivity was carried out by EDF, which was heavily based on visual inspection. Hourly temperature and alkalinity data from grab sampling were only checked through a range check to eliminate unrealistic values, but there was minimal significant removal of this data.

The following steps were carried out for the data cleaning and correction for hourly pH. Firstly, performing the rules-based anomaly detection and correction as a first pass at quality control, including range check (pH ranges from 6 to 10 in the Loire River), data persistence check (pH relatively constant in few days), significant change check (jump or drop within a few hours), calibration and drift event detection check. This step was performed automatically with the support of *pyhydroqc*, a Python package for automating aquatic sensor data processing (A. S. Jones et al., 2022). Secondly, error

detection was manually inspected by comparing values between upstream and downstream, together with the daily discharge. This step used the interactive plot with the support of *plotly* package to check the errors that were identified in previous steps. The use of daily discharge was to eliminate false detection of abnormal data, especially in the case of high discharge, where there are often sudden changes in pH and conductivity. There was 10.6% data (about 3 years of data) that was assessed as anomalous and was discarded. Finally, missing data will be completed based on several cases. Linear interpolation was applied for missing data within 6 hours (2.3% of data). Linear interpolation between upstream and downstream stations was applied for missing either upstream or downstream (7.5% of data). Linear interpolation between adjacent stations was applied when missing data in both upstream and downstream at the Dampierre station, but existed in adjacent stations (0.5% data). The remaining missing data were then filled based on the seasonal Kalman smoother, which estimates the missing values while considering the seasonal patterns and annual trend (*tsmoothie* package) (0.3% data).

Deleted: was

The data cleaning procedure was similar for hourly DO. We first removed physically impossible values and then applied a low-pass filter to remove instrument noise in the DO signal. We then removed values that exceeded plausible hourly changes in DO (e.g., a leap from 10 to 15 mg L⁻¹) using 95% confidence intervals for hourly changes on a monthly basis as our cutoff. We finally used visual inspection to flag data of questionable validity and corrected for linear drift and anomalous drops or jumps in DO data. We then filled all remaining missing values with a seasonal Kalman filter (3% data). The data cleaning and correction for hourly DO were detailed by Diamond et al. (2025).

Alkalinity Reconstruction: As daily TA data were not available for the entire 32-year period, a continuous daily TA time series was reconstructed from the continuous daily conductivity data.

To reconstruct daily alkalinity from conductivity, we employed the *IterativeImputer* function with *BayesianRidge* estimator (i.e., regularized linear regression) by using *scikit-learn*, a Python package. The *BayesianRidge* estimator filled the missing daily alkalinity by iteratively modeling the linear relationship between daily conductivity and available alkalinity data, while regularization accounts for potential changes in their relationship over 32 years. This process begins by estimating data for the period with the fewest missing data, then continues iteratively until the imputed values converge, meaning subsequent iterations produce minimal changes in the estimates. This iterative process allows the imputer to adapt to underlying trends and shifts in the data. Besides, to verify the stability of the relationship between alkalinity and conductivity, we performed linear regressions on a 4-year period of 32 years dataset, which revealed quite similar slopes across all periods except 1990-1993 (**Figure A2**).

Figure A2. Relationship between measured total alkalinity and continuously measured conductivity in the Loire River.

Appendix B: Model Validation and Uncertainty

This appendix details the methods for handling model outputs, validates key model parameters, and assesses the impact of uncertainty on the final conclusions.

B1. Handling of Metabolism Model Outputs

The streamMetabolizer model can occasionally produce physically unrealistic values, such as negative GPP or positive ER. This issue typically arises when diel variations in dissolved oxygen (DO) are weak—meaning the DO levels are similar between day and night—making it difficult for the model to accurately separate the contributions of GPP and ER (Appling et al., 2018). When the diel DO signal is minimal, the GPP is likely close to zero, which can lead to the model estimating a negative median GPP value. Consequently, it is common practice to set these negative GPP estimates to zero (Błaszczak et al., 2019). In our study, rather than forcing these estimates to zero, we replaced unrealistic estimates with the 75th percentile of the modeled posterior distribution for that day. This approach avoids artificially setting values to zero while still acknowledging that the true value is likely small.

In general, this correction did not substantially alter the annual GPP or ER calculations. Replacing negative GPP with the 75th percentile increased annual GPP by an average of 1.3% (ranging from 0.1% to 5.3%), while setting negative GPP to zero resulted in a smaller increase, ranging from 0.04% to 3.4% (Figure B1). Similarly, the annual ER calculations across different treatments for unrealistic ER values

784 show no significant differences, with an average flux variation of around 1%, except in 1995, where the
785 difference reaches 15% (Figure B2).

