Abstract. The western Black Sea shelf, where Danube River contributes the largest river discharge into the Black Sea, is particularly sensitive to river-induced eutrophication, which peaked in the 1980s and 1990s due to human-induced nutrient input. Nutrient input to the western Black Sea shelf and eutrophication is decreasing since the mid-1990s due to the collapse of eastern European economies after 1989 and ongoing mitigation measures to reduce nutrient emissions. The assessment of nutrient inputs to the Black Sea prior to the 1960s however is ~~complicated~~hindered by the scarcity of information on earlier Danube nutrient loads. Thus, to define what pristine conditions have looked like to provide a reference for nutrient reduction targets remains challenging. In this study, we aim to trace modern and historical nitrogen sources to the western Black Sea Shelf during the last ~~~56,000~~~56,000 years with special focus on the past ~~100200~~100200 years, using sedimentary records of TOC, TIC, nitrogen, and $\delta^{15}\text{N}$.

Our results demonstrate that climate effects determine the balance~~relative contribution~~ of riverine nitrogen ~~discharge into the Black Sea on the one hand, and pelagic nitrogen fixation in the pelagic system on the other, seem largely determined by climate effects. Specifically to fuel marine primary production on the NW shelf. Additionally, this balance of riverine N input and N fixation~~ is not only controlled by the ~~concentration~~amount of nutrients discharged by rivers, but also by the freshwater volume itself, which controls the intensity of thermohaline stratification and thereby the timing and intensity of nutrient recycling from the deep basin back into the euphotic ~~epipelagic. Based on analytical data of geochemical and isotopic properties of dated sediment cores, we identified a gradient from the nearshore sediment directly at the Danube Delta, where riverine N is dominant to offshore sediment in 80 m water depth, with pelagic N fixation being dominant in the past. Our results based on stable isotopes also surface water. In cold and dry sub-boreal climate pelagic N-fixation dominates over riverine N discharge, while in warm and wet Atlantic climate riverine N discharge appears as dominant N source to sustain primary production on the NW shelf. Stable nitrogen isotopes further~~ demonstrate the increased deposition of nitrogen from human activities in all stations

Formatiert: Einzug: Links: 1,5 cm, Hängend: 1,5 cm, Abstand Vor: 0 Pt., Nach: 6 Pt.

across the shelf and the concomitant changes in deposition rates of organic matter as indication for perturbations in the epipelagic community due to the human-induced eutrophication. Finally, our stable isotope data indicate that human-induced eutrophication can be traced back to the ~~12th~~ 11th century CE, ~~which raises the question which point in time is a feasible reference for nutrient reduction goals as and highlights that~~ the Danube nutrient ~~loads~~ load was not pristine since at least ~~in the 800~~ 900 years.

1 Introduction

The Black Sea is a semi-enclosed sea, which is connected to the Mediterranean through the Bosphorus. The limited inflow of saline mediterranean water through the Bosphorus in combination with freshwater discharge by ~~the~~ rivers creates a strong thermohaline stratification, which separates the ventilated surface water from oxygen-free, euxinic waters, thereby creating the largest anoxic water body on earth, and hence makes the Black Sea unique. ~~This~~ The oxycline between the ventilated surface water and the euxenic deep water promotes substantial rates of N-loss by bacterial denitrification (Fuchsman et al. 2019) or anammox (Kuypers et al. 2007) in the water column. However, H₂S in euxenic environments reduces the degradability of organic matter (Raven et al. 2018, Kok et al. 2000), which also protects the isotopic signature of nitrogen therein. Additionally, Möbius & Dähnke (2015) found that the plankton community of the Danube River Plume efficiently assimilates nitrogen from the water and thereby outcompetes ammonium oxidising and denitrifying bacteria. This means that the plankton community efficiently keeps the nitrogen in particulate organic matter until it is eventually deposited as organic matter on the shelf sediment close to the Danube Delta so that water column denitrification is not a significant sink of nitrogen on the Danube-influenced shelf.

~~The~~ thermohaline stratification makes the Black Sea ~~very~~-susceptible to climate ~~but also~~ and human pressures. The climatic ~~variability~~ oscillation in the Black Sea region between cold ~~and~~ dry periods and mild ~~and~~ wet winters and periods appears to be governed by the North Atlantic Oscillation (NAO) and East Atlantic-West Russia (EAWR) teleconnection patterns (Oguz et al. 2006). The Black Sea exhibits a ~~very efficient~~ close coupling between ~~the~~ anthropogenic and climatic forcing, as ~~displayed~~ in seen driving the dramatic ecosystem changes that were observed during the 1980s and 1990s (Oguz et al. 2006).

The general circulation of the Black Sea is dominated by the persistent Rim Current, which circulates counterclockwise along the shelf break and horizontally mixes water masses throughout the whole basin (Oguz et al. 2005). Several coastal eddies are part of the Rim Current System and provide additional mixing across the shelf.

The north-western shelf is wider than elsewhere in the Black Sea and is substantially influenced by the discharge of several rivers (Dnipro, Dniester) of which Danube is the most significant. These rivers transport sediments into the coastal zone and the Danube built up a large Delta that spreads out into the Black Sea (Panin et al. 2016, Constantinescu et al. 2023).

65 Additionally, Danube is the largest source of freshwater to the Black Sea, and the discharge intensity directly affects the salinity
gradient in the surface water particularly in the western the Black Sea and thereby the intensity of stratification. The degree of
stratification controls the vertical mixing and thus the ventilation of the deep water with oxygen and also the replenishment of
N and P in the euphotic zone at the surface, which determines the susceptibility of Black Sea biogeochemical cycles to climate
forcing. A high discharge of freshwater due to Atlantic climate intensifies the stratification and results in an upward shift of
70 the oxycline and a reduced availability of nutrients in the surface water of the central Black Sea and higher availability of
riverine nutrients in the river plume (Fulton et al. 2012). Conversely, low discharge of freshwater in boreal climate results in
a deep oxycline and the upwelling of deep water that is enriched in phosphorous and depleted in nitrogen (Fulton et al. 2012).
Upwelling of low N and high P deep water into the surface water reduces the molar N:P ratio, which favours N-fixation
(diazotrophy) and thereby reduces the ~~contributionproportion~~ of riverine N in fuelling primary production (Fuchsman et al.
75 2008).

The Danube River ~~representsis~~ the second-largest river in Europe and hence drains a vast catchment area, which has been
intensively used by humans since several millennia and thereby ~~turned-thatmade this t river-into~~ a significant source of nutrients
to the north-western shelf. The increase in European population with spread of agricultural activities peaking first around 250
80 yr AD, resulted in significant deforestation in central Europe, ~~causing erosion~~ and ~~hence,~~ growth of river deltas (Maselli &
Trincardi 20232013, Kaplan et al. 2009). That sediment transported towards the sea ~~leadled also~~ to increased nutrient transport
and hence, pre-industrial eutrophication. The recent eutrophication of Danube accelerated in the 1960 – 1990 CE period, during
the ‘green revolution’), which resulted in a significant eutrophication of the north-western Shelf and a degradation of habitats
there (Kovacs & Zavadsky, 2021). ~~Remediation measurements since the early 1990s CE 2021). The collapse of east- European~~
85 ~~economies after 1990 CE and remediation measures later~~ led to a substantial decrease of the Danube DIN load, which is now
below the level of 1960 (Kovacs & Zavadsky, 2021). ~~Consequently,~~ Möbius and Dähnke (2015) investigated present-day
nutrient inputs to the shelf and argued that the majority of riverine DIN is now taken up ~~by primary production~~ in the river
plume and ~~that~~ the nitrogen load ~~isbeing~~ exported to the shelf ~~asin~~ organic matter.

90 In this paper, we use nitrogen isotopes to identify nitrogen sources. Analysis of stable isotopes is a versatile tool as ~~they-haveit~~
~~provides~~ distinct isotopic signatures; (Kendall et al. 2007), which are expressed using the delta notation in the following.
~~ForThe delta notation expresses the isotopic ratio of an element in a start-nitrogensample (e.g. $^{15}\text{N}/^{14}\text{N}$) in relation to the~~
~~isotopic ratio in a standard material, and it was designed to conveniently express the variability of isotopic ratios in natural~~
~~systems in which the range is very small (McKinney et al. 1950). Nitrogen~~ in ammonium and nitrate from fixation of
95 atmospheric N_2 is isotopically light with $\delta^{15}\text{N}$ values around 0 ‰ (Zhang et al. 2014). This signature is preserved in
organisms such as algae, which assimilate dissolved DIN to produce organic nitrogen compounds. However, molecules with
the lighter ^{14}N tend to diffuse and react slightly faster than molecules with the heavier ^{15}N , which results in kinetic fractionation
and slightly increases the relative concentration of ^{14}N in the product while ^{15}N is enriched in the remaining substrate.

