Key points:

- Applying Machine Learning on multi-event data reveals key drivers of flash flood losses such as flow velocity and emergency response.

- The first probabilistic flash flood loss model provides robust estimates of company and household losses, including uncertainty information.

- High knowledge about emergency action ~~preparedness~~ during extreme flash floods was found to reduce building losses of households by up to 77%.

Abstract. In light of the increasing losses from flash floods intensified by climate change, there is a critical need for improved loss models. Loss assessments predominantly focus on fluvial flood processes, leaving a significant gap in understanding the key drivers of flash floods and the effect of emergency response~~preparedness~~ on losses. To address these gaps, we introduce FLEMO$_{flash}$—a novel multivariate probabilistic Flood Loss Estimation Model compilation for flash floods. The models are developed for companies and households based on survey data collected after flash flood events in 2002, 2016, and 2021 in Germany. FLEMO$_{flash}$ employs a data-driven feature selection approach, combining machine learning techniques (Elastic Net, Random Forest, XGBoost) to select ~~identify~~ key drivers influencing flash flood losses and Bayesian networks to model probabilistic loss estimates, including uncertainty. Model-based findings show that in extreme hazard scenarios, successful implementation of emergency measures ~~high preparedness~~ can reduce building losses by up to 47% for large companies. Households who knew exactly what to do during high water depth were able to reduce their building losses by 77% and

contents losses by 55%. Thus, FLEMO$_{flash}$ can support risk communication and management by providing reliable estimation of flash flood losses. ~~along with the loss differential considering the level of risk preparedness.~~

1 Introduction

Flash floods characterized by their rapid onset and short duration, rank amongst the most devastating natural disasters, leading to significant loss of life and property (Zain et al., 2021). The flash flood events in western Germany and neighbouring countries during July 2021 caused an estimated USD 54 billion in losses (Munich Re, 2025), marking it as the costliest natural disaster in the history of Germany to date. Other notable examples include events in the Elbe and Danube rivers in Germany in 2002, which resulted in USD 9 billion losses (Kreibich et al., 2007). The 2017 flash floods in the Houston area of Texas during Hurricane Harvey resulted in losses ranging from USD 90 to 160 billion (Rözer et al., 2021). The 2012 event in Beijing caused total losses of USD 1.86 billion (Wang et al., 2013), and the monster flood of Pakistan in 2022 caused losses worth USD 30 billion (Chughtai, 2022). With the ongoing climate change crisis and high population density, the risk of flash floods is anticipated to increase in the future; thus, emphasizing the need for flash flood loss modelling to derive quantitative estimates of expected losses in monetary terms.

While progress has been made related to fluvial flood loss models for households (Lüdtke et al., 2019; Thieken et al., 2008), there remains a limited understanding of the variables and mechanisms influencing flash flood losses. Unlike fluvial floods that have longer lead time and slower rise in water levels (Laudan et al., 2020), flash floods are characterized by rapid and unprecedented rise in water levels. Moreover, due to high flow velocities, sediment transport, and shorter lead times, flash floods often cause more losses than fluvial floods. The sudden nature of flash floods makes them extremely difficult to predict (Dougherty and Rasmussen, 2020), necessitating loss modelling tailored to these events. Unlike floods caused by slowly rising water levels, and dyke breaches, flash floods exhibit heterogeneity in hazard characteristics such as water depth, flow velocity, inundation duration, and contamination indicators (Kreibich and Dimitrova, 2010). Furthermore, earlier studies suggest significant differences in the variables and processes that influence losses in different flood types (Mohor et al., 2020). Thus, understanding the flash flood process is crucial, despite our previous understanding of the losses caused by fluvial floods. A comprehensive understanding of the complex processes behind flash floods is essential to develop sustainable and cost-efficient flash flood risk management strategies.

Traditionally, flood loss estimation relied on univariate stage-damage functions (SDF) (Middelmann-Fernandes, 2010). To improve the description of complex damage processes, the Flood Loss Estimation MOdel (FLEMO$_{ps}$) for the private sector, was developed as rule-based, multivariate, deterministic model (Thieken et al., 2008). Merz et al. (2013) and Sieg et al. (2017) introduced decision tree-based damage models that explicitly quantify uncertainty associated with both data variability and model structure uncertainty through bootstrap aggregation. Subsequently, Bayesian Networks were used (BN-FLEMO), enabling the modelling of complex flood loss processes through conditional probability relationships (Lüdtke et al., 2019; Schoppa et al., 2020; Schröter et al., 2014; Vogel et al., 2018).

In parallel, various machine learning approaches have also been developed for flood loss estimation, including neural networks (Salas et al., 2023), random forests (Ghaedi et al., 2022), Bayesian regression (Mohor et al., 2021). Among these, Bayesian networks are particularly advantageous due to their probabilistic representation of conditional dependencies among multiple variables, handle missing data, and model transferability (Schröter et al., 2014). Bayesian models enhance the understanding of flood loss dynamics by quantifying uncertainty and offering probabilistic estimates. For instance, Wagenaar et al. (2018) developed a regional and temporal transferable BN-FLEMO for microscale residential applications, which was later upscaled to mesoscale by Lüdtke et al. (2019). In addition to the FLEMO typology, various synthetic, multivariate, rule-based flood loss models have been proposed for fluvial flood contexts (Amadio et al., 2019; Dottori et al., 2016; Nofal et al., 2020; Sairam et al., 2020).

