Abstract. Organic hydroperoxides (ROOHs) are key components of atmospheric aerosols. Determining the acid-catalyzed hydrolysis rate constants (k_A) of ROOHs is crucial for assessing their atmospheric fate and environmental impacts. However, available k_A values are limited due to the difficulty in obtaining authentic ROOH standards. Herein, we solved this issue by developing a computational strategy and probing the structure-activity relationship of k_A values. We screened the proton model, a critical prerequisite for density functional theory (DFT) calculations of k_A , by comparing experimental k_A values of four ROOHs with DFT-calculated values using different proton models. Results show the $H_3O^+(H_2O)_1$ model reliably predicts k_A values with DFT method. Further investigation of 52 ROOHs reveals that substituents at the C_α site of the -OOH group, including -NH₂, -N(CH₃)₂, -OH, -OCH₃, -CH=CH₂, -SH, and -PH₂, can facilitate acid-catalyzed hydrolysis. Notably, the -NH₂ and -N(CH₃)₂ substituents exhibit stronger facilitating effect than the well-documented -OH and -OCH₃ substituents. Additionally, we clarified that not all nitrogen- or oxygen-containing substituents equally enhance k_A , as their efficacy depends on the substituents attached to the O or N atoms. This study provides a reliable computational strategy and essential guidelines for predicting k_A values of ROOHs, enabling accurate simulations in atmospheric chemistry models.

1 Introduction

Aerosol liquid water, a crucial constituent of atmospheric aerosols, acts as a reactive medium that enables aqueous-phase chemical transformations (Jin et al., 2020; Su et al., 2022; Shi et al., 2024; Wu et al., 2018). The aqueous-phase transformations of organic compounds substantially modify the physicochemical properties of aerosols, such as chemical composition, optical characteristics, and hygroscopicity, ultimately altering the health and climate effects of aerosols (McNeill, 2015; Herrmann et al., 2015; Zheng et al., 2021; Liu et al., 2023; Lei et al., 2022; Zhang et al., 2024). Recently, aqueous-phase chemistry has gained increasing research interest due to its unique reaction mechanism compared to gas-phase chemistry. However, the complexity and diversity of these reaction pathways have limited our understanding of aqueous-phase chemistry. The lack of kinetic data for the aqueous-phase chemistry of organic compounds further hinders its application in precise simulations of

three-dimensional (3-D) atmospheric chemistry models (Ervens et al., 2024; Wieser et al., 2024; Abbatt and Ravishankara, 2023).

Organic hydroperoxides (ROOHs) are ubiquitous in aerosols and predominantly derived from atmospheric oxidation processes involving organic peroxy radicals (RO_2^\cdot) or Criegee intermediates (CIs) (Wang et al., 2023). Characterized by one or more hydrophilic peroxide groups ($-\text{OOH}$), ROOHs are highly reactive and usually experience rapid aqueous-phase transformations, forming low-volatile multi-functional species or reactive oxygen species (Enami, 2021; Krapf et al., 2016; Dovrou et al., 2019; Wei et al., 2022; Wei et al., 2021; Wei et al., 2022; Wang et al., 2019). Laboratory evidence demonstrates that ROOHs can account for 20%-60% isoprene- or monoterpene-derived secondary organic aerosol (SOA) (Wang et al., 2023; Enami, 2021; Epstein et al., 2014). Therefore, investigating the transformation kinetics of ROOHs is essential for improving our understanding of aqueous-phase chemistry.