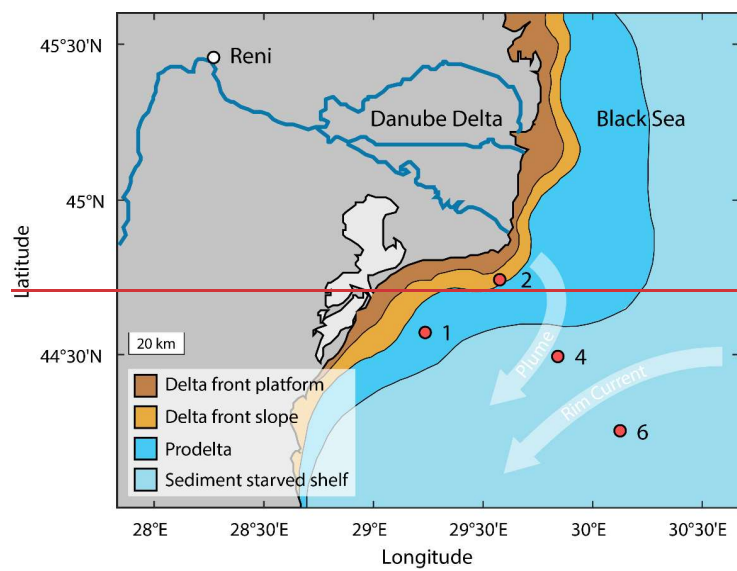

Consequently, the initial isotope signature evolves as the nitrogen is propagating through different pools. The fractionation effects of serial turnover accumulate and cause that ammonium in soils is isotopically enriched to $\delta^{15}\text{N}$ values in the range of 5 to 10 ‰, while nitrogen in manure and sewage can be isotopically enriched up to 30–25 ‰ (Kendall et al. 2007). Since the isotopic signature of a nitrogen pool reflects the combined effects of its history such as sources, turnover, and mixing, conclusions about the environment can be drawn from isotopic analyses. Johannsen et al. (2008) and Bratek et al. (2020) demonstrated that the $\delta^{15}\text{N}$ value of riverine nitrate is closely related to the intensity of anthropogenic land use. Dähnke et al. (2008b) and Serna et al. (2010) used the ^{15}N signature of anthropogenic nitrogen to identify the onset of human-induced eutrophication of River Elbe in sediment of North Sea and Skagerrak. Similarly, Anderson and Cabana et al. (2006) demonstrated that the $\delta^{15}\text{N}$ value of riverine nitrate is also related to the DIN load. ~~We~~In the following, we will apply this method to ~~plankton-biomass~~organic matter that was deposited to the sediment from the Danube-influenced shelf to reconstruct nitrogen sources to this part of the Black Sea. Specifically, we will combine observations on N isotopes and nitrogen content to identify sources and processes. For example, if the $\delta^{15}\text{N}$ value changes but the N content remains stable, then this indicates a change in the N source. For another example, if the $\delta^{15}\text{N}$ increases and the N content decreases, then this indicates the effect of remineralisation (Möbius et al. 2013).

~~We~~The present study aimed to ~~reconstruct~~identify present and historic nitrogen sources to the Danube-influenced north-western (NW) shelf of the Black Sea by analysing sediment cores along a transect from the Danube Delta towards the shelf break. ~~The sediment along this transect reflects~~Similar studies by Fulton et al. (2012) and Cutmore et al. (2025) focussed on sediment from the deep basins and the continental slope of the Black Sea but did not cover the north-western shelf where the major rivers discharge into the Black Sea. Aiming to close this gap, our samples along a transect from the Danube Delta towards the shelf break reflect the gradient from a dominant influence of the Danube River Plume to the dominant influence of water masses from the open Black Sea, which ~~both~~ imprint the specific signature of their respective nitrogen sources into the sediment record. We ~~have~~ analysed the sediment for ~~contents of~~ organic carbon and nitrogen, and the composition of stable nitrogen isotopes to identify natural and anthropogenic nitrogen sources over the past 5000–7000 years.

2 Material & Methods

2.1 Working area and samples

Sampling was performed in early May 2016 during R/V Mare Nigrum cruise MN 148 in the Romanian Shelf area at four stations that span a transect from nearshore to offshore (Tab. 1, Fig. 1). The water depth at the sampling stations ranged from 22 m (Station 2) to 80 m (Station 6). From each station, sediment cores (20–40 cm length, 6 cm in diameter) were taken with a Multicorer. The sediment cores were immediately sliced in 1 cm intervals and frozen for further analysis. The sediment from stations 4 and 6 was wet sieved through a 400 μm sieve after slicing to collect mussel shells for radiocarbon dating. The <400 μm fraction was freeze-dried and homogenized for analysis of $\delta^{15}\text{N}$, organic carbon and nitrogen content.

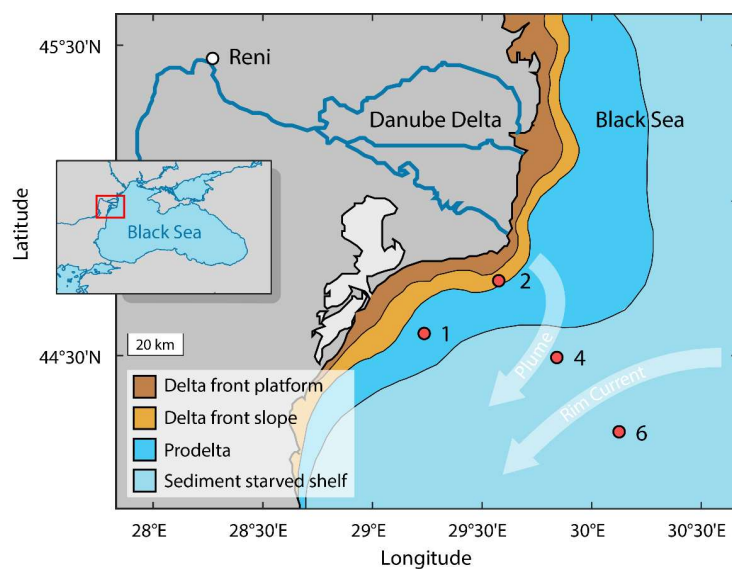

Figure 1: Map showing the sampling stations of the sediment cores 1, 2, 4 and 6 in the northwestern Black Sea during RV Mare Nigrum cruise 148 and major depositional units of the Danube Delta (after Panin et al. 2016). The light arrows indicate the general surface water currents of Danube River Plume and Rim Current. The insert map indicates the study area (red rectangle) within the Black Sea area.

Table 1: Summary of meta data of sediment cores from Mare Nigrum cruise 148.

Core	Latitude	Longitude	Water depth (m)	Core length (mcm)
1	45° 58.4	29° 18.8'	30	42
2	44° 74.9	29° 58.2'	2722	35
4	44° 49.9	29° 84.8'	62	29
6	44° 25.2	30° 13.1'	80	27

2.2 Analyses of sediment samples

- 145 The sediment samples were analysed for total carbon and total nitrogen content with an elemental analyser (Carlo Erba NA 1500) via gas chromatography, calibrated against acetanilide. The total organic carbon content (TOC) was analysed after a threefold removal of inorganic carbon using 1 mol L⁻¹ hydrochloric acid. Sediment carbonate content was then calculated as the difference of total carbon content and TOC content. The standard deviation of sediment samples was ~~better~~less than 0.6% for TOC and 0.08 % for nitrogen.
- 150 Nitrogen isotope analyses were performed with a CE 1108 elemental analyser (ThermoFinnigan) connected to a mass spectrometer (Finnigan 252) via a split interface (Conflow). Two international standards were used for calibration (IAEA-N1: $\delta^{15}\text{N} = 0.4 \text{ ‰}$, IAEA-N2: $\delta^{15}\text{N} = 20.3 \text{ ‰}$), and an additional, internal standard was measured for further quality assurance. The standard deviation for repeated measurements was $< 0.2 \text{ ‰}$.

2.3 Radiocarbon Dating

- 155 The radiocarbon ages of organic sediment (TOC) were obtained from 2 bulk sediment samples from Station 4, and 6 bulk sediment ~~slieessamples~~ from Station 6. Additionally, 6 bivalve shells from different sediment layers of Station 6 (two samples of *Modiolula phaseolina* and four samples of *Mytilus galloprovincialis*) were analysed to date the carbonate. These two species were used because the top 8 cm of the sediment are characterized by *Modiolula phaseolina*, whereas *Mytilus galloprovincialis* is dominant in deeper layers. The radiocarbon analyses were carried out at Beta Analytic Inc., U.K., following standard procedures for accelerator mass spectrometry (AMS) radiocarbon dating. The radiocarbon ages are corrected for $\delta^{13}\text{C}$.
- 160 ~~Calibration of the radiocarbon~~Radiocarbon ages were calibrated to years ~~BP~~before present (0 a ~~BP~~BP₁₉₅₀ = 1950 CE) ~~is according to using the age~~Marine20 calibration ~~of Stuivercurve~~ (Heaton et al. 2020), 1998. The sample ages were further corrected with a reservoir age of ~~500 ± 40~~111 ± 63 years (Siani et al. 2000N = 5), based on data from Romanian and Bulgarian

shelf sediment as provided by the Marine Reservoir Correction Database (Reimer & Reimer 2001). The age of sediment samples between dated samples was estimated by linear interpolation.

2.4 Radiometric measurements ²¹⁰Pb, ¹³⁷Cs Dating

For ¹³⁷Cs, ²²⁶Ra, and ²¹⁰Pb measurement low-level gamma spectrometry was used. Sample preparation was carried out as described in Bunzel et al. (2020). Briefly, the cores were sectioned into slices of 1 cm thickness and frozen during transportation and storage. Each section was dried and homogenized by a ball mill. Aliquots of each sample were sealed in gas-tight Petri dishes and stored for minimum 28 days for equilibration of Radium-226 with daughter isotopes ²²²Rn, ²¹⁴Pb and ²¹⁴Bi. Measurements were performed by a High-purity low-level germanium detector (BE 3830P-7500SL-ULB Mirion Technologies / Canberra, Ruesselsheim, Germany). Measurement times varied between 90 000 s - 600 000 s depending on sample activity. For calibration an artificial reference material was prepared from silica gel and reference solutions of ¹³⁷Cs and ²²⁶Ra. (Eckert & Ziegler Nuclitec GmbH, Braunschweig, Germany). Sediment ages were calculated from ²¹⁰Pb results according to the CRS model (Appleby & Oldfield 1978), assuming a constant rate of supply of atmospheric ²¹⁰Pb. For consistent use of units, all ²¹⁰Pb dating results are stated in years before present with 1950 CE as 0 (in a BP₁₉₅₀).