However, all these loss models were developed to simulate damage processes during fluvial floods. In this study, we present the first probabilistic flash flood loss model – Flood Loss Estimation Model affected by flash floods (FLEMO$_{flash}$) using a BN-based approach and gain new knowledge about flash flood damage processes based on the conditional probabilities among multiple influencing variables. We use machine learning based feature importance~~feature importance assessment~~ to select the most important variables from our dataset~~our dataset~~~~The study identifies the important variables and underlying processes that govern the flash flood losses.~~ ~~Additionally, we examine t~~The ~~predictive~~ performance of FLEMO$_{flash}$ model is compared ~~and compare it against with~~ conventional SDF models. Finally, we illustrate the loss processes with the CPT and Markov blanket ~~effect of preparedness~~ in controlling the extent of loss reduction.

2 Data and Methods

2.1 Multievent empirical data in different regions

FLEMO$_{flash}$ is built based on self-reported flash flood losses along with associated information of the affected companies and households. The data was collected through different surveys using computer-aided telephone interviews with representatives of affected companies and households following three highly damaging flash flood occurrences in Germany (Kellermann et al., 2020; Kreibich et al., 2017). These include the 2002 event in the Elbe catchment in Eastern Germany, the 2016 heavy precipitation event, and the most recent July 2021 event in Western Germany. The variables potentially influencing losses are extracted and homogenized from the datasets of the 2002, 2016, and 2021 flood surveys. The variables are grouped into five categories, as presented in Table 1 for companies and Table 2 for households, respectively. An overview of all variables, along with the corresponding survey questions, response categories, and details on variable construction, is presented in Table S1 and Table S2. The loss variable represented as relative loss ($rloss$), is defined as the ratio between the reported loss and replacement cost on the [0,1] interval. A value of 0 indicates no loss, while 1 indicates complete loss (Kreibich and Dimitrova, 2010; Schoppa et al., 2020; Sieg et al., 2017). For companies, losses are estimated for three categories of assets - buildings, equipment, and goods & stock. For households, losses are estimated for buildings and contents. Survey responses with no data on loss were excluded from the dataset.

2.2 Terrain analysis for the identification of flash flood cases

Since the surveys covered regions affected by both flash floods and riverine floods, we applied a terrain-based filtering to exclude riverine cases. We calculated the median slope within a 10 km radius around the location of each observation using the Digital Elevation Model with a 90 meters resolution from the Shuttle Radar Topographic Mission. This process was repeated for 14 reference municipalities known to have experienced flash flood events in the past or described as prone to flash floods (see Table A1). The minimum value among the median slope from these 14 municipalities was then used as the slope threshold (see Table S4). Observations with slope values equal to or above this threshold were classified as flash flood cases. Other metrics, such as river basin concentration time, may indeed provide a more process-based characterization of flash flood potential. Nevertheless, we used slope alone as a pragmatic solution that balances two competing needs: maintaining physical relevance in identifying flash flood prone companies and ~~households, and~~households and retaining a sufficient number of data points for robust model development. The cases with ~~It is important to note that larger~~ longer warning lead times in the sample are likely to be due to ~~may be attributed~~ warnings of ~~to~~ high precipitation ~~warning rather~~ than to flood-specific warnings. ~~This comes from one of the three flood events considered in this study. However, selection of flash floods using the slope criteria implies that only high precipitation events which qualified the slope threshold were included in the study."~~

Table 1. List of variables for companies. The variable type stands _C_ for continuous, _O_ for ordinal, and _N_ for nominal. An overview of all variables, along with the corresponding survey questions, response categories, and details on variable construction, is presented in Table S1.

	Predictors		Type and range
Hazard	_wd_	Water depth	_C_: 0 cm to 963 cm above ground
	_d_	Inundation duration	_C_: 0 to 1440 h
	_v_	Velocity indicator	_O_: 1 = low flow to 3 = torrential flow
	con	Contamination	_O_: 0 = no contamination to 4 = heavy contamination
~~Preparedness/~~Emergency response	_wt_	Warning lead time	_C_: 0 to 240 h
	_ws_	Early warning source	_O_: 0 = no warning to 4 = official warning through authorities
	_ew_	Early warning received	_N_: 0 = no, 1 = yes
	_me_	Emergency measures undertaken	_N_: 0 = no, 1 = yes
	_ep_	Emergency plan	_N_: 0 = no, 1 = yes
	_kh_	Knowledge about hazard	_N_: 0 = no, 1 = yes
	_ms_	Emergency measures success	_O_: 0 = no measure undertaken, 1 = completely ineffective to 3 = very effective
Precaution	_fe_	Flood experience	_O_: 0 = no experience to 5 = recent flood experience
	_pr_	Precaution indicator	_O_: 0 = no precaution, 1 = medium precaution, 2 = very good precaution.
	_in_	Insurance	_N_: 0 = no, 1 = yes
Company characteristics	_sec_	Sector	_O_: 1 = Agriculture, 2 = Manufacturing, 3 = Trade, 4 = Finance, 5 = Services
	_ss_	Spatial situation	_O_: 1 = several buildings, 2 = entire building, 3 = one or more floors, 4 = less than one floor

2016 data source: Survey "Pluvial Flooding and Flash Floods in May/June 2016: Damage of private households", University of Potsdam, German Research Centre for Geosciences, Deutsche Rückversicherung AG, 2017.

The final database available for developing loss models consists of 241, 379, 355, 1131, 1448 observations for company building, equipment, goods & stock, household building, and contents, respectively. The percentage of missing data for different variables in each of the asset is summarized in Fig S1 (companies) and Fig S2 (households). To maximise the amount of training data for model building, we employed the k nearest neighbour technique to impute the missing data. We tested a range of k-neighbours for our datasets (k =1,3,5,7,9) and selected the value with best performance.