Hydrolysis has been identified as an important transformation pathway for ROOHs, yielding hydrogen peroxide (H_2O_2) and thereby affect atmospheric oxidation capacity (Enami, 2021; Qiu et al., 2019; Qiu et al., 2020; Hu et al., 2021; Dai et al., 2024). Recent studies have found that two types of α -substituted ROOHs, α -hydroxyalkyl-hydroperoxides (α -HHs) and α -alkoxyalkyl-hydroperoxides (α -AHs), exhibit rapid hydrolysis under acid-catalyzed conditions, yielding H_2O_2 accompanied by aldehydes or alcohols (Qiu et al., 2020; Hu et al., 2021; Enami, 2022; Hu et al., 2022; Endo et al., 2022). Their lifetimes are extremely short from seconds to minutes at $\text{pH} < 4$, with first-order rate coefficients increasing significantly as pH decreases (Qiu et al., 2020; Hu et al., 2021; Hu et al., 2022). Moreover, a latest study further demonstrated that some monoterpene-derived α -acyloxyalkyl-hydroperoxides also decay significantly at low pH (Chang et al., 2025). This highlights the significance of acid-catalyzed hydrolysis in transforming ROOHs and modifying the oxidation capacity of the surrounding atmosphere. However, the currently available data on acid-catalyzed hydrolysis rate constants (k_A) are still very limited, impeding a comprehensive understanding of this aqueous-phase transformation process. The k_A data lack manifests in two aspects: i) current research on α -substituted ROOHs is confined to those with hydroxyl, alkoxy, and acyloxy substituents, while the k_A values of α -substituted ROOHs with other substituents remains unclear; ii) despite recent studies have indicated that non- α -substituted ROOHs, which are more abundant in the atmosphere, have longer lifetimes up to days in aqueous phase, detailed investigations for their k_A values are lacking (Dai et al., 2024; Zhao et al., 2022). Therefore, a comprehensive investigation of k_A values for structurally diverse ROOHs in atmosphere is urgently needed to advance our understanding of this aqueous-phase transformation process.

Acquiring k_A values for diverse ROOHs through laboratory experiments is significantly challenging due to the lack of commercial standards and the prerequisite synthesis of target compounds. Given these experimental limitations and the structural diversity of ROOHs, a viable approach is to use the quantum chemical method to conduct structure-activity relationship investigation. However, previous DFT calculation studies using naked H_3O^+ as a proton model have overestimated hydrolysis rates (Hu et al., 2022), since H_3O^+ would cluster with water molecules in solution and reduce the proton activity (Agmon et al., 2016). Hence, it is urgent to develop a more suitable H_3O^+ cluster model within the DFT calculation strategy to accurately and efficiently predict the k_A values of ROOHs.

In this study, we initially selected four types of ROOHs with experimental k_A values as tested compounds to search for a suitable H_3O^+ cluster model. Utilizing the screened H_3O^+ cluster model and DFT calculations, the acid-catalyzed hydrolysis of 45 ROOH model compounds was systematically investigated to elucidate the structure-activity relationship of k_A values. These model compounds were selected mainly considering the diverse structures at the C_α and C_β sites of the -OOH group. The investigation was further extended to atmospheric ROOHs to validate the structure-activity relationship revealed by the model compounds. The developed H_3O^+ cluster model and the revealed structure-activity relationship can be instrumental in predicting the k_A values of atmospheric ROOHs. The established kinetic database for ROOHs would further improve the predictions of 3-D chemical models and deepen our understanding of atmospheric aqueous chemistry.

2 Computational Details

2.1 Electronic structure calculations

All structure optimizations and energy calculations were performed using the Gaussian 09 program (Frisch et al., 2009). Geometry optimization and frequency calculation for the reactants (R), products (P), transition states (TS), pre-reactive complexes (RC), intermediates (IM), and post-reactive complexes (PC) were conducted at the M06-2X/6-31+G(d,p) level of theory (Zhao and Truhlar, 2008). Single-point energy (SPE) calculations were performed at the M06-2X/6-311++G(3df,2pd) level. The employed quantum chemistry calculation method can be succinctly represented as M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p). Previous studies have demonstrated that the M06-2X method is suitable for predicting energies and kinetics for the aqueous-phase reactions of organic compounds with a good balance between accuracy and computational efficiency (Ji et al., 2020; Shi et al., 2024; Zhang et al., 2022; Piletic et al., 2013). The solvation model based on density (SMD) was applied to account for the effects of solvent water molecules in the aqueous phase (Marenich et al., 2009). Intrinsic reaction coordinate calculations were used to confirm that the well-defined TSs connect with the corresponding reactants and products (Fukui, 1981). For reaction pathways where TSs could not be successfully located, relaxed scan methods were employed to obtain free-energy surfaces (Zhao et al., 2023; Ryu et al., 2018). Gibbs free energy (G) values for each structure at 298.15 K were calculated by combining the SPE with the Gibbs correction energy calculated at the theoretical level of geometry optimization. A correction factor of 1.89 kcal mol⁻¹ was applied to the activation free energy (ΔG^\ddagger) and reaction free energy ($\Delta_r G$) calculations for reactions where the number of molecules decreases or increases by one from R to TS or from R to P to explain the free energy change from the gas phase standard state of 1 atm to the aqueous phase standard state of 1 mol L⁻¹ (Sadlej-Sosnowska, 2007; Zhang et al., 2015). The combined use of Molclus 1.9.9.9 and Gaussian 09 programs was applied to search for the global minimum of the reactants (Lu., 2022).