786
787 **Figure B1.** Comparison of annual GPP estimates based on different approaches for handling negative
788 GPP values: retaining negative GPP, setting negative GPP to zero, and replacing negative GPP with
789 the 75th percentile of estimated GPP from the *streamMetabolizer* model.

Figure B2. Comparison of annual ER estimates based on different approaches for handling negative ER values: retaining negative ER, setting negative ER to zero, and replacing negative ER with the 75th percentile of estimated ER from the *streamMetabolizer* model.

B2. Validation of the Gas exchange coefficient (k_{600})

The k_{600} values used in this study, which were derived from the K_{600} output of the *StreamMetabolizer* model, were compared with the seven k_{600} values calculated from seven fitted equations proposed by Raymond et al. (2012) for streams and small rivers. Both k_{600} estimates exhibited similar seasonal fluctuations, with the lowest values occurring in summer and the highest in winter (Figure B3). The comparison revealed that the mean absolute percentage error (MAPE) between the *StreamMetabolizer* estimates and the mean k_{600} from the seven fitted equations ranged from 36% to 62%. Specifically, the Raymond et al. (2012) k_{600} estimates tended to be higher in summer (low discharge) and lower in winter (high discharge) compared to those estimated by the *StreamMetabolizer* model (Figure B4). Such discrepancies can arise because *streamMetabolizer* co-estimates K_{600} with GPP and ER by fitting observed DO dynamics, making its estimate sensitive to the strength of the biological signal, whereas empirical equations rely solely on hydraulic proxies for turbulence. At high flow (winter), *streamMetabolizer* may underestimate k_{600} because the strong turbulence and deep water can weaken the biological signal (i.e., the daily change in dissolved oxygen), which the model relies on for its estimations. The Raymond et al. (2012) hydraulic equations, by contrast, are driven by high velocity and are less sensitive to this biological signal dampening. At low flow (summer), *streamMetabolizer* may estimate a higher k_{600} because the biological signal is very strong and clear in the shallow, warm,

821 and productive water. The model may attribute a larger portion of the observed oxygen change to gas
822 exchange to best fit the data.

823 However, the k_{600} values derived from StreamMetabolizer fall within the same order of magnitude as
824 those from the seven fitted equations (Figure B3). To maintain internal consistency between the
825 metabolic and FCO₂ calculations, the k_{600} estimates from streamMetabolizer were used for all
826 subsequent flux calculations.

B3. Uncertainty Analysis

Estimating FCO₂ and NEP using models such as PyCO₂SYS and streamMetabolizer often involves large uncertainties, particularly when considering the propagation of errors in all model input data and the summing/multiplying of these uncertainties in calculating fluxes (Battin et al., 2023; Kirk & Cohen, 2023). Estimating FCO₂ and NEP involves uncertainties from multiple sources. While a full error propagation was beyond the scope of this study, we assessed the impact of the largest source of input uncertainty: the reconstruction of daily TA, which was based on daily conductivity. The error in TA could potentially affect conclusions regarding the temporal distribution of CO₂ sink/source states throughout the year, as well as comparisons with NEP.

The average error in the reconstructed TA was ± 190 $\mu\text{mol/L}$. Propagating this uncertainty through the pyCO₂SYS model resulted in an uncertainty of $\pm 11\%$ in the final pCO₂ estimates. As shown in Table B1, this level of uncertainty did not alter the main conclusions of the study. The annual distribution of

858 trophic states remains consistent, with a maximum deviation of only 3% fluxes. Moreover, the
859 dominance of the CO₂ source–heterotrophic state throughout the year remains almost unchanged, with
860 less than a 1% difference under any range of TA uncertainty, though the magnitude of FCO₂ could vary
861 up to 602 to 841 gC m⁻² y⁻¹.

862 **Table B1.** Impact of TA uncertainty on the occurrence and FCO₂ of each trophlux state.

	Period	CO ₂ source						CO ₂ sink					
		Heterotrophic			Autotrophic			Heterotrophic			Autotrophic		
		Min	Mean	Max	Min	Mean	Max	Min	Mean	Max	Min	Mean	Max

863

864 **B4. Methodological considerations for the Heterotrophic-Sink State**

865 The Heterotrophic-Sink state (NEP < 0, FCO₂ < 0) represents a condition where the river is a net CO₂
866 sink from the atmosphere despite ongoing net ecosystem respiration. As discussed in the main text, we
867 primarily attribute this transient state to significant CO₂ undersaturation in the water column resulting
868 from intense prior autotrophic uptake. A recent analysis by Diamond et al. (2025) using this same dataset
869 provides strong evidence for this mechanism. They found that heterotrophic-sink events were
870 temporary, lasting an average of 4.7 ± 4.1 days, and that 76% of these events were immediately preceded
871 by an autotrophic-sink state. This confirms our interpretation that the heterotrophic-sink state is not a
872 stable condition but rather a short-lived transitional phase as the river shifts from being an autotrophic-
873 sink to either an autotrophic-source or a heterotrophic-source state. An additional potential contributing
874 factor is the possible underestimation of GPP by the diel oxygen method. If oxygen produced within
875 dense benthic macrophyte beds does not fully mix into the water column on a diel timescale, the reach-
876 integrated GPP would be underestimated. This would result in a calculated NEP that is more negative
877 than the true value, which could contribute to the Heterotrophic-Sink state.