2.3 Machine Learning-based feature selection

Flood damage processes vary by region, flood type, and asset type (Mohor et al., 2020; Sairam et al., 2021; Wagenaar et al., 2018). To derive the most significant drivers of flash flood losses from our list of variables, this study adopts a data-driven feature selection approach to the empirical data. Feature selection involves identifying variables that have the highest influence on the target variable (i.e. relative loss). We train multiple models – nonlinear models: Random Forest (RF), Extreme Gradient Boosting (XGBoost), and linear model: Elastic Net (EN).

RF is an ensemble machine learning method primarily used for classification and regression tasks, developed by Breiman (2001). RF generates an ensemble of decision trees, each trained on a random subset of the data using bootstrap sampling. At each node within these trees, a random subset of features is considered for splitting. The final prediction for a given input is obtained by averaging the predictions from all individual trees. This approach helps RF reduce overfitting and enhances the model's generalization ability. XGBoost, similarly to RF, is an ensemble learning algorithm that benefits from a decision tree-based structure. However, the key difference compared to RF is that in XGBoost, each tree corrects the errors from the previous ones. The process starts with a simple model and iteratively adds trees that focus on the residuals or errors made by the existing ensemble. With its efficient implementation, XGBoost demonstrates superior performance and handles large-scale data more effectively than RF (Chen and Guestrin, 2016). While RF and XGBoost are non-linear models, EN is a regularization technique used in linear regression, combining both Lasso (L1) and Ridge (L2) regularization penalties. It effectively addresses multicollinearity in datasets by shrinking the less influential predictors toward zero (Lasso) while additionally providing some degree of regularization to prevent overfitting (Ridge). EN's ability to handle correlated features and select relevant predictors makes it a valuable tool in regression tasks (Zou and Hastie, 2005).

During training, we employed a nested cross-validation framework with 10 splits and 10 repeats, resulting in a total of 100 evaluations. We selected the best set of hyperparameters, which obtained the least mean absolute error, which was then applied to the final feature selection. From each resulting final model, we derived the feature importance. Next, we calculated each variable's weighted feature importance and overall rank. The final selection of the variables (Fig 1) is elaborated upon in the results section.

2.4 Probabilistic FLEMO$_{flash}$ development

Based on the identified features, a multivariate probabilistic Flood Loss Estimation MOdel (Bayesian Network – BN) is

150   calibrated for predicting flash flood losses (Jensen and Nielsen, 2007; Kitson et al., 2023; Scutari and Denis, 2021). BNs are probabilistic graphical models where the predictor and target variables are connected through a directed acyclic graph (DAG). Each variable is depicted as a node, and related nodes are connected through arcs. These connections allow for the estimation of conditional probability distributions, facilitating an understanding of the underlying processes and probabilistic estimation of rloss (Vogel et al., 2018). The continuous variables are discretized using an equal frequency discretization approach (Scutari

155   and Denis, 2021), and a discrete BN is formulated. The number of bins is determined based on the model performance against different numbers of bins – the number of bins resulting in the best model performance is chosen. The specification of a discrete BN involves defining a set of variables $(X_1, \dots X_n)$, constructing a DAG representing the probabilistic dependencies among variables, and obtaining the conditional probability distribution $P\left(\frac{X_i}{parents(X_i)}\right)$ for each variable (X_i) in the DAG, where $parents(X_i)$ denotes the parents of node X_i in the DAG. The final joint probability distribution for the set of variables

160   connected in a discrete BN is formulated as (Pearl, 1988):

$$P(X_1, \dots, X_n) = \prod_{i=1}^{n} P\left(\frac{X_i}{parents(X_i)}\right) \tag{1}$$

Within the predicted bins of the discrete BN ($rloss$ bins), we fit a continuous distribution by applying weighted sampling to the empirical loss data, resulting in a smoothed representation of the loss distribution (Schoppa et al., 2020). For further details on the BN structure learning we refer to Text S1 and Figure A1.

2.4.1 Comparison to stage damage function

165   We compared FLEMO$_{flash}$ to a univariate stage-damage function (SDF), a conventional model in flood loss estimation (Gerl et al., 2016). We implemented the linear functional form of deterministic SDF (SDF-D) and probabilistic SDF (SDF-P) to assess the added value of the multivariate and probabilistic model. SDF-D is formulated as:

$$rloss_i = \alpha + \beta(wd)_i + \varepsilon_i \tag{2}$$

where $rloss_i$ is the relative loss for a given water depth (wd_i). α, β and ε_i are the intercept, regression coefficient, and error of observation i, respectively. Further, to implement the SDF-P, we assume that the relative loss follows a zero-and-one-

170   inflated Beta distribution (Schoppa et al., 2020):

$$Y_i \, BEINF(\lambda, \gamma, \mu_i, \phi) \tag{3}$$

$$logit(\mu_i) = \alpha + \beta(wd)_i \tag{4}$$

In the above equation 3, we only predict the μ, whereas other distribution parameters are assumed constant across the observations. SI (Table S3) contains further information on the prior choice for model parameters as well as specification for Markov chain Monte Carlo sampling.

2.4.2 Model validation and sensitivity

175 We evaluate the performance of the FLEMO$_{flash}$, SDF-D, and SDF-P models individually for the different types of assets in both, companies and households. We employed 10-fold cross-validation, which was repeated (n=100) with independent random seeds to obtain robust estimates. To address parameter sensitivity of FLEMO$_{flash}$ model performances due to Bayesian network structure learning, we systematically evaluated three critical factors:

1. Number of predictors (f1-f5): Section 2.3 identifies the ensemble-based important predictors, and the top five were used
180 to develop the BN model. We demonstrated the model performance with varying number of predictors.
2. Number of discretization bins (b3-b8): Continuous variables were binned using quantile-based stratification.
3. Number of neighbours (k1-k9): Missing data were imputed with k-nearest neighbours.