2.5 Data integration and analyses

Sediment ages of cores 1 and 2 are based on results of Constantinescu et al. (2023), which sampled the same stations simultaneously and applied ²¹⁰Pb and ¹³⁷Cs dating. Observed Danube DIN loads are based on data from Kovacs & Zavadsky (2021), which presented DIN loads at Reni station at the upstream margin of the Danube Delta (Fig. 1). Both datasets were mapped to the corresponding sediment depths of cores 1 and 2 by linear interpolation. As the result, an interpolated ²¹⁰Pb / ¹³⁷Cs age and an interpolated DIN load was assigned to each of our sediment measurements of cores 1 and 2.

Using the interpolated DIN load and measured sediment N concentration, we derived two linear models from the DIN load – sediment N content correlation: Model 1 without y- intercept and Model 2 with y intercept. From the DIN load – $\delta^{15}\text{N}$ correlation, we derived Model 3.

The apparent isotopic fractionation factor (ϵ) was calculated by means of Rayleigh plots (Möbius 2013). From the analysed subset of sediment samples, we used the largest value of the total N content as the reference for the calculation of the remaining fraction (f), which consequently plots at the coordinate origin.

Based on $\delta^{15}\text{N}$ vs. N content plots we visually identified sediment layers with similar conditions. The underlying assumption was that in periods with a roughly constant trend in $\delta^{15}\text{N}$ vs. N content indicates that a particular condition dominated during this period.

hat formatiert: Hochgestellt

2.6 Data transformation

The age data in Figure 7 were log transformed to emphasise the results from the most recent centuries. The data include age values after 1950 CE, which have a negative sign on the BP₁₉₅₀ scale and can't be log transformed. All plotted age data were thus converted to the BP₂₀₂₀ scale where 0 a BP₂₀₂₀ refers to the year 2020 CE. The axis labels correspond to the BP₁₉₅₀ scale, so that when reading data from the diagram, the age data is displayed in the BP₁₉₅₀ scale.

3 Results

3.1 Radioisotope measurements and dating

205 **3-Results**

3.1-Radioisotope-measurements-and-dating

Sediment organic matter at Station 4 was dated ~~4030 ± 50 years~~1035 ± 97 a BP at 7.5 cm core depth and ~~2580 ± 50 years~~2837 ± 98 a BP at 16.5 cm core depth by radiocarbon (¹⁴C) dating. The age of organic sediment at Station 6 spans from ~~60 ± 50 years~~137 ± 93 a BP at the sediment surface to ~~4880 ± 50 years~~5679 ± 104 a BP at 16.5 cm depth. Radiocarbon-based ages of bivalve shell carbonates at Station 6 span from ~~3130 ± 50 years~~3504 ± 108 a BP at the sediment surface to ~~5070 ± 50 years~~5880 ± 110 a BP at 16.5 cm depth. The results of radiocarbon dating are summarised in Table 2 and plotted in Figure 2. At Station 6, dated carbonates were systematically older than the organic sediment, and this difference was larger at the sediment surface than at depths (Tab. 2, Fig. 2). Ultimately, organic sediment and carbonate shells represent two different carbon pools, which are affected individually by early diagenesis. In the following, we will focus only on the organic sediment. No radiocarbon measurements were performed on sediment of Station 1 and 2.

~~Additionally, Additional to ¹⁴C, we measured ¹³⁷Cs and unsupported ²¹⁰Pb~~were measured in Station 4 sediment, where unsupported ²¹⁰Pb was highest at the sediment surface (306 Bq / kg dry sed.) and decreased exponentially with depth. ²¹⁰Pb was below detection limit below 4 cm sediment depth (Fig. 2). The estimated sediment ages ranged from -75 a BP at 0.5 cm sediment depth to 44 a BP at 3.5 cm sediment depth. Similarly, ¹³⁷Cs activity was highest at the sediment subsurface (79 Bq / kg dry sed.), but was detectable to deeper sediment layers than unsupported ²¹⁰Pb (Fig. 2). No ²¹⁰Pb and ¹³⁷Cs measurements of sediment from Station 6 ~~is~~are available.

Table 2: Results of radiocarbon dating of ~~bulk~~organic sediment and carbonate shells from Cores 4 and 6.~~The uncertainty of conventional ¹⁴C dates was generally ± 30 a, and for calibrated calendar years ± 50 a, respectively age ± 1 sd, using Marine20 and ΔR = -111 ± 63 a. 0 a BP equals 1950 CE.~~

Measurements of unsupported ^{210}Pb (orange circles) and ^{137}Cs (blue circles). Numbers along ^{210}Pb plot indicate sediment age according to CRS model. No ^{210}Pb or ^{137}Cs data are available for Core 6.

3.2 Sediment cores

The characteristics of sampled sediment reflected the proximity of the respective stations to the shore and the Danube Delta. Station 1 was in the shallow Prodelta (Fig. 1), where the sediment was layered mud with various shades of grey, and black layers at 28 cm, 37 cm, 41 cm, and 44 cm sediment depth. Living *Mytilus* bivalves were found at the top layer and empty *Mytilus* shells within the black layers. Core 2 was sampled from the delta front slope (Fig. 1), and sediment was layered mud with various shades of beige, grey, and black. The sediment record of core 2 is affected by the sharp increase of sand content in some layers, which are the result of increased transport of sand from the Sfântu George branch due to the cutting off all the meanders in Sfântu Gheorghe between 1984 and 1988, which led to an accelerated flow, riverbed erosion and transport of coarser sediment in the main channel of that branch. Stations 4 and 6 were in-are located on the sediment staved shelf (Fig. 1) where sedimentation rates were are lowest. In Core 4, the top 0-3.5 cm were *Modiolula* shells in grey mud, then grey mud without shells down to 6 cm, and light grey mud from 6 to 26 cm sediment depth. Similarly in Core 6, *Modiolula* shells in mud

hat formatiert: Schriftart: Kursiv

hat formatiert: Schriftart: Kursiv

hat formatiert: Schriftart: Kursiv

hat formatiert: Schriftart: Kursiv

were found at the top 0-5 cm, followed by light grey mud in 5-10 cm, and grey mud in 10-15 cm sediment depth. In 15-20 cm sediment depth, we found dark grey mud, and black mud with *Mytilus* shells in 20-25 cm depth.

hat formatiert: Schriftart: Kursiv

3.3 Bulk sediment characteristics

Generally, N stable isotopic composition of sediment ($\delta^{15}\text{N}$) follows a gradient from the shore towards to open Black Sea: The entire nearshore sediment cores of stations 1 and 2 are isotopically enriched (mean $\delta^{15}\text{N} = 6.7\text{‰}$) with respect to atmospheric N_2 ($\delta^{15}\text{N} = 0.0\text{‰}$), while the distant stations were isotopically less enriched and were as light as 1.6 ‰. The nearshore sediment cores had higher concentration in organic matter than the more offshore cores.