2.2 $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ model selection

95 A previous study found that the naked H_3O^+ model overestimated acid-catalyzed hydrolysis rates of ROOHs by combining with feasible DFT method (Hu et al., 2022). This is probably because H_3O^+ clusters with water molecules in the aqueous solution and the proton activity decreases (Agmon et al., 2016). The protonated water cluster model has been found to predict the acid-catalyzed hydrolysis kinetics of other organic compounds such as epoxydiols with high accuracy (Piletic et al., 2013). Here, we screened an appropriate cluster model for H_3O^+ by comparing calculated k_A values for reactions between
100 $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ($n = 1, 2, 3$) and the selected ROOHs with experimental values. The selected ROOHs are C_{13} α -AH, C_{12} α -AH₍₁₎, C_{12} α -AH₍₂₎, and C_{10} α -HH, with their structures shown in Fig. S1. The structures of $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ($n = 1, 2, 3$) are presented in Fig. S2.

2.3 Reaction rate constants calculation

The second-order reaction rate constants k_A of the elementary reactions in acid-catalyzed hydrolysis pathways were
105 calculated using transition state theory (Eq. (1)) (Zhao et al., 2023; Xu et al., 2019). The pseudo-first-order rate constants (k'_A) were calculated by combining k_A with the concentration of protonated water clusters, which are determined by pH. Corresponding acid-catalyzed hydrolysis lifetimes ($\tau_{1/e}$) can be subsequently derived by $\tau_{1/e} = 1/k'_A$.

$$k_A = \sigma \frac{k_B T}{h} \exp\left(-\frac{\Delta G^\ddagger}{RT}\right), \quad (1)$$

where σ is the reaction path degeneracy, T is the temperature (298.15 K), k_B is the Boltzmann constant (J K^{-1}), h is the Planck
110 constant (J s), R is the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), ΔG^\ddagger is the activation free energy.

3 Results and discussion

3.1 Selection of suitable $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ model

We investigated the acid-catalyzed hydrolysis of four ROOHs, i.e., C_{13} α -AH, C_{12} α -AH₍₁₎, C_{12} α -AH₍₂₎, and C_{10} α -HH,
115 using four different proton models $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ($n = 0, 1, 2, 3$) with the DFT method. The calculated free-energy profiles for these reactions are presented in Figs. S3-S6. Concluded from the reaction profiles, a two-step acid-catalyzed hydrolysis pathway is revealed for these four ROOHs, with the first step being the rate-limiting step. As shown in Fig. S7, the H^+ of $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ attacks the -OOH group of the selected four compounds, leading to C_α -O bond rupture and simultaneous formation of a carbocation intermediate and H_2O_2 in the first step. Subsequently, the carbocation reacts with water molecules and yields the corresponding protonated alcohols.

120 Using the activation free energies of the rate-limiting step, the pseudo-first-order rate constants k'_A were calculated over a pH range of 0-14 using the M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p) method. The calculated k'_A values for the four selected ROOHs with H_3O^+ and three H_3O^+ cluster models are presented in Fig. 1, along with the experimentally

determined hydrolysis rates at different pH values (Qiu et al., 2020; Enami, 2022; Hu et al., 2022; Endo et al., 2022). The $\text{H}_3\text{O}^+(\text{H}_2\text{O})_1$ model was found to best reproduce the experimental data among all H_3O^+ cluster models. In most cases, the discrepancies between the calculated and the experimental k'_A values are within a factor of 0.5 to 2.2. Two exceptions are C_{10} α -HH at pH 3.3 and C_{12} α -AH₍₂₎ at pH 4.5, but their uncertainties remain within one order of magnitude, an acceptable error range. In contrast, the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_3$, $\text{H}_3\text{O}^+(\text{H}_2\text{O})_2$, and H_3O^+ models result in much larger discrepancies, with errors reaching 8.7×10^{-2} , 1.1×10^{-3} , and 2.1×10^8 times, respectively. Therefore, the computational strategy combining the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_1$ model with the M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p) method is well-suited for predicting k_A values of ROOHs.

Figure 1. Variation of calculated pseudo-first-order acid-catalyzed hydrolysis rate constants (k'_A) for four ROOHs along with the available experimental values (Qiu et al., 2020; Enami, 2022; Hu et al., 2022; Endo et al., 2022). (a) C_{13} α -AH, (b) C_{12} α -AH₍₁₎, (c) C_{12} α -AH₍₂₎, and (d) C_{10} α -HH.