For each combination, we validated the model for each cross-validation fold using three performance metrics: mean absolute error (MAE), continuous ranked probability score (CRPS), and mean bias error (MBE) (Gneiting and Katzfuss, 2014; Jensen
185 and Nielsen, 2007; Krüger et al., 2021; Schoppa et al., 2020). Detailed information on the validation procedure and three scores used to compare the models are provided in SI.

3 Results and Discussion

3.1 Drivers of flash flood losses

An ensemble of linear and non-linear machine learning models ensures that both linear and non-linear relationships between
190 the predictors and flood loss are captured. Water depth emerges as the most important predictor of damage across all asset types (Fig 1), which is consistent with previous loss models (Kreibich et al., 2010; Merz et al., 2013; Schoppa et al., 2020; Sieg et al., 2017; Thieken et al., 2008). For companies, emergency measures success and number of employees are also significant factors influencing the flood loss estimation. Among other flood characteristics, duration is ranked fourth for building (Fig. 1a), velocity is ranked third for equipment (Fig. 1b), and contamination is the fifth most significant driver for
195 goods & stock (Fig. 1c), respectively. In case of households, human stability and contamination are most important hazard variables after water depth.

The significance of water depth and emergency measures has also been emphasized by Hasanzadeh Nafari et al. (2016) in case of fluvial flood losses. Exposure variables such as number of employees significantly influence company losses. Additionally in case of households, losses are more influenced by variables representing flood vulnerability such as knowledge about
200 emergency action (Fig. 1d-e). These findings are in line with the previous studies (Kreibich et al., 2005; Sairam et al., 2019; Zander et al., 2023) that highlight the potential for adaptation measures to reduce flood losses. By quantitatively

comparingidentifying the varied drivers of flash flood losses, these results also emphasize the importance of multivariable loss estimation models that capture the interplay across these drivers and their influence on losses.

Although flow velocity has been identified as a significant contributor to flash flood losses (Kreibich and Dimitrova, 2010), it
205   does not appear among the most significant factors in the current study. In our analysis, we represent hydrodynamic forces using velocity (v) and human stability (hs). While velocity provides a subjective yet direct measure of local strength of flow current, human stability reflects on the perceived difficulty of standing in flood waters. As shown in Figure 1(d-e), human stability emerges as the second most influential factor affecting loss in households, indicating that the combined effect of water depth and velocity play a crucial role for the flash flood model.

215   **Boosting) and one linear model (Elastic Net).**

3.2 Probabilistic multivariate flash flood loss model

3.2.1   FLEMOflash Bayesian network structure

The FLEMOflash models are developed using a score-based structure learning algorithm and BN models are developed to capture the multivariate dependencies among variables. Data-driven BNs with the best performance were evaluated by domain

220 experts to ensure consistency with the existing understanding about the underlying dynamics of flood loss processes (Fig. 2). The direction of the arrow represents an association between two variables but does not necessarily represent causality (Lüdtke et al., 2019; Sairam et al., 2020). Water depth emerged as the most important predictor for loss estimation across all asset types and is directly connected to the $rloss$ node in all BN structures (Fig. 2). In case of companies and households, the losses are influenced predominantly by water depth. Company characteristics (number of employees and size premise) significantly

225 impact the losses for company assets (Fig. 2a-c). The measure success (ms) predictor is directly connected to $rloss$ in case of building and equipment (Fig 2a-b) and indirectly connected to $rloss$ through water depth for goods & stock (Fig. 2c). In households, building $rloss$ is directly connected to water depth, contamination, and knowledge about emergency action (Fig 2d). For contents, $rloss$ is directly connected to water depth and knowledge about emergency action, with contamination, human stability, and income also playing important roles (Fig. 2e). Additionally, human stability, which is a factor of both depth and velocity, influences household losses through water depth. The direct connection of $rloss$ with measures success

230 for companies' assets (Fig. 2a-c), and with knowledge about emergency action for households (Fig. 2d-e) highlights the significance in mitigating flood losses. We derived joint probability distribution for all asset types and the findings reveal trade-offs between preparation strategies for different target losses.

3.2.2   Performance and comparison

The performance of the FLEMO$_{flash}$ BN structure was tested considering varying numbers of predictors, bins, and k-nearest

240   neighbors. In the BN structure, null value was assigned to one predictor at a time (from lowest-5 rank to highest-1 rank based on feature importance – Fig 1) to examine the performance using the remaining variables (Fig 3). The performance metrics (MAE, CRPS) vary with the number of predictors. The model's ~~predictive~~ performance improved with the number of predictors. For instance, the MAE values for all asset types decreased as the number of predictors increased. Based on the performance metrics, the optimum number of predictors was found to be five. However, the Markov ~~b~~Blanket of loss consists

245   of two predictors (water depth and knowledge of emergency measures) for households: contents loss, and three predictors otherwise. Similarly, CRPS values also showed a declining pattern with increasing number of predictors, indicating better probabilistic predictions. The MBE was relatively stable, suggesting that bias in the prediction did not significantly change with the number of predictors.

Examining the performance with optimal predictors while modifying the number of bins, revealed significant differences for

250   companies but not for households, which could be attributed to the fact that the number of data points for companies is relatively limited and more heterogenous (Schoppa et al., 2020) compared to households. Company buildings model (C:BUI) with too few bins tend to lose information, resulting in higher MAE and CRPS values. Conversely, the goods & stocks model (C:GNS) performed better with fewer bins. For household models, MAE was not sensitive to the choice of bins, but model performance was slightly better with 8 bins. The MBE for company models showed fluctuations around zero, indicating some

255   sensitivity to the choice of bins and potential bias.