hat formatiert: Hochgestellt

hat formatiert: Hochgestellt

hat formatiert: Tiefgestellt

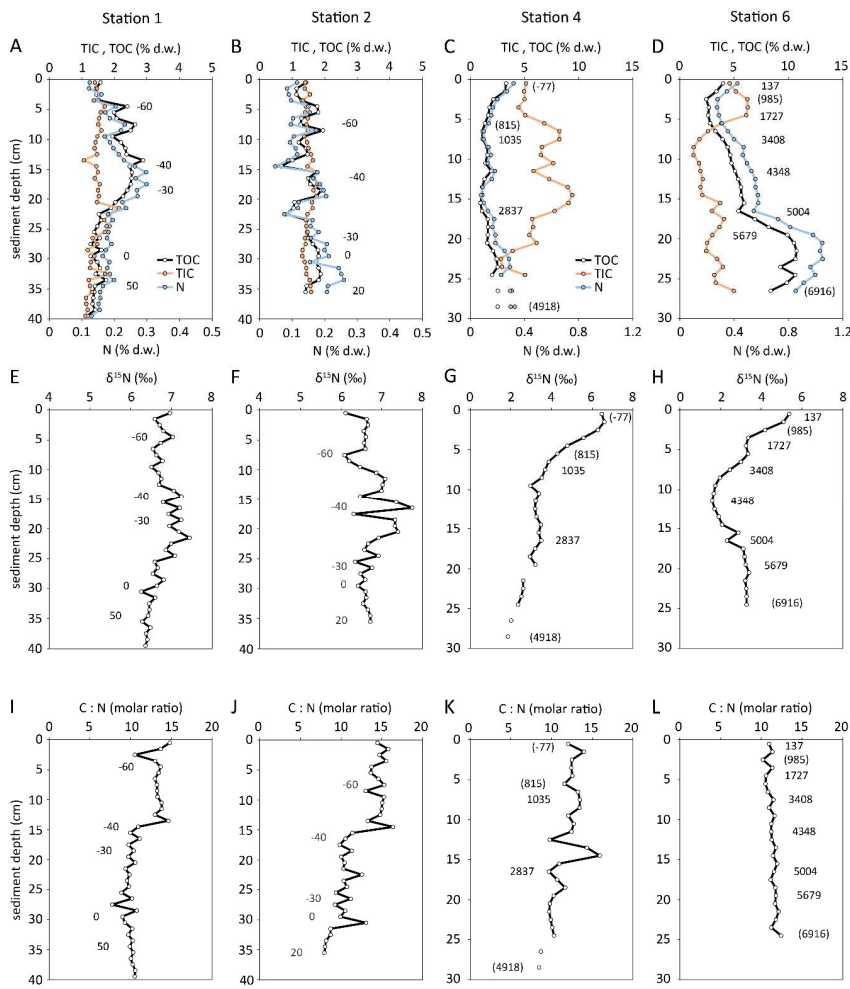

hat formatiert: Hochgestellt

Sediment from stations 1 and 2 was distinct from stations 4 and 6 ~~with respect to parameter values and their trends with~~. While sediment ~~depth close to the delta at stations 1 and 2 consisted of silt, silty clay and very fine sand, the sediment starved shelf station 4 and 6 sediment consisted of shelly clay (*Modiolula* and *Mytilus*)~~. In detail, sediment at station 1 had ~~comparatively low~~ contents of TOC (1.2 – 2.9 % d.w.), TIC (1.1 – 2.1 % d.w.), and N (0.12 – 0.30 % d.w.). While TOC and N had a maximum in 17 cm sediment depth, TIC had no discernible variation with sediment depth. The molar TOC / N ratio decreased from 15 at the sediment surface to 8 at ~~35~~ 18 cm sediment depth, ~~and increased again to 10 at 35 cm~~. Sediment at station 2 was similarly low in TOC, TIC, and N ~~and content~~ had only small variation with sediment depth. TOC contents were in the range of 0.7 to 1.9 % dry weight, the TIC contents in the range of 1.3 to 1.8 % dry weight, and N contents in the range of 0.05 to 0.26 % dry weight. The molar TOC / N ratio increased significantly from 8 at 35 cm sediment depth to 15 at the sediment surface, while no significant variation in $\delta^{15}\text{N}$ values was observed (Fig. 3). The stations 4 and 6 on the continental slope were markedly different from stations 1 and 2. At station 6, small shell fragments of the bivalve *Modiolula phaseolina* were present in the upper 8 cm. Below 8 cm depth, bivalve shells of *Mytilus galloprovincialis* were found. At these stations, the organic carbon and nitrogen content decreases in the upper 3 to 7 cm of the cores (TOC 1.1 to 4.0 %; N 0.10 to 0.42 %, Fig. 3). At station 4, there is a slight increase in organic carbon (1.0 to 2.5 %) and nitrogen (0.10 to 0.30 %) content below 7 cm depth. The TOC and TN contents strongly increased with depth at station 6 (TOC: 2.7 to 9.2 %, N: 0.3 to 1.0 %). In contrast, the molar TOC / N ratios decreased with sediment depth at station 4 and slightly increased with depth at station 6 (Fig. 3 K, L).

hat formatiert: Hochgestellt

hat formatiert: Schriftart: Kursiv

hat formatiert: Schriftart: Kursiv

Based on $\delta^{15}\text{N}$ vs. N content plots, we identified 4 zones with distinct trends of N content and N isotopic signature. Zone 1 is the uppermost sediment layer where N content increased towards the sediment surface and N isotopes were most enriched (Fig. 4, filled circles). This was the only zone we could identify in the coastal stations 1 and 2. In the offshore stations 4 and

hat formatiert: Hochgestellt

280

6, Zone 2 further below has decreasing N content and increasing $\delta^{15}\text{N}$ values (Fig. 4, open circles). Zone 3 was present only at station 6 and has constant N content but decreasing $\delta^{15}\text{N}$ values, which were as low as -1.6‰ (Fig. 4, closed triangles). Zone 4 is characterised by decreasing N content but constant $\delta^{15}\text{N}$ values of 3.3‰ (Fig. 4, open triangles). The measurements of sedimentary $\delta^{15}\text{N}$ and N content from Zone 2 (see Fig. 4, open circles) from Stations 4 and 6 were further analysed for the apparent isotope enrichment factor (ϵ) by means of Rayleigh plots. The estimated values were $\epsilon = -1.1 \pm 0.2\text{‰}$ for Station 4, and $\epsilon = -3.0 \pm 0.3\text{‰}$ for Station 6, respectively (Fig. 5).

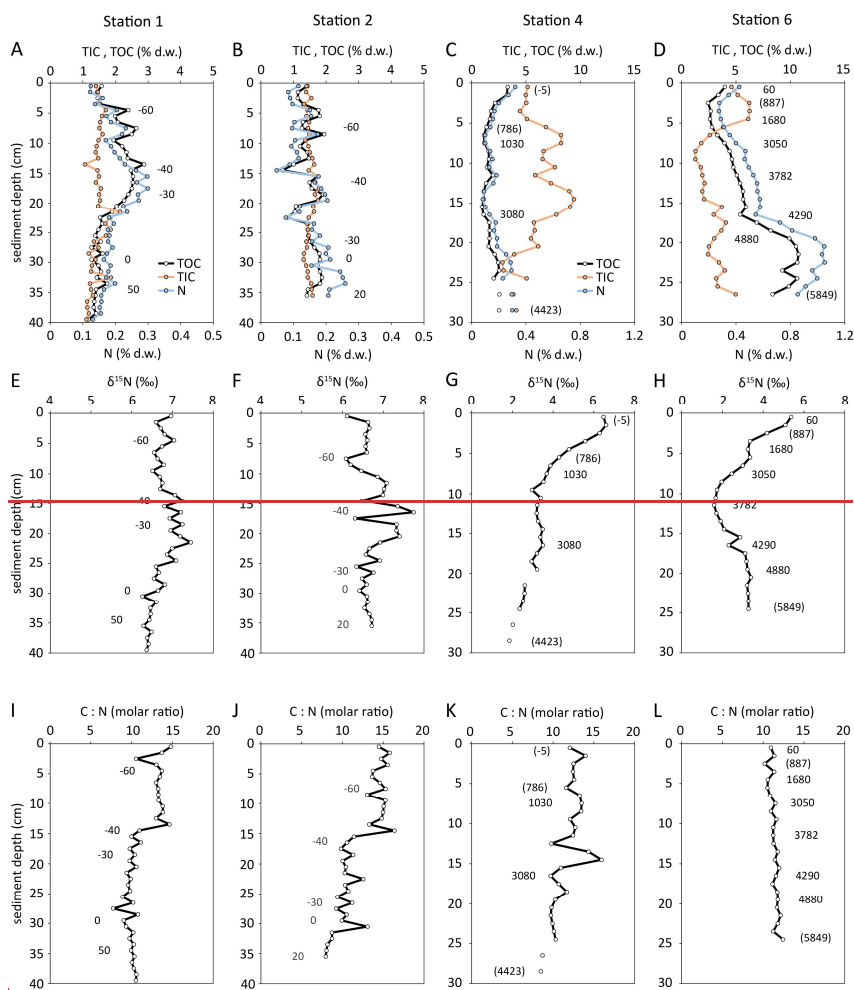

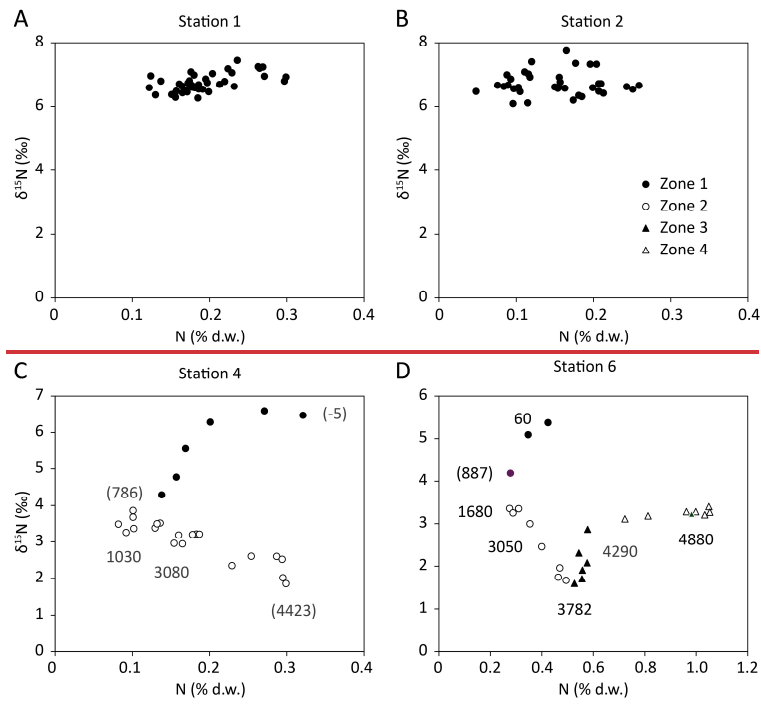

Figure 3: From Stations 1-6, depth profiles of TIC (carbonate), TOC (organic sediment), total nitrogen (panels A - D), measured $\delta^{15}\text{N}$ values of bulk sediment (panels E - H), and molar TOC / N ratio of organic sediment (panels I - L). Numbers refer to the sediment age BP (0 a BP = 1950 CE, negative age values are after 1950 CE, positive age values are before 1950 CE), based on ^{210}Pb (Stations 1, 2) and ^{14}C (Stations 4, 6). Numbers in parentheses were estimated by linear interpolation.