3.2 Structure-activity relationship of acid-catalyzed hydrolysis rate constants

Employing the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_1$ model and the M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p) method, we conducted a systematic investigation for structure-activity relationships of k_A values across 45 ROOH model compounds (Fig. 2a). We selected the simplest unsubstituted primary, secondary, and tertiary ROOHs, i.e., $\text{CH}_3\text{CH}_2\text{OOH}$, $\text{CH}(\text{CH}_3)_2\text{OOH}$, and $\text{C}(\text{CH}_3)_3\text{OOH}$, as the reference compounds to assess the influence of substituents. Specifically, the influence of substituents was examined by comparing the k_A values of α -substituted primary, secondary, and tertiary ROOHs, as well as β -substituted tertiary ROOHs, represented as $\text{CH}_2(\text{X})\text{OOH}$, $\text{CH}(\text{CH}_3)(\text{X})\text{OOH}$, $\text{C}(\text{CH}_3)_2(\text{X})\text{OOH}$, and $\text{C}(\text{CH}_3)_2(\text{CH}_2(\text{X}))\text{OOH}$, with the corresponding unsubstituted ones, respectively. Here, X denotes substituents including $-\text{NH}_2$, $-\text{OH}$, $-\text{OCH}_3$, $-\text{CH}=\text{CH}_2$, $-\text{SH}$, $-\text{PH}_2$, $-\text{F}$, $-\text{Cl}$, and $-\text{CHO}$, covering the major functional group types found in atmospheric ROOHs. Therefore, the effects of different carbon skeletons at the C_α site (primary, secondary, and tertiary) and different substituents at the C_α and C_β sites of the $-\text{OOH}$ group on the k_A values of ROOHs were revealed.

Figure 2. Molecular structure and acid-catalyzed hydrolysis pathways of ROOH model compounds. (a) Molecular structure of 45 ROOH model compounds; (b) One-step and two-step acid-catalyzed hydrolysis pathways of ROOHs.

For the selected 45 ROOH model compounds, their reaction free-energy profiles were calculated and shown in Figs. S8-S12. They follow two distinct reaction pathways, which are simplified and illustrated in Fig. 2b. $\text{CH}_3\text{CH}_2\text{OOH}$, $\text{CH}_2(\text{X})\text{OOH}$, and $\text{CH}(\text{CH}_3)(\text{X})\text{OOH}$ ($\text{X} = \text{F}, \text{Cl}, \text{CHO}$) undergo a one-step reaction pathway, where $\text{H}_3\text{O}^+(\text{H}_2\text{O})_1$ and an H_2O molecule simultaneously attack the $-\text{OOH}$ group and the C_α , respectively, leading to the formation of protonated alcohols and H_2O_2 . Meanwhile, the other ROOH model compounds follow the two-step reaction pathway via the formation of a carbocation intermediate, similar to that of C_{13} α -AH, C_{12} α -AH₍₁₎, C_{12} α -AH₍₂₎, and C_{10} α -HH.