The number of neighbours used for data imputation does not show any significant difference in predictive performance. The MBE showed minor variations, remaining close to zero across different numbers of neighbours, suggesting that the bias in the

predictions was not significantly affected by the imputation. The k-nearest neighbours (kNN) method of imputation assumes that the missing values can be inferred based on similarity of feature space. This may not hold equally well across variables, particularly for those with weak correlation to other features. To evaluate the robustness of the imputation process, we compared the distributions of variables before and after imputation and found them to be largely consistent (not shown for brevity). Nevertheless, the imputation process may still introduce uncertainty or reduce natural variability in the data. Future studies could benefit from sensitivity testing using alternative imputation techniques and explore models that explicitly incorporate imputation uncertainty.

Overall, building assets in both company and household sectors performed better compared to other asset types. This superior performance is due to the effective inference of the relationship between water depth and building $rloss$ (Gerl et al., 2016; Lüdtke et al., 2019; Merz et al., 2013; Vogel et al., 2018). Additionally, the emergency response of mitigation measures for companies and knowledge about emergency action for households also boosted performance.

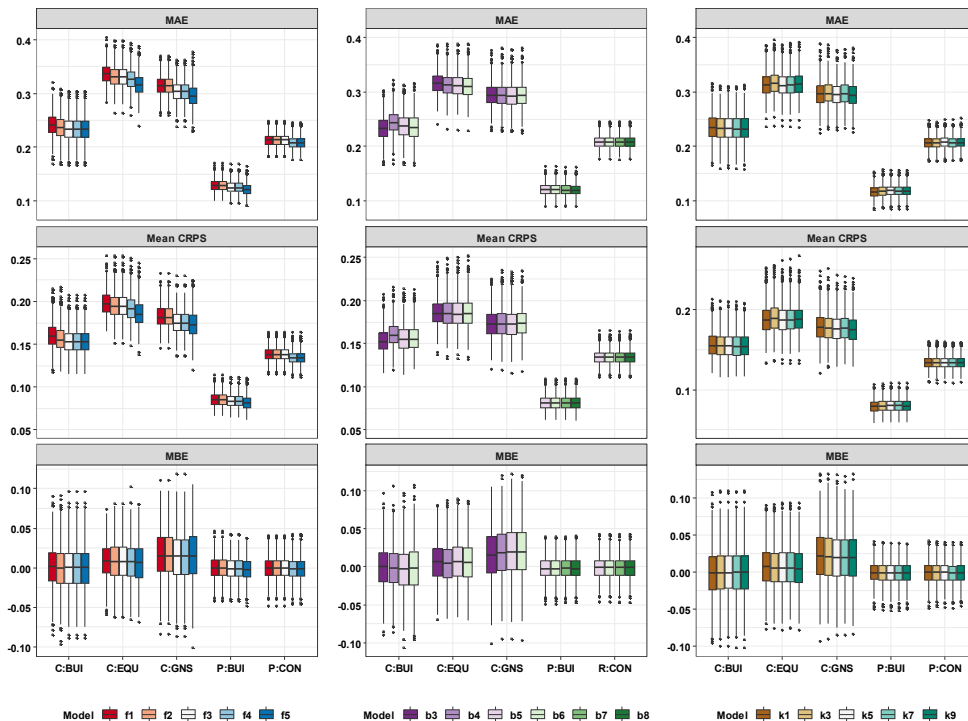
270


Figure 3. Model sensitivity of FLEMO_{flash} to number of predictors (f1-f5), bins (b3-b8), number of neighbours used for data imputation (k1-k9) evaluated using mean average error (MAE), continuous ranked probability score (CRPS), and mean bias error (MBE) for the five asset types (x-axis). Each bocplot summarizes 100 repetitions of a fivefold cross-validation (companies) and tenfold cross-validation (households) with randomized data partitioning. Best-performing configurations were identified through a sequential tuning process: first selecting the number of predictors based on the first panel, then optimizing bin count in the second panel with predictors fixed, and finally selecting the number of neighbours in the third panel with both previous parameters fixed. Best-performing configurations are: Companies – Buildings (C:BUI) f5, b6, k7; Companies – Equipment (C:EQU) f5, b6, k5; Companies – Goods and Stock (C:GNS) f5, b6, k9; Private Households – Buildings (P:BUI) f5, b8, k1; Private Households – Contents (P:CON) f5, b8, k3.

280   The FLEMO_{flash} model with the best performance, identified in Fig 3 was compared to SDF models (Fig 4). The FLEMO_{flash} model consistently outperformed both the SDF-probabilistic and SDF-deterministic models across all five asset types due to its comprehensive representation of loss processes (Schröter et al., 2014). Study by Schoppa et al. (2020) also noted a similar observation reporting that probabilistic multivariate models performed better than univariate models for fluvial flood loss estimation. These findings highlight that FLEMO_{flash} outperformed in estimating losses while also indicating the need for

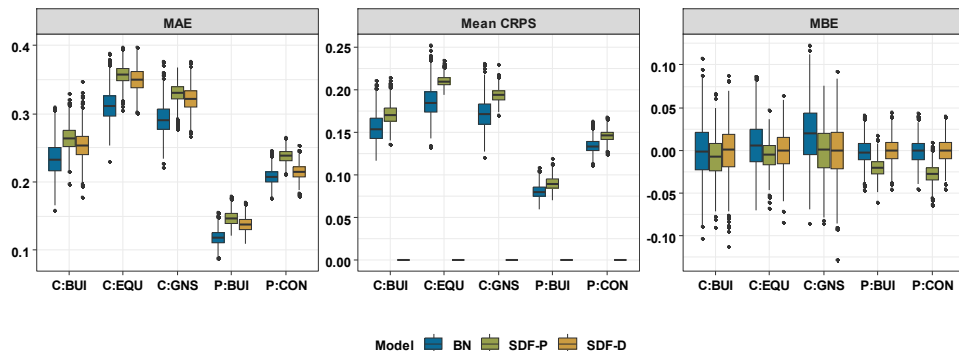
285   improvement to address biases in the predictions.