3.4 N isotope signatures

Based on the $\delta^{15}\text{N}$ vs. N content plots of Figure 4, we identified 4 zones with distinct trends in N content and $\delta^{15}\text{N}$ value. At the sediment surface, N content increased towards the sediment surface and N isotopes were most enriched (Fig. 4, filled circles), and we reference this sediment layer as Zone 1 in the following. Zone 1 comprised the whole sampled sediment column at the coastal stations 1 and 2, and sediment in this layer had $\delta^{15}\text{N}$ values in the range 6 – 7 ‰ and N content around 0.2 % (Fig. 4 A, B). In the deeper stations 4 and 6, $\delta^{15}\text{N}$ values were in the range 4 – 6.5 ‰ and N content roughly around 0.3 % (Fig. 4 C, D). Zone 1 reaches back until ca. 900 a BP (Fig. 4 C, D). Below the sediment layer of Zone 1, the trend of $\delta^{15}\text{N}$ vs. N content changes clearly. The $\delta^{15}\text{N}$ values still increased towards the surface, but the N content decreased, and we refer to this sediment layer as Zone 2. The $\delta^{15}\text{N}$ values increased from ca. 2 ‰ to ca. 4 towards the surface, while the N content decreased from ca. 0.4 % to 0.2 % (open circles in Fig. 4 C, D). Since the trend of $\delta^{15}\text{N}$ vs. N content in the sediment layer indicates kinetic fractionation by remineralisation, data from this layer were further analysed for the apparent isotope enrichment factor (ϵ) by means of Rayleigh plots. The estimated values were $\epsilon = -1.1 \pm 0.2$ ‰ for Station 4, and $\epsilon = 3.0 \pm 0.3$ ‰ for Station 6, respectively (Fig. 5). In Core 4, this Zone went back to 4.9 ka BP, and in Core 6 back to 4.3 ka BP.

The Zones 3 and 4 were only present at station 6. Sediment in the layer of Zone 3 was characterized by a constant N content of ca. 0.6 % while $\delta^{15}\text{N}$ values were decreasing from ca. 3 ‰ down to 1.6 ‰ (Fig. 4 D, closed triangles). This layer was dated 5.0 ka BP to 4.3 ka BP. Zone 4 is characterised by N contents that decreased from ca. 1.1 % down to 0.6 %, while $\delta^{15}\text{N}$

values were constant at ca. 3.3 ‰ (Fig. 4, open triangles).

Zone 4 comprised sediment from the bottom end of the core with an age of 6.9 ka BP to sediment with an age of 5.0 ka BP.

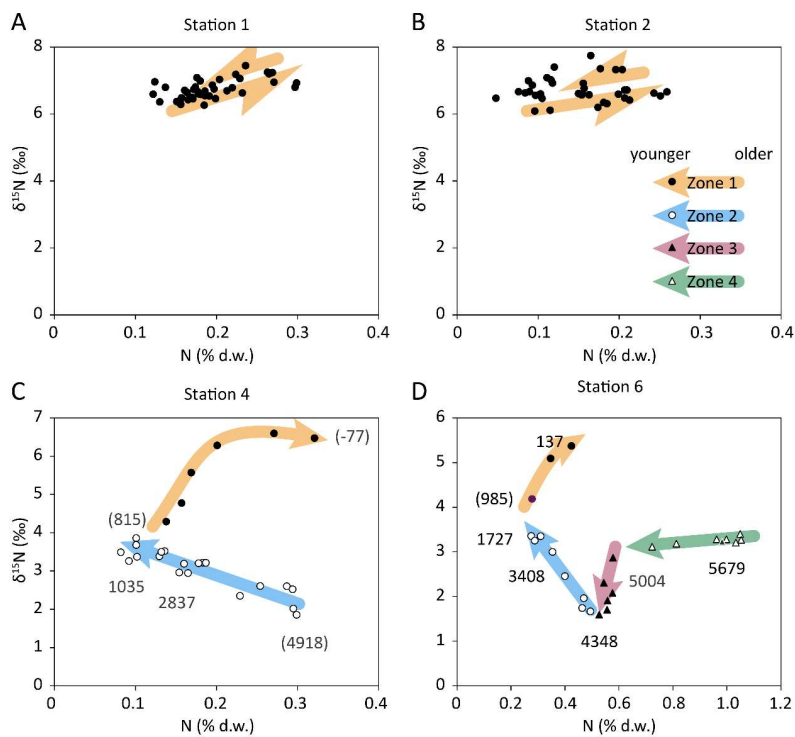

Figure 4: Sedimentary $\delta^{15}\text{N}$ vs. sedimentary nitrogen concentrations at Station 1 (A), Station 2 (B), Station 4 (C), and Station 6 (D). The different symbols indicate different process zones within the sediment column: Zone 1) filled circles indicate modern eutrophication, Zone 2) open circles indicate diagenetic enrichment, Zone 3) filled triangles indicate the gradual transition between two isotopically distinct nitrogen sources, and Zone 4) open triangles indicate Unit II sapropel. Numbers refer to the ^{14}C -based sediment age, numbers in parentheses were estimated by linear interpolation. Coloured arrows represent the arrow of time for distinct trends of $\delta^{15}\text{N}$ vs. N content.

Figure 5: Rayleigh plots of $\delta^{15}\text{N}$ vs. sedimentary N content of samples from Zone 2 of Stations 4 and 6 (see also Figure 4 C, D, open circles).

3.3 Correlation analyses

3.5 Danube DIN load models

The correlation of Danube DIN loadloads with sediment N contentcontents and $\delta^{15}\text{N}$ values in the nearshore cores 1 and 2 at a given time was examined to develop a simple empirical model for reconstructing historical DIN loads for the period before measurements are available. Using core 2, no meaningful correlation was found (not shown). Using core 1, the DIN load of Danube at Reni station (Kovacs & Zavadsky, 2021) correlated significantly with the bulk N content (Pearson's $R = 0.80$) and less significant with $\delta^{15}\text{N}$ (Pearson's $R = 0.35$). We derived two linear models from the DIN load—sediment N content correlation: Model 1 without y-intercept and Model 2 with y-intercept. From the DIN load— $\delta^{15}\text{N}$ correlation, we derived model 3. The N content-based Models 1 and 2 reconstruct the had average residuals with respect to observed DIN loads of the 1955–2015 period reasonably well $36 \pm 26 \text{ kt / yr}$ and $42 \pm 31 \text{ kt / yr}$, respectively (Fig. 6 B, D). The average residuals of the $\delta^{15}\text{N}$ -based Model 3 reconstructs the observed DIN load less accurately were $61 \pm 33 \text{ kt / yr}$ (Fig. 6 F). For the period 1800–1950, all three models reconstructed estimated that the Danube DIN load was 236 to 318 kt / yr in 1800 CE and increased gradually with 0.2 to 0.5 kt / yr².

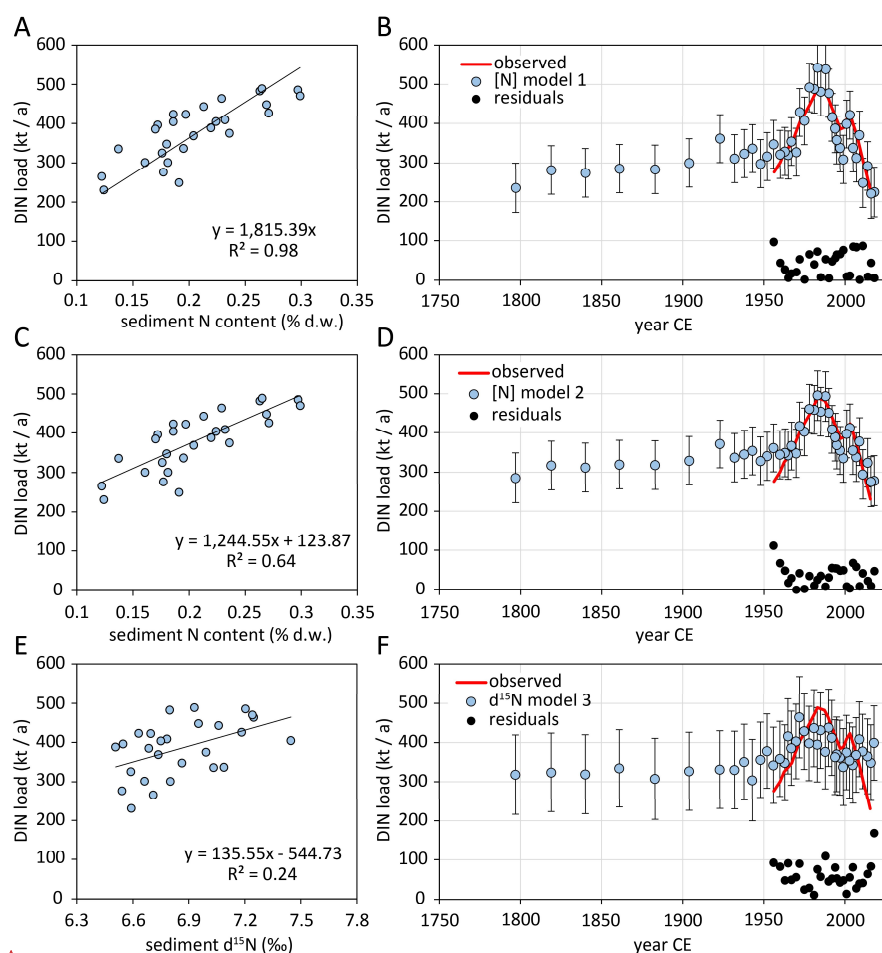

Figure 6: Linear correlations of Danube DIN loads with sediment N content at station 1 at a given time, based on sediment dating (Constantinescu et al. 2023) (A, C) and sediment $\delta^{15}\text{N}$ values (E), and reconstructed DIN loads based on these correlations (B, D, F). Error bars indicate prediction intervals with 90 % confidence. Red plotslines indicate DIN observation data for 1955 – 2015, data from Kovacs & Zavadsky (2021).