Based on reaction activation free energies, the k_A values for 45 ROOH model compounds were calculated, as well as k'_A values under different pH conditions (Table S1 and Fig. 3). As shown in Fig. 3a, the k'_A of tertiary ROOH is the highest among the three unsubstituted ROOHs at the same pH, followed by secondary and primary ROOHs, aligning with the previous research findings (Hu et al., 2022). Furthermore, to clarify the effects of substituent types, we calculated the enhancement factors (EF) for k'_A of substituted ROOHs relative to their unsubstituted reference compounds. The EF for α -substituted ROOH model compounds, $\text{CH}_2(\text{X})\text{OOH}$, $\text{CH}(\text{CH}_3)(\text{X})\text{OOH}$, and $\text{C}(\text{CH}_3)_2(\text{X})\text{OOH}$ are shown in Fig. 3b-d, with $\text{CH}_3\text{CH}_2\text{OOH}$, $\text{CH}(\text{CH}_3)_2\text{OOH}$, and $\text{C}(\text{CH}_3)_3\text{OOH}$ as reference compounds, respectively. Substituents such as $-\text{NH}_2$, $-\text{OH}$, $-\text{OCH}_3$, $-\text{SH}$, and $-\text{CH}=\text{CH}_2$ increase k'_A , with EF values ranging from 5.1×10^3 - 6.4×10^{23} for primary, 1.3×10^5 - 5.0×10^{18} for secondary, and 1.4 - 5.7×10^{13} for tertiary ROOHs. The $-\text{PH}_2$ substituent shows a divergent effect, increasing k'_A of primary and secondary ROOHs with the EF values of 1.3×10^5 and 2.5 , respectively, but decreasing that of tertiary ones. While $-\text{OH}$ and $-\text{OCH}_3$ are known to facilitate the acid-catalyzed hydrolysis of ROOHs (Hu et al., 2021; Qiu et al., 2020; Hu et al., 2021; Enami, 2022; Hu et al., 2022; Endo et al., 2022), our study is the first to show that $-\text{NH}_2$, $-\text{SH}$, $-\text{CH}=\text{CH}_2$, and $-\text{PH}_2$ can also enhance it. Among them, $-\text{NH}_2$ has the highest EF, followed by $-\text{OH}$ and $-\text{OCH}_3$, $-\text{SH}$, $-\text{CH}=\text{CH}_2$, and $-\text{PH}_2$. In contrast, $-\text{F}$, $-\text{Cl}$, and $-\text{CHO}$ significantly decrease the k'_A .

Figure 3. Calculated pH-dependent pseudo-first-order rate constants (k'_A) of ROOH model compounds and substituent enhancement effects on k'_A . (a) Calculated k'_A -pH profiles for reference ROOHs: $\text{CH}_3\text{CH}_2\text{OOH}$, $\text{CH}(\text{CH}_3)_2\text{OOH}$, $\text{C}(\text{CH}_3)_3\text{OOH}$, and $\text{C}(\text{CH}_3)_2\text{OCH}_3\text{OOH}$. (b-f) Enhancement factors ($\text{EF} = k'_A, \text{ROOHs} / k'_A, \text{reference}$) for (b) $\text{CH}_2(\text{X})\text{OOH}$ vs. $\text{CH}_3\text{CH}_2\text{OOH}$, (c) $\text{CH}(\text{CH}_3)(\text{X})\text{OOH}$ vs. $\text{CH}(\text{CH}_3)_2\text{OOH}$, (d) $\text{C}(\text{CH}_3)_2(\text{X})\text{OOH}$ vs. $\text{C}(\text{CH}_3)_3\text{OOH}$, (e) $\text{C}(\text{CH}_3)_2(\text{CH}_2(\text{X}))\text{OOH}$ vs. $\text{C}(\text{CH}_3)_3\text{OOH}$, and (f) $\text{C}(\text{CH}_3)_2(\text{OY})\text{OOH}$ vs. $\text{C}(\text{CH}_3)_2\text{OCH}_3\text{OOH}$.

To further evaluate the effectiveness of acid-catalyzed hydrolysis for these α -substituted model compounds in the atmosphere, we calculated their $\tau_{1/e}$ values at pH 3.8 and 0.9, representing typical aerosol conditions in inland China and the Southeastern United States, respectively (Wang et al., 2022; Jia et al., 2018; Ding et al., 2019; Shi et al., 2019; Xu et al., 2020; Wang et al., 2020; Guo et al., 2015). Compared to the typical atmospheric retention time of ambient aerosols with approximately 1-2 weeks (Hodzic et al., 2016; Kristiansen et al., 2016), Table 1 shows the calculated k_A and $\tau_{1/e}$ values of the α -substituted ROOH model compounds that undergo effective acid-catalyzed hydrolysis on this time scale at pH 3.8 and 0.9. The $\tau_{1/e}$ values for $-\text{NH}_2$ -substituted primary ROOH, $-\text{NH}_2$ - and $-\text{OH}$ -substituted secondary ROOHs, as well as $-\text{NH}_2$ -, $-\text{OH}$ -, and $-\text{OCH}_3$ -substituted tertiary ROOHs range from less than 1 second to 5.5 hours at pH 3.8. As pH decreases to 0.9, effective hydrolysis occurs for $-\text{OH}$ -substituted primary ROOH, $-\text{OCH}_3$ -substituted secondary ROOH, and $-\text{SH}$ -substituted tertiary ROOH, with $\tau_{1/e}$ ranging from 40.9 min to 6.8 d. The $\tau_{1/e}$ values for other compounds exceeding 2 weeks are shown in Table S1, indicating the limited effectiveness of acid-catalyzed hydrolysis under typical atmospheric conditions. In summary, substituents such as $-\text{NH}_2$, $-\text{OH}$, and $-\text{OCH}_3$ can facilitate effective acid-catalyzed hydrolysis of ROOHs under typical ambient conditions, while the $-\text{SH}$ substituent is only effective under exceptionally low pH. Although $-\text{OH}$ and $-\text{OCH}_3$ substituents are well-documented, we show that the $-\text{NH}_2$ substituent leads to significantly shorter $\tau_{1/e}$ for the corresponding ROOHs. α - NH_2 -substituted ROOHs are primarily formed via the reactions of CIs with ammonia or the oxidation of tertiary amines (Li et al., 2024; Kjaergaard et al., 2023; Ma et al., 2021). This suggests that their acid-catalyzed hydrolysis may be an important atmospheric aqueous-phase transformation process, particularly in regions with high amine and ammonia concentrations.