878 Appendix C: Statistical Analyses of Long-Term Trends

879 This appendix provides detailed results from the statistical analyses used to identify and quantify the
880 long-term changes discussed in the main text.

881 C1. Change-Point Analysis

882 We evaluated the long-term changes in FCO₂ and metabolism using a statistical change point analysis,
883 which identifies points in a time series where the statistical properties, such as the mean or variance,
884 undergo significant shifts. We first applied seasonal decomposition on the daily time series to extract
885 trend, seasonal, and residual components using the *statsmodels* Python package (Seabold & Perktold,
886 2010).
887 The long-term trend component was analyzed using a piecewise linear regression method (model
888 = "linear" in *ruptures*, a Python package), while shift point detection by standard deviation (changes in
889 variance by model = "normal" in *ruptures*) was employed for the seasonal components. This process was
890 also applied to related parameters, including daily discharge, temperature, GPP, and ER. The results of
891 this analysis (Figure C1) informed the division of the 32-year record into the three decadal periods used
892 for comparison throughout the manuscript.

894 **Figure C1.** Change-point analysis on the decomposed time series: (a) long-term trend components and
895 (b) seasonal components of daily discharge, temperature, and fluxes of GPP, ER, ~~NEP~~, and FCO₂.
896 The red vertical lines indicate the change periods.

897 **C2. Inter-Decadal Statistical Comparisons**

Deleted: -

To quantitatively assess differences between the three identified decades, we performed non-parametric Kruskal-Wallis tests followed by post-hoc Mann-Whitney U tests. The results (Figure C2) provide statistical validation for the observed shifts in key variables between the decadal periods.

Figure C2. Statistical comparison of key variables across decades within each trophlux. Boxplots show median (horizontal line), interquartile range (box), and distribution of annual values (black dots). Colored boxes represent different decades: blue (1990-2000), orange (2001-2010), and grey (2011-2021). Statistical significance of differences between decades was assessed using Kruskal-Wallis tests, with significant pairwise differences (Mann-Whitney U test) indicated by horizontal bars with asterisks (* $p<0.05$, ** $p<0.01$, *** $p<0.001$).

Appendix D: Analysis of Hydroclimatic and External Drivers on FCO₂

This appendix presents the analyses that explore the potential drivers behind the observed long-term trends, particularly the decline in external CO₂ sources.

Table D1. The correlations (R^2) between annual FCO₂, -NEP, and hydroclimatic conditions (discharge, temperature) in each trophlux state

Figure D1. Relationship of daily fluxes and daily discharge or daily water temperature. Points are colored by year, as indicated by the color bar.

933

934

935 Figure D2. Relationship of annual fluxes and annual discharge or annual water temperature. Points are
936 colored by year, as indicated by the color bar.

937

938 Figure D3. A decreasing trend in the groundwater level in Montifault (20 km from the study site). (a)
939 raw data, (b) after removing pumping effects with the EROS model (Data source: (Thiéry, 2018)).
940 NGF stands for "Nivellement Général de la France," which is the official vertical datum for France.

Figure D4. pH and alkalinity in groundwater monitoring stations in the vicinity (5 km radius) of the Dampierre study site (1990–2021). Points represent individual measurements, and solid lines are LOESS smoothers with 95% confidence intervals (shaded areas). Data source: <https://hubeau.eaufrance.fr/page/api-qualite-nappes>

Data availability

The hourly temperature, conductivity, dissolved oxygen, and pH data used in this study are owned by Électricité de France (EDF). Due to EDF's data-sharing policy, these data are not publicly available but can be accessed upon reasonable request by contacting EDF directly. Other publicly available datasets used include discharge (<https://www.hydro.eaufrance.fr>), river water quality (www.naiades.eaufrance.fr).

Author Contribution

ANT led the manuscript effort. ANT, JSD, GA, and FM came up with the research question and designed the study approach. ANT and JSD conducted the data curation and preparation, and ANT conducted the statistical analyses. ANT wrote the paper with contributions from all authors.

Competing interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

We express our gratitude to Electricité de France (EDF) for generously providing us with extensive long-term datasets in the Middle Loire River.