Figure 4. Comparison of FLEMO_flash predictive performance against SDF-probabilistic and SDF-deterministic using MAE, CRPS, and MBE for the five assets (x-axis). Each boxplot summarizes 100 repetitions of a fivefold cross-validation (companies) and tenfold cross-validation (households) with randomized data partitioning.

3.3 Description of loss processes by FLEMO_flash

The loss processes described by FLEMO_flash is illustrated using the predictive density of predicted losses under scenarios of hazard, exposure and vulnerability. For brevity, this section primarily focusses on the FLEMO_flash model for household buildings (Fig 5), with a similar interpretation, results of other asset types are shown in ~~extended to other asset types (~~Fig S3-S6~~)~~. The nodes of the model comprise of water depth, human stability, inundation duration, contamination, knowledge about emergency action, and relative losses, each with 7, 4, 7, 5, 6, and 8 classes, respectively. The Conditional Probability Table (CPT) was populated with joint probabilities to find the predictive density of loss given the condition of other nodes. The conditional probability of $rloss$ based only on water depth indicates a monotonic relationship. Shallow inundations are associated with very low losses, while deeper water substantially increases the probability of severe losses (Fig 5e). The highest probabilities are concentrated along the diagonal, confirming this trend. For instance, depths <0.28 m are most likely associated with very low losses (<0.017), whereas depths ≥2.3 m are strongly associated with high losses (> 0.42). Similar patterns of increasing loss probability with greater water depth are observed across all asset types (Fig. S3–S6). Water depth also influences human stability: while shallow flooding results in low instability, extreme depths markedly increase the probability of instability (0.54) (Fig. 5b, Fig. S6a).

Contamination emerges as another important driver of losses. In uncontaminated conditions (class 0), the probability of very low losses (<0.01) is high (0.82). Conversely, under severe contamination (class 4), the probability of very high losses (>0.427) increases to 0.30 (Fig. 5c), reflecting the destructive impact of oils, chemicals, and sewage entering buildings (Kreibich et al., 2005; Laudan et al., 2020). Households exposed to inundation lasting [13–50) hours showed a high probability of experiencing moderate contamination levels (classes 1–2). Knowledge about emergency action shows a strong mitigating effect. The CPT

(Fig. 5d) demonstrates that households with low awareness (Ke ≤ 2) face a high probability of severe losses, whereas
households with very good knowledge (Ke ≥ 5) display a substantially higher probability of reduced losses. Comparable
findings are observed for household contents (Fig. S6c). This agrees with Kreibich et al. (2021), who also reported that clear
awareness of emergency actions substantially reduces damages. Importantly, socioeconomic status indirectly shapes
vulnerability, as higher-income groups are more likely to report very clear knowledge of emergency actions after receiving
warnings (Fig. S6b).

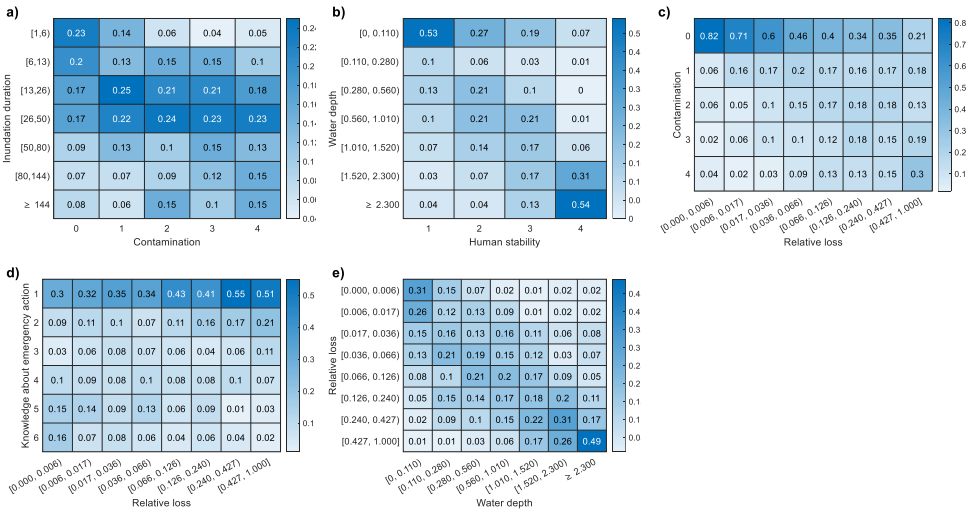
For companies (Figs. S3–S5), the CPT results reveal consistent patterns across buildings, equipment, and goods & stock.
Smaller companies (with fewer employees or smaller premises) show higher probabilities of severe losses, whereas larger
firms and premises are more strongly associated with lower loss outcomes (Figs. S3b, S4d, S5c). Across all asset types, the
success of emergency measures emerges as a dominant factor, as unsuccessful measures are strongly associated with a high
probability of severe losses (Figs. S3d, S4b, S5a). Contamination further amplifies losses, with severe categories linked to
markedly higher probabilities of loss. Together, these results emphasize that hazard intensity (water depth, velocity,
contamination), exposure (number of employees, size premises) and vulnerability factors (effectiveness of emergency
measures) interactively determine relative losses for companies.


Figure 5. Conditional probability table (CPT) of the Bayesian network for the residential building. Each heatmap illustrates the conditional probabilities of a child node given its parent node. Parent node states are shown along the x-axis, and child node states along the y-axis. Darker shades of blue indicate higher probability values. Numerical values are displayed in each cell, with an accompanying colorbar showing the probability scale. (a) Inundation duration given contamination (b) Water depth given human

stability (c) Contamination given relative loss (d) Knowledge about emergency action given relative loss (e) Relative loss given water depth.