Table 1. Calculated acid-catalyzed hydrolysis second-order reaction rate constants (k_A) and corresponding lifetimes ($\tau_{1/e}$) of 14 ROOH model compounds under two selected scenarios, Inland China (pH 3.8) and Southeastern United States (pH 0.9).

| Compounds | Formulas | k_A ($\text{L mol}^{-1} \text{s}^{-1}$) | $\tau_{1/e}$, pH 3.8 | $\tau_{1/e}$, pH 0.9 |
|--|---|---|-----------------------|-----------------------|
| $\text{CH}_2(\text{X})\text{OOH}$ | $\text{CH}_2(\text{NH}_2)\text{OOH}$ | 1.01×10^3 | 6.3 s | < 1 s |

| | $\text{C}(\text{CH}_3)_2(\text{OCH}=\text{CH}_2)\text{OOH}$ | 1.62×10^{-3} | — | 1.4 h |

It is intriguing to discuss why substituents such as $-\text{NH}_2$, $-\text{OH}$, $-\text{OCH}_3$, $-\text{CH}=\text{CH}_2$, $-\text{SH}$, and $-\text{PH}_2$ can enhance the acid-catalyzed hydrolysis of ROOHs. As discussed above, a common feature for the acid-catalyzed hydrolysis of these substituted

ROOHs is the formation of carbocation intermediates during their two-step reaction pathway. As illustrated in Fig. 4, the greater the enhancing potential of a substituent, the lower the reaction free energy required for carbocation intermediate formation, resulting in higher intermediate stability. This suggests that the stabilizing effect of these substituents on carbocation intermediates is the driving force behind the enhanced acid-catalyzed hydrolysis. Exceptions for the -OH- and -OCH₃-substituted ROOHs should be caused by the slight difference in their two-step reaction pathways (Fig. S7). According to electronic effect theory (Naredla and Klumpp, 2013; Olah, 2001), substituents -NH₂, -OH, -OCH₃, -SH, -CH=CH₂, and -PH₂ stabilize carbocation intermediates through conjugated electron donation into the unoccupied orbital of the carbocation. This stabilizing effect follows the order: -NH₂ > -OH ≈ -OCH₃ > -SH ≈ -CH=CH₂ ≈ -PH₂. This order aligns with the observed trend in k_A values, where α -NH₂-substituted ROOHs exhibit higher k_A values than α -OH- and -OCH₃-substituted ones, which in turn are higher than α -SH-, -CH=CH₂-, and -PH₂-substituted ones (Table S1). Similarly, the stabilizing effect of these substituents on carbocation intermediates can also explain the order of k_A values for tertiary ROOHs > secondary ROOHs > primary ROOHs. Tertiary ROOHs exhibit higher k_A values due to stronger hyperconjugation interactions between the unoccupied p orbital of the carbocation and the additional C-H σ -bonds from the methyl group, which stabilize the carbocation intermediates (Alamiddine and Humbel, 2013).

Figure 4. Calculated schematic free-energy surfaces for carbocation formation during acid-catalyzed hydrolysis of C(CH₃)₂(X)OOH. Substituents X denotes NH₂, OH, OCH₃, CH=CH₂, SH, and PH₂. Free energies are calculated at the M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p) level with the SMD solvation model, with ROOH and H₃O⁺(H₂O)₁ set as the reference state (R) at 0 kcal mol⁻¹. Transition states (TS) and intermediates (IM) are labeled.