4 Discussion

4.1 Sedimentary signatures Overview

Based on $\delta^{15}\text{N}$ and N content measurements on sediment from the NW shelf we identified four distinct sediment layers where each one is characterised by a distinct combination of $\delta^{15}\text{N}$ and N content dynamics (Fig. 4), and we thus assume that these four layers represent the record of distinct conditions on the NW shelf. In the following, we will interpret the data from these four Zones and discuss the implications for the major events–nitrogen sources for the primary productivity on the shelf during these periods

We start by combining data from cores 1, 4, and 6 into a joint plot to construct a composite timeline plot (Fig. 7) and to read the sediment record imprinted in the Black–Seanorthwestern shelf. We excluded data from Core 2 due to the absence of correlation of Danube DIN load and sedimentary N content and $\delta^{15}\text{N}$ (see results, 3.3). The individual $\delta^{15}\text{N}$ plots are matching well in periods where the plots are overlapping and the continuity of the composed $\delta^{15}\text{N}$ plot suggests that organic matter in the water column was mixed across the entire shelf prior to deposition on the sediment (Fig. 7). Similarly, we combined the N content data from cores 1, 4, and 6, and found systematic offsets between the cores (Fig. 7) in the sense that sediment farther from the delta had higher N content than sediment from the same period that was deposited closer to the delta. However, we still find simultaneous variations of N content over time, which we interpret as a result of higher deposition rates of terrigenous material closer to the delta. The corresponding sedimentation rates of terrigenous matter were up to 10 mm yr^{-1} close to the delta (Constantinescu et al. 2023) and as low as 0.03 mm yr^{-1} (Tab. 2) at the deeper shelf. The higher sedimentation rates closer to the delta effectively diluted the deposited organic matter more than the low sedimentation rates did farther from the delta. The Black Sea has experienced several major events in the past 10 ka, which imprinted their specific signatures into Now we continue to discuss our observations from the four distinct $\delta^{15}\text{N}$ / N Zones (Fig. 4) individually to elucidate how variations in climate forcing, stratification of the water column, and human activity are reflected in the sediment record of the deep basins. However, as the NW shelf.

Formatiert: Standard

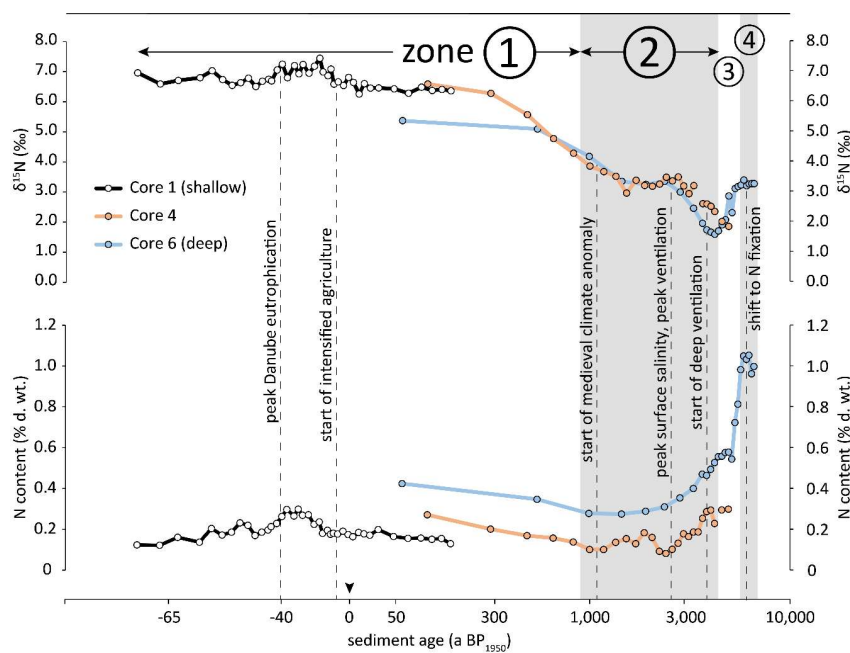

Figure 7: Evolution of N content and $\delta^{15}\text{N}$ values in sediment cores in our study were retrieved 1, 4 and 6 from the shallow-nearshore shelf and the upper NW shelf slope, we discuss. Grey and white backgrounds indicate $\delta^{15}\text{N} / [\text{N}]$ zones 1 – 4, additionally marked by circled numbers. Vertical dashed lines mark significant events mentioned in the following discussion. Age scale is log transformed (see methods 2.6 for details).

4.2 the extend of the influence of basin-wide events on the nearshore sediment records. Since we sampled the most offshore and Strong stratification and sapropel formation: 6.9 - 5.7 ka BP

The oldest sediment we found in our cores dates back 6.9 ka BP at station 6, we start with this sediment record.

At 5.8 ka BP, which is the age of the oldest sediment we have analysed at station 6 that time, the Black Sea was influenced by a humid Atlantic climate, which led to with high freshwater discharge, input from the rivers and seawater influx from the Mediterranean through the Bosphorus, leading to a strong thermohaline stratification, and a shallow chemocline. The

reconstructed $\delta^{15}\text{N}$ value of phytoplankton during this period was in the range of 1.4 to 4.4 ‰ (Fulton et al. 2012). The Unit II b sapropel was deposited in the Black Sea basins during this phase, and we found similarly high TOC values in Core 6 and a matching $\delta^{15}\text{N}$ value of 3.3 ‰ in sediment of this age (Fig. 3). ~~We thus conclude that the N/ $\delta^{15}\text{N}$ trend of Zone 4 (Fig. 4, open triangles) is equivalent with sediment unit II b.~~

The Atlantic phase lasted until approx. 5.1 ka BP, when the climate became colder and dryer. This sub-boreal climate resulted in substantially reduced riverine input, a weaker salinity gradient and thus a deeper circulation, which enhanced the pelagic ventilation. The concomitant upwelling of N-deficient and P-enriched water reduced the N:P ratio in the euphotic zone to 3.5–6, and the reconstructed $\delta^{15}\text{N}$ value of phytoplankton during this period ~~shallow chemocline at that time~~ was in the range of 0.3 to 2.1 ‰ (Fulton et al. 2012). Although the basin-wide influx of riverine nutrients was reduced during this period, we found the highest rates of mass accumulation and carbon accumulation at this time (4.3 ka BP to 3.8 ka BP), and we conclude that the N/ $\delta^{15}\text{N}$ trend of Zone 3 (Fig. 4, closed triangles) is equivalent with sediment unit II a. The deeper ventilation of the pelagic resulted eventually in the oxygenation of the bottom water on the shelf and thus enabled enhanced diagenesis in the water column and of the upper sediment layer. The result is advanced remineralisation of the sedimented organic matter with the corresponding N/ $\delta^{15}\text{N}$ trend of Zone 2 in cores 4 and 6 (Fig. 4, open circles). ~~confirmed by Cutmore et al. (2024) have not detected the proxy for H_2S in the photic zone during this period (3.9–2.7 ka BP), which agrees with the time frame of Zone 2 in our samples. However, it seems that bottom water oxygenation happened at approx. 4.4 ka BP in the shallower station 4 (62 m) and thus significantly earlier than at the deeper station 6 (80 m) at which marked remineralization did not occurred before 3.8 ka BP. The differences in the onset of remineralisation on the shelf could indicate the rate at which the oxycline descended. The deposition of eoccoliths started during in this period (Hay et al. 1991, Coolen 2011), which is marked by and we find a substantial increase of carbonate content in sediment at from stations 4 and 6 from 3.0 to 2.5 ka BP onwards until approx. 0.8 ka BP (Fig. 3).~~

Around 2.1 ka BP, the sub-boreal climate gradually shifted to the current subatlantic climate with a trend towards warmer and wetter climate and increased riverine influence (Fulton et al. (2025) through the 2012). The youngest major event reflected in core 6 is the massive eutrophication during the ‘Green Revolution’ starting in the 1960s with intensive discharge of nutrients, which in turn resulted in enhanced primary production, enhanced oxygen consumption in deeper water layers, and thus a shallower oxycline. The increased deposition of organic matter with isotopically enriched nitrogen is evident in all cores and is described as Zone 1 (Fig. 4, closed circles).

In summary, the sediment cores of this study reflect all major events in the Black Sea of the past 6,000 years. Although we sampled sediment cores very close to the Danube Delta, we are confident that these sediments recorded signals from the Danube Plume and from the Black Sea, and that we can draw relevant conclusions from our results. In line with results of Fulton et al. (2012), our sedimentary analysis confirms that nitrogen cycling in the Black Sea was controlled by basin-wide

processes, with its isotopic signatures spread throughout the Black Sea. Station 6 is influenced by the basin-wide Rim Current (Fig. 1), and the $\delta^{15}\text{N}$ profile is similar to the 0.2 ka BP of the $\delta^{15}\text{N}$ profile in Figure 4 in Fulton et al. (2012). We conclude that this core's N-profile is rather determined by basin-wide processes. In contrast, the N distribution in cores 1 and 2 are more driven by the discharge of freshwater and nutrients from River Danube.

4.2 Nitrogen sources to the Northwestern Shelf

During the Atlantic climate phase between 6.9 to 5.1 ka BP, riverine discharge of freshwater was high, which led to a strong thermohaline stratification, low ventilation of the pelagic, and a shallow chemocline. The presence of isorenieratene in the sediment, which is interpreted as an indicator that the chemocline was being so shallow that hydrogen sulphide ascended into the photic zone (Cutmore et al., 2024), and these euxinic conditions would have substantially constrained the degradation of sinking particles in the water column and in the sediment once they have been deposited. As a result, current measured isotopic values of sediment from this period are probably close to the original isotopic signature. With respect to nitrogen, we have measured a $\delta^{15}\text{N}$ value of 3.3 ‰ in this sediment layer, which is consistent with riverine N from a pristine catchment with no anthropogenic land use (Johannsen et al. 2008, Bratek et al. 2020) and thus indicates that riverine nitrogen was the dominant N source to the NW shelf. Fulton et al. (2012) reconstructed the $\delta^{15}\text{N}$ value of phytoplankton in the range of 1.4 to 4.4 ‰ for this period, and our results agree with this reconstruction. We thus conclude that the N / $\delta^{15}\text{N}$ trend of Zone 4 (Fig. 4 open triangles, Fig. 7) indicates the sapropel with high organic matter concentration that was deposited in the Black Sea basins during this phase and was termed stratigraphic unit II b (Ross et al. 1970). Our data from this period had similarly high TOC values in Core 6 and a matching $\delta^{15}\text{N}$ value of 3.3 ‰ (Fig. 3). And since freshwater discharge was high during the Atlantic climate phase, riverine N from Danube and adjacent rivers appears as the dominant N source to the NW shelf.