330   Further, we analyse to what extent these adaptation strategies are helpful in reducing $rloss$. ~~Effect of preparedness~~

Through feature selection and Bayesian Networks we identified emergency measures success (ms) and knowledge about emergency action (ke) for companies and private households respectively, as the significant variables ~~(see Tables S2 and S3 for details on the questions and responses)~~ within the Markov Blanket of ~~rloss~~$rloss$ (see Tables S2 and S3 for details on the questions and responses). ~~Further, we analysed to what extent these adaptation strategies are is helpful in reducing rloss$rloss$.~~

335 ~~For simplification, we have categorized measures success (msms) and knowledge about emergency action (keke) into three categories of low, medium, and high. Building on this, we conceptualised preparedness using these variables and categorized it into low, medium, and high levels. For companies, high preparedness was defined as having undertaken emergency measures that were perceived to be mostly or completely effective ($ms = 3$) and low preparedness ($ms = 1$) reflected low perceived effectiveness of such measures. For households, high preparedness was defined as having a clear understanding of emergency~~

340 ~~actions based on official warnings ($ke \geq 5$), and low preparedness reflected limited to no understanding of what to do ($ke \leq 2$). While preparedness has been extensively studied in the context of fluvial or riverine floods (Lüdtke et al., 2019; Schoppa et al., 2020; Wagenaar et al., 2018), its role in flash floods has not yet been systematically investigated. To address this gap,~~ W~~w~~e applied the FLEMO$_{\text{flash}}$ model to derive predictive densities of $rloss$. Results were summarized using the median and associated uncertainty (25$^{\text{th}}$ and 75$^{\text{th}}$ percentiles) for selected combinations of hazard, exposure, and vulnerability conditions,

345 rather than displaying the full predictive densities (Figure 6). For clarity of interpretation, Figure A1 illustrates step by step how predictive densities are derived from the ~~prior and~~ posterior distributions using kernel density estimation based on 1,000 resampled values. ~~, while~~ Figure A2 provides an overview of the posterior and predictive densities across varying levels of measure success ~~(preparedness)~~ under same conditions of water depth and number of employees.

For company building, the ~~rloss~~$rloss$ Markov blanket consists of water depth (~~wd~~wd), number of employees (~~emp~~emp), and

350 emergency measures success (~~ms~~ms). T~~t~~he incurred loss increases with increasing water depth but combining the water depth and number of employees, ~~. Considering the company characteristics,~~ the relative loss experienced by companies with 9 to 12 employees is higher compared to those with 38 or more employees. We further investigate the role of successful implementation of emergency measures in reducing loss. ~~When taking preparedness into consideration, we see its significance in reducing loss.~~ For example, when considering only water depth and number of employees~~hazard & exposure~~, companies

355 with 38 or more employees, inundated by water depths ranging from 1.85 m to 2.40 m above the ground, experience a $rloss$ of 0.38. However, with successful implementation of emergency measures ~~high preparedness~~ (~~ms~~ms=3), this ~~this~~ $rloss$ decreases to 0.20, representing a substantial 47% reduction. On the other hand, when emergency measures were ~~not~~ implemented or perceived to be ineffective (~~ms~~$ms = 0$ or~~rms = 1~~)~~with low preparedness~~, the $rloss$ increases to 0.50, marking a 32% increase in estimated losses.

360 For household buildings, considering hazard and exposure with a water depth of ≥ 2.3 m above ground and no contamination, the predicted $rloss$ is 0.22. However, when residents had clarity on emergency actions ~~with high preparedness~~ ($Ke \geq 5$) this

loss decreases to 0.05, reflecting a 77% reduction. Conversely, ~~with low preparedness~~ when residents did not have clear knowledge on emergency action ($Ke \leq 2$), the $rloss$ rises to 0.27, a 23% increase. Similarly, for ~~Preparedness also plays a crucial role in mitigating losses to~~ household contents, we observed that when considering only water depths (hazard) of ~~. For instance, when considering only water depths of~~ height 2.3 m above ground, the $rloss$ is 0.38. With ($Ke \geq 5$)~~high preparedness~~, this loss drops to 0.17, a 55% reduction. In contrast, with ($Ke \leq 2$)~~low preparedness~~, the $rloss$ increases to 0.44, representing a 16% rise. ~~In both companies and households, losses are consistently higher with low preparedness and lower with high preparedness. The extent of this difference varies depending on hazard and exposure characteristics.~~ These findings highlight the potential~~effect~~ of successful implementation of emergency measures and knowledge about emergency action in reducing ~~preparedness in reducing the risk of~~ flash flood losses (Barendrecht et al., 2020; Berghäuser et al., 2023; Bubeck et al., 2013; Sairam et al., 2019; Surminski and Thieken, 2017)~~risk~~.