Based on the above analysis, we deduced that the presence of N and O atoms is the main reason for the strongest facilitating effect of -NH₂, -OH, and -OCH₃ in the acid-catalyzed hydrolysis of ROOHs. This raises an interesting question of how do substituents attached to N or O atoms affects the k'_A values. To explore this, we examined the effect of substituents attached to O atom as a test case and calculated the EF for k'_A of C(CH₃)₂(OY)OOH (Y being substituents) compared to the reference compound C(CH₃)₂OCH₃OOH. As shown in Fig. 3f, substituents -CH₂CH₃ and -CH₂CH₂CH₃ lead to only a minor

reduction for k'_A . This is validated by the similar experimental k'_A of C_{12} α -AH₍₁₎ and C_{13} α -AH, which possess $-OCH_2CH_3$ and
 220 $-OCH_2CH_2CH_3$, respectively (Hu et al., 2022). Substituents $-CH(CH_3)_2$ and $-C(CH_3)_3$ increase the k'_A , with EF values of 10.6
 and 45.9, respectively. However, $-CH=CH_2$ and $-CHO$ substituents dramatically decrease k'_A by approximately 5 and 10 orders
 of magnitude, respectively. As shown in Table 1, the $C(CH_3)_2(OY)OOH$ with Y being four alkyl substituents undergo rapid
 acid-catalyzed hydrolysis with $\tau_{1/e}$ values ranging from 3.5 s to 6.0 min even at pH 3.8, while $C(CH_3)_2(OCH=CH_2)OOH$ only
 undergoes effective reaction at pH 0.9 ($\tau_{1/e} = 1.4$ h). In contrast, the acid-catalyzed hydrolysis of $C(CH_3)_2(OCHO)OOH$ is
 225 difficult to occur. These findings underscore that not all oxygen-containing substituents at the C_α site are equally effective in
 promoting acid-catalyzed hydrolysis of ROOHs, highlighting the importance of specific structural features. The substituent
 effects on the O atom could be reasonably extrapolated to the N atom. It should be noted that although the direct acid-catalyzed
 hydrolysis of $C(CH_3)_2(OCHO)OOH$ is impossible, the indirect reaction initiated by the hydrolysis of the ester group $-OCHO$
 has been proposed (Chang et al., 2025; Zhao et al., 2018), which is beyond the range of this study.

230 For the β -substituted ROOHs, tertiary $C(CH_3)_2(CH_2(X))OOH$ ($X = -NH_2, -OH, -OCH_3, -CH=CH_2, -SH, -PH_2, -F, -Cl$ and
 $-CHO$) were chosen as model compounds, as they potentially exhibit higher k'_A values compared to primary and secondary
 ones. By calculating the EF for k'_A values of $C(CH_3)_2(CH_2(X))OOH$ relative to the reference compound $C(CH_3)_3OOH$, we
 found that all nine substituents reduce the k'_A (Fig. 3e). Thus, we conclude that substituents at C_β site could hinder the acid-
 catalyzed hydrolysis. The unfeasible acid-catalyzed hydrolysis of them aligns with previous experimental results of Liu et al.
 235 that non- α -substituted monoterpene-derived organic peroxides exhibit greater persistence in aqueous environments (Zhao et
 al., 2022).

3.3 Acid-catalyzed hydrolysis of atmospheric ROOHs

To evaluate the applicability of the structure-activity relationship derived from model compounds to more complicated
 atmospheric ROOHs, we investigated the acid-catalyzed hydrolysis of seven ROOHs derived from isoprene (Wennberg et al.,
 240 2018), α -pinene (Zhang et al., 2017; Clafflin et al., 2018), trimethylamine (Kjaergaard et al., 2023; Ma et al., 2021), and
 dimethyl sulphide (Berndt et al., 2019). These ROOHs feature distinct substituents at the C_α site, including $-N(CH_3)_2$,
 $-N(CH_3)(CHO)$, $-OH$, $-CH=CH_2$, $-SCH_3$, and $-CHO$, and unsubstituted. As shown in Fig. 5, the order of k'_A values for these
 ROOHs at the same pH (3.8 or 0.9) according to their substituents is as follows: $-N(CH_3)_2 > -OH > -N(CH_3)(CHO) >$
 $unsubstituted > -CH=CH_2 > -SCH_3 > -CHO$, similar to the trends observed in model compounds in four aspects. First, a -
 $N(CH_3)_2$ or $-OH$ substituent at the C_α site of trimethylamine- $OOH_{(1)}$ or α -pinene- $OOH_{(1)}$ results in their high k'_A values, with
 $\tau_{1/e}$ values less than 2 d (pH 3.8) and 3.6 min (pH 0.9), respectively. Second, the introduction of a $-CHO$ group to the N atom
 in the $-N(CH_3)(CHO)$ substituent of trimethylamine- $OOH_{(2)}$ leads to a remarkable reduction in k'_A values, with $\tau_{1/e}$ values
 exceeding 45 d, even at pH 0.9 (Table S2). The possible reaction of trimethylamine- $OOH_{(2)}$ initiated by the hydrolysis of -
 $N(CH_3)(CHO)$ group is not considered in this work (Zhang et al., 2015). Third, α -pinene- $OOH_{(3)}$, which features a $-CHO$
 250 substituent exhibits the lowest k'_A values. Finally, the $-CH=CH_2$ and $-SCH_3$ substituents contribute to the relatively low k'_A
 values of isoprene- OOH and dimethyl sulfide- OOH , respectively. Although the existence of enhancing substituents, their k'_A