From 4.3 Shift to Nitrogen Fixation: 5.0 - 4.4 ka BP

The humid Atlantic phase lasted until approx. 5.1 ka BP and was replaced by sub-boreal climate, which resulted in substantially reduced riverine input and a weakened salinity gradient due to increased surface salinity (Giosan et al. 2012). The weaker stratification and intensified ventilation led to a deeper circulation, which enhanced the pelagic (Fuller et al., 2012). This conclusion is supported by the absence of isorenieratene, in the 3.9 – 2.7 ka BP sediment ventilation (Fulton et al. 2012). We observed a clear change in bulk $\delta^{15}\text{N}$ values and N content around 5.0 ka BP at the most offshore station 6 and found a similarly low $\delta^{15}\text{N}$ value of 1.9 ‰ in station 4 sediment (Fig. 3, open circles) from the period in which deep circulation may have favoured N-fixation (Fig. 7, Zone 3). We suggest that the N source gradually shifted from riverine N to N-fixation in the 5.0 – 4.4 ka BP period and is represented by the N / $\delta^{15}\text{N}$ trend of Zone 3 (Fig. 4 closed triangles, Fig. 7). The sediment

Formatiert: Block, Zeilenabstand: 1,5 Zeilen

of this period is equivalent with sediment Unit II a, which is the upper part of the organic-rich sapropel layer, which indicates that the chemocline was much deeper during this period (Cutmore et al. 2024). (Ross et al. 1970). The intensified and deeper mixing of the pelagial water column would not only mix oxygen downwards but would also enable the upward transport of nitrogen depleted and phosphate enriched deep water into the epipelagic. In surface water, which resulted in N : P ratios in the euphotic zone in the range of 3.5 – 6 and which thereby favoured N- fixation by cyanobacteria (Fulton et al. 2012). The reconstructed $\delta^{15}\text{N}$ value of phytoplankton during this period was in the range of 0.3 to 2.1 ‰ (Fulton et al. 2012), which in combination with reduced discharge of riverine N, the upwelling would result in low N:P ratios and thereby set the stage for N-fixation; additional proxies confirms dominant N-fixation (Cutmore et al. 2025). N-fixation has a strong negative isotopic effect and results in plankton matter with a comparatively low $\delta^{15}\text{N}$ value in the range of approximately –2 to 1 ‰ (Minagawa & Wada 1986). In sediment from the period in which deep circulation should have favoured N-fixation, we indeed observed a bulk sediment $\delta^{15}\text{N}$ value as low as –1.6 ‰ at the most offshore station 6 and found a similarly low $\delta^{15}\text{N}$ value of –1.9 ‰ in station 4 sediment (Fig. 3, open circles). We thus conclude that the N-source gradually shifted from riverine N to N-fixation in the 4.5–3.8 ka BP period.

At However, the time the $\delta^{15}\text{N}$ values we have observed in sediment from the NW shelf are slightly higher than the values observed by Fulton et al. (2012) and Cutmore et al. (2025), which have sampled locations farther from the Danube Delta and with deeper bottom depth. This offset hints that isotopically most depleted nitrogen was sedimented, approximately from 3.6 ka BP onwards; carbonate coecoliths from the haptophyte plankton algae *Gephyrocapsa huxleyi* (formerly *Emiliana huxleyi*) started to accumulate in the sediment as coecolith ooze of Unit I (Hay et al. 1991, Xu et al. 2001, Coolen 2011), which raises heavier N from riverine inputs had a higher contribution to the question of whether this is a coincidence. Low N:P ratios which favour N-fixation also enable *G. N* supply at *huxleyi* to form blooms (Lessard et al. 2005). Additionally, the coecolithophorid haptophyte *Braarudosphaera bigelowii* was demonstrated to host endosymbiotic, unicellular UCYN-A like cyanobacteria, which can fixate nitrogen (Thompson et al. 2012, Mills et al. 2020), and thereby provides a possible causation for the simultaneous deposition of coecoliths and isotopically depleted nitrogen. Moreover, Cutmore et al. (2024) found pentose heterocycle glycolipid (HG) in NW shelf than at more distant parts of the Black Sea sediment where the organic matter with the lowest $\delta^{15}\text{N}$ was deposited and interpret this as an indicator for the presence of marine nitrogen-fixing cyanobacteria in symbiosis with marine diatoms. Finally, Coolen et al. (2009) found a single phylotype to dominate the *G. huxleyi* record in the 3.4 to 2.6 ka BP period, which was absent before and after. While it is possible that the co-occurrence of coecoliths and isotopically depleted N in the sediment record is a coincidence, the combined observations hint to the possibility that *G. huxleyi* may have contributed to N-fixation in the Black Sea.

4.4 Oxygenated sediment at the shelf break: 4.4 - 0.9 ka BP

The intensified and deeper circulation during the sub-boreal phase resulted in an intensified ventilation of the shelf, ~~which water as confirmed by Cutmore et al. (2025), which did not detect the proxy for H₂S in the photic zone during this period (3.9 – 2.7 ka BP) while this proxy (isorenieratene) was always present before and after this period and thereby indicates an~~ exceptional deep ventilation. The deeper ventilation of the water column gradually increased the exposure of shelf sediments to oxygen and thereby enabled enhanced remineralisation of deposited organic matter there. ~~Since Möbius et al. (2010) demonstrated that early diagenesis can alter the isotopic signature and thus overprinted the depleted isotope signature of N-fixation, we examined our results from Zone 2 of cores 4 and 6, where N contents decreased towards the surface while $\delta^{15}\text{N}$ values increased. In core~~ Möbius et al. (2010) demonstrated that early diagenesis is indicated by increasing $\delta^{15}\text{N}$ values and decreasing N concentrations, which we indeed found in Cores 4 and 6 in the period 4.4 to 0.9 ka BP (marked as Zone 2 in in Fig. 4, Fig. 7). During this period, the highest $\delta^{15}\text{N}$ value and lowest N concentration coincided with the peak of surface water salinity (Giosan et al. 2012), which we interpret as an indication that benthic remineralisation was most pronounced when the salinity gradient was weakest and thus ventilation was most intense (Fig. 7).

In Core 4, the apparent enrichment factor of $\epsilon = -1.1 \pm 0.2 \text{ ‰}$ falls well within the range of published values for remineralisation of organic matter (Möbius et al. 2010) ~~which supports our conclusion), and we think~~ that the observed increase in $\delta^{15}\text{N}$ values in ~~core 4~~ Zone 2 is rather a result of remineralisation and not an indication of changes in nitrogen sources. However, ~~we found a different situation in Core 6, where the apparent enrichment factor of Zone 2 of core 6 with the same period was much higher ($\epsilon = -3.0 \pm 0.3 \text{ ‰}$ is implausibly high. But the high apparent value can~~ $\epsilon = -3.0 \pm 0.3 \text{ ‰}$ is implausibly high. But the high apparent value can be explained if we unusual for remineralisation alone. We thus assume a combination that Core 6 reflects the combined effect of early diagenesis and a gradual shift from N fixation to isotopically more enriched riverine ~~input by the recent sub-atlantic climate phase. N input.~~

In summary, ~~the more coastal~~ we conclude that between 4.4 – 0.9 ka BP station 4 appears being was supplied by a mix more or less stable mixture of N-fixation and riverine N from river discharge between 4.4 – 1.0 ka BP and from pelagic nitrogen fixation.

The more offshore station 6 was initially supplied by isotopically depleted nitrogen from N-fixation circa 3.84.4 ka BP, which was gradually complemented by isotopically enriched nitrogen until 1.30.9 ka BP (Fig. 4), and we assume 4). This would imply that the enriched N was discharged by influence of the Danube and adjacent rivers as their discharge gradually increased over the past 3 River plume extended from station 4 to station 6 in this period. At around 1.0 ka BP (Giosan, $\delta^{15}\text{N}$ values of sediment from Cores 4 and 6 were around 4 ‰, which is substantially above the values reported by Fulton et al. (2012) and Cutmore et al. (2025) for this period, which reported $\delta^{15}\text{N}$ values of 1 ‰ and 0.5 ‰, respectively. This difference underlines that the sediment record from the NW shelf reflects different processes than the sediment from more distant parts of the Black Sea.

In cores

520 Into the period 4.4 – 0.9 ka BP also falls the occurrence of coccoliths from station the haptophyte plankton algae *Gephyrocapsa*
huxleyi (formerly *Emiliania huxleyi*) in the sediment, which starts approximately at 3.6 ka BP (Hay et al. 1991, Coolen 2011).
We find a corresponding increase in TIC in sediment from Cores 4 and 6, the trend of decreasing from 3.6 ka BP onwards
until approx. 0.9 ka BP (Fig. 3). Since low water N:P ratios not only favour N-fixation but also enable *G. huxleyi* to form
blooms (Lessard et al. 2005), the presence of coccoliths might indicate that the outer shelf was still influenced by N-deficit
and thus by N-fixation.