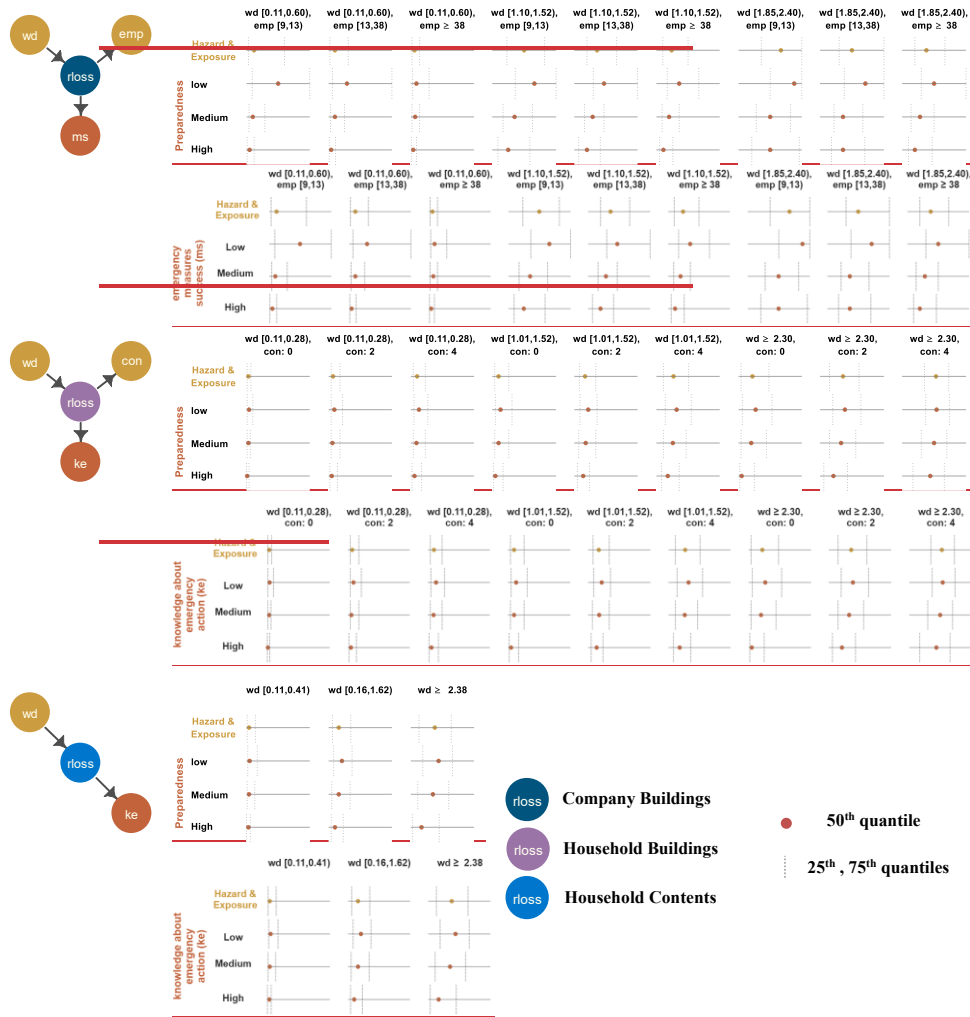
While residents with high knowledge about emergency actions are more likely to take effective emergency measures, thereby reducing the severity of flood loss (Kreibich et al., 2005; Sairam et al., 2019), the knowledge about emergency action (ke) variable as considered in this study, does not capture which exact actions respondents undertook. Though the specific actions likely varied across respondents, empirical evidence indicates that having clear knowledge of emergency action generally contributes to reduced flood losses, consistent with previous findings (Kreibich et al., 2021).


Figure 6. FLEMOflash **application for company buildings, private household buildings and contents, considering relative loss Markov blankets. The first row in each panel shows the probabilistic predictive density of relative loss on the interval [0,1] based on the specific scenarios of hazard and exposure combination. The second to fourth rows in each panel illustrate the changes in relative loss with different levels of emergency measures success (ms) and knowledge about emergency action (ke) preparedness for the given hazard and exposure combinations.**

~~While Preparedness is crucial in mitigating potential losses (Barendrecht et al., 2020; Berghäuser et al., 2023; Bubeck et al., 2013; Sairam et al., 2019; Surminski and Thieken, 2017). r~~Residents with high ~~knowledge about emergency actions levels of preparedness are more likely to take effective emergency measures, thereby reducing the severity of flood loss (Kreibich et al., 2005; Sairam et al., 2019), the knowledge about emergency action (ke) variable as considered in this study, . Despite its importance, the way preparedness is conceptualized in this study has certain limitations. Specifically, the variable does not capture which exact actions respondents undertook. Though the Therefore, it would be misleading to speculate particular actions directly resulted in reduced losses. While the specific actions likely varied across respondents, empirical evidence indicates that having clear knowledge of emergency action generally contributes to reduced flood lossesbetter preparedness, consistent with previous findings (Kreibich et al., 2021).~~

4 Conclusions

This study introduces FLEMO$_{flash}$ - new set of multivariate flash flood loss models for estimating relative losses for companies and households. The machine learning based feature selection highlights~~identified~~ key loss drivers comprising hazard, company characteristics, and emergency response. Results ~~further~~ demonstrate that successful implementation of measures for companies and knowledge about emergency action for private households ~~preparedness~~ can substantially reduce losses. In extreme hazard scenarios, losses were reduced by nearly half for larger companies, and households that received timely warnings and has clear knowledge were able to reduce building losses by 77% and contents losses by 55%. While FLEMO$_{flash}$ already provides a ~~robust~~ tool to support risk analyses, and impact-based forecasting, future developments could further strengthen its applicability by integrating complementary hydrological indicators (e.g., basin concentration time), incorporating building-level susceptibility factors (e.g., construction materials, structural condition, floor count), and expanding the empirical database by including high loss observations and more diverse geographic regions. It is important to note that the model's performance and predictive capacity, as presented are specific to the empirical dataset and survey variables available for FLEMO$_{flash}$, and the results should be interpreted within the context and limitations of the underlying data.

Appendix

Table A1. Overview of 14 municipalities affected by past flash flood events.

Name of Municipality	Latitude (N)	Longitude (E)	Reference (including research papers, official reports, municipal flash flood maps, media coverage of past events)
Triftern	48.3957	13.0060	(LfU, 2017), Thieken et al. (2022)