values is lower than the unsubstituted α -pinene-OOH₍₂₎, which is attributed to the reducing effect of an additional -OH substituent at the C _{β} site for isoprene-OOH, and the primary C _{α} of sulfide-OOH compared to tertiary C _{α} of α -pinene-OOH₍₂₎. The reproduction of the substituents effect trend on k'_A values in atmospheric ROOHs demonstrates that the structure-activity relationship derived from model ROOHs can be effectively extended to atmospheric ROOHs.

Figure 5. Calculated pseudo-first-order rate constants (k'_A) of seven atmospheric ROOHs under two selected pH values. pH 3.8 and pH 0.9 represent typical aerosol conditions in inland China and the Southeastern United States, respectively.

4 Conclusions

This study demonstrates that combining the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_1$ proton model with the M06-2X/6-311++G(3df,2pd)//M06-2X/6-31+G(d,p) method can accurately predict the acid-catalyzed hydrolysis kinetics of ROOHs. This approach provides a reliable framework for predicting the reaction kinetics of other atmospheric ROOHs. Furthermore, the study identifies new functional groups, including -NH₂, -N(CH₃)₂, -OH, -OCH₃, -CH=CH₂, -SH, and -PH₂, substituted at the C _{α} site of the -OOH group, which can enhance the acid-catalyzed hydrolysis kinetics of ROOHs. Notably, the newly identified -NH₂ and -N(CH₃)₂ substituents exhibit a greater enhancing effect than the well-documented -OH and -OCH₃ substituents. Contrary to the assumptions based on chemical intuition, it is clarified that not all nitrogen- or oxygen-containing substituents at the C _{α} site of the -OOH group can equally enhance acid-catalyzed hydrolysis of ROOHs, and the effects depend on the substituents attached to the O or N atoms. Importantly, the structure-activity relationship for commonly encountered substituents was elucidated for the acid-catalyzed hydrolysis kinetics of ROOHs, providing guidelines for qualitatively assessing the feasibility of acid-catalyzed hydrolysis of atmospheric ROOHs in aerosol water. The predicted kinetic data can be incorporated into 3-D chemical models to better simulate the atmospheric aqueous-phase chemistry of ROOHs.

This study also reveals that carbocation intermediates are formed during the acid-catalyzed hydrolysis of some ROOHs. The formed carbocation could further react with anions and organics, which are abundant in ambient aerosols besides water. Our preliminary studies indicate that the reaction of the formed carbocation with abundant sulfate anions is barrierless and exothermic, leading to the formation of less-volatile organic sulfates (Figs. S3-S6 and S13-S19). Meanwhile, these carbocations could also mediate the formation of oligomers and N-heterocycles according to the aqueous-phase carbocations chemistry of the α -dicarbonyls (Ji et al., 2020; Shi et al., 2024; Zhang et al., 2022). These findings emphasize the importance of investigating the impact of acid-catalyzed hydrolysis of ROOHs on aerosol composition and properties. Additionally, the aqueous-phase transformations of atmospheric ROOHs with multiple hydrolysable functional groups should be further investigated.

Data availability. All data were available in the main text or supplementary materials. The other relevant data are available upon request from the corresponding authors.

Author contributions. HX and RY contributed to conceiving the idea, editing, and revision. QZ contributed to conceiving the idea, performing DFT calculations, analyzing results and interpreting data, and writing the original draft.