525 4.5 Anthropogenic eutrophication and recovery: 900 a BP to present

At around 900 a BP₁₉₅₀, we observed an increase in $\delta^{15}\text{N}$ values and N content and increasing $\delta^{15}\text{N}$ in Zone 2 stops circa 0.8
ka BP, and N content and $\delta^{15}\text{N}$ values increased substantially in younger sediment layers (Fig. 3, closed circles), which
indicates increased that the condition changed on the NW shelf. The $\delta^{15}\text{N}$ values eventually exceeded the values from Zone 1
535 when N from pristine rivers was the dominant N source. Instead, the high $\delta^{15}\text{N}$ values indicate the deposition of organic matter
with significantly N that was isotopically enriched nitrogen. This enriched nitrogen is present in all sampled cores, and a
plausible source of sufficiently enriched ^{15}N is riverine discharge of nitrogen from anthropogenic by human activities such as
agriculture and urbanization (Johannsen et al. 2008, Bratek et al. 2020). The effect of eutrophication due to anthropogenic
activities is especially obvious in cores 1 and 2, where the $\delta^{15}\text{N}$ values increase from $6.6 \pm 0.1\text{‰}$ in the 50 – 0 a BP period to
535 $7.1 \pm 0.1\text{‰}$ in core 1 and $6.9 \pm 0.5\text{‰}$ in core 2 during the peak eutrophication during the 1980–1990 period (–30 to –40 a BP,
see Fig. 3). When the nitrogen load of Danube significantly dropped after the 1990s (Kovačević & Zavadsky, 2021), the $\delta^{15}\text{N}$
values decreased along with the riverine nitrogen load back towards values below 7 ‰. It is noteworthy that the transition to
The deposition of substantially enriched N apparently happened started around 830 ± 50 900 ± 120 a BP BP₁₉₅₀ in both cores 4
and 6, (Figure 7), and thus much earlier than the industrialisation in the 20th century when the usage of artificial fertiliser
540 became common widespread. Fulton et al. (2012) and Cutmore et al. (2025) consistently found a significant increase of
sediment $\delta^{15}\text{N}$ values in cores from the shelf and deep basins, starting at around 0.5 ka BP₁₉₅₀, which supports our observation
that the deposition of enriched nitrogen began much earlier than the industrialisation. The difference of approximately 400
years between the onset of enriched nitrogen deposition on the Danube influenced shelf (this study) and the deeper locations
further south (Fulton et al. 2012, Cutmore et al. 2025) most likely reflects the differences in the sensitivity of these locations
545 to signals from the Danube.

The apparently early onset of isotopically enriched nitrogen deposition could be an artifact of bioturbation in which benthic
macrofauna mixes modern, isotopically enriched nitrogen from the sediment surface downwards and thus into older sediment
layers. The sediment cores retrieved at stations 4 and 6 were populated by sessile tunicates and small bivalves (*Modiolula*
550 *phaseolina*), which are not strong bioturbators and are unlikely to provide sufficient sediment mixing to transport
anthropogenic ^{15}N down to 7 cm sediment depth at station 4. Our measurements of particle-associated ^{210}Pb further indicates

that the mixed surface layer reaches down to 4 cm at maximum (Fig. 2), which is significantly above the deepest occurrence of enriched nitrogen at 7 cm depth (Fig. 3). The ~~much~~ deeper penetration of ^{137}Cs does not contradict our interpretation as ^{137}Cs ~~can have~~ has a ~~much~~ higher mobility in marine sediment as ^{210}Pb and has probably migrated into deeper sediment layers as described by Wang et al. 2022. Additionally, the carbonate content of Cores 4 and 6 decreased simultaneously with increased $\delta^{15}\text{N}$, which is not a plausible result of sediment mixing by bioturbation. Instead, the decreasing carbonate content in the modern surface layer ~~might indicate~~ indicates a change in the nutrient regime with a ~~reduction of shift from~~ coccolithophorid blooms to dinoflagellate blooms in the coastal area. ~~Fulton (Giosan et al. (2012) consistently found a significant increase of sediment $\delta^{15}\text{N}$ values in cores from the shelf and deep basins, which starts around 0.5 ka BP and supports our observation that the deposition of enriched nitrogen started much earlier than the industrialisation.)~~

An ~~alternative~~ explanation for the early deposition of enriched nitrogen ~~is likely could be the~~ intensified N discharge during the Medieval Warm Period / Medieval Climate Anomaly (Mann et al. 2009), ~~which was a~~. During this local climate optimum in Europe between 1000 ~~a BP~~ and 700 ~~a BP~~ ~~and led to BP~~ BP, a substantial population growth ~~wit~~ led to expansion of agricultural land use and urbanization ~~in and thereby to substantial deforestation in Europe.~~ (Giosan et al. ~~2012~~, 2012) ~~presented the reconstructed land cover usage of The Medieval Climate Anomaly coincides with the Danube river catchment area in which the share onset of anthropogenic land use exceeded 40 % at around 800 a BP and increased steeply afterwards. These 40 % of land use and the concomitant deforestation in a catchment area typically result in $\delta^{15}\text{N}$ values of riverine nitrate of approximately 6 ‰ (Bratek et al. 2020), which is discharged into the Black Sea (Johannsen et al. 2008, Bratek et al. 2020) to be eventually deposited to the sea floor. The hypothetical $\delta^{15}\text{N}$ value of approximately 6 ‰ corresponds well with our observations in the sediment layer of that age~~ N deposition on the NW shelf (Fig. 3).

7). The pre-industrial eutrophication of the Danube River is further supported by our reconstruction of Danube DIN loads for the 19th century (Fig. 6). The modelled DIN loads based on correlations of observed DIN load and sedimentary bulk nitrogen content suggest that the Danube DIN load was in the range of 236 to 286 kt / a in 1800 CE, which is in the range of the current load (Kovacs & Zavadsky, 2021). Although the river DIN load with shelf sediment $\delta^{15}\text{N}$ values were substantially less correlated than with shelf sediment bulk N content, the reconstructed DIN load based on $\delta^{15}\text{N}$ is similar to the N content-based results. Additionally, the average slope of the Danube River DIN load trend in 1800 – 1950 of $0.35 \pm 0.16 \text{ kt} / \text{yr}^2$ can be linearly extrapolated approximately 800 years backwards until the modelled Danube River DIN load approaches zero. Although this extrapolation reaches very far into the past with respect to the relatively short period of underlying observation data and is thus ~~a coarse~~ an estimate with a substantial amount of uncertainty, our model results are in line with an early onset of anthropogenic eutrophication of Danube. Our approach to reconstruct historical Danube River DIN loads relies on the assumption that quantity and isotopic composition of Danube River DIN ~~translate~~ translate linearly to Black Sea sedimentary N content or bulk $\delta^{15}\text{N}$ values, although the dissolved N is assimilated into phytoplankton, transported, deposited in the delta, and partially degraded by early diagenesis. The approach appears valid for the 1955 – 2015 period, and we are not aware of

hat formatiert: Schriftart: Times New Roman

hat formatiert: Schriftart: 9 Pt.

conflicting results to challenge our approximations of historic Danube DIN loads. The results of the offshore stations 4 and 6, which go far back into the past, and in combination with results from the coastal station 1, which recorded the N deposition of the last 200 years in more detail, give a coherent picture of the steadily increasing eutrophication of the Danube for at least 800 900 ± 120 years, which has only decreased again in the last 30 years. The sediment record of Station 2 is not reflecting these processes in sufficient detail likely due to its location on the active delta front slope (Fig. 1). The sediment there is biased by sand deposits from the Sfântu Gheorghe Danube branch as a result of cutting off all the meanders of Sfântu Gheorghe, between 1984 and 1988, which led to an accelerated flow in the main channel and scouring of its river bed (Constantinescu et al., 2023).

4.3 Diagenetic overprint of the initial sediment record

We have already discussed above that euxinic conditions preserved the initial isotopic composition in the sapropel and that ventilation of the bottom water resulted in a pronounced remineralisation of shelf sediment, which then led to changes in the isotopic composition of the remaining organic matter. Analogously, remineralisation apparently shifted the TOC/N ratio from 10 to 15 in the most exposed nearshore sediment (Fig. 3). The early diagenesis within the sediment could have additional consequences such as carbonate dissolution due to acidification of the porewater by CO₂ production during remineralisation. The putative carbonate dissolution could explain the contradictory results that the presence of the plankton algae *Gephyrocapsa huxleyi* in the Black Sea is proven by molecular evidence in the sediment (Coolen et al. 2009, Coolen 2011) since 7 ka BP, but the characteristic carbonate coccoliths are present in sediment cores only from 3.6–2.5 ka BP (Hay et al. 1991, Xu et al. 2001, Coolen 2011) onwards. The dissolution of old, ¹⁴C-depleted carbonate due to acidic porewater would produce correspondingly ¹⁴C-depleted DIC. Additionally, carbonate dissolution has a strong kinetic fractionation effect (Skidmore et al. 2004), which depletes the produced DIC even further and may result in a complex pattern of age-offsets (e.g. Barker et al. 2007). The isotopically depleted DIC ascends to the sediment surface by molecular diffusion and sediment compaction, where it is precipitated into carbonate shells of growing bivalves as demonstrated by Poirier et al. (2019) for benthic Foraminifers. Analogously, bivalves growing in ¹⁴C-depleted porewater would also appear older in radiocarbon dating than the surrounding organic sediment, and our radiocarbon dating results of shells at station 6 (Tab. 2). The youngest major event reflected in the sediment record is the massive eutrophication during the 'Green Revolution' starting in the 1960s with intensified discharge of nutrients, resulting in enhanced primary production, enhanced oxygen consumption due to enhanced organic matter decomposition in deeper water layers, and thus a shallower oxycline. The increased deposition of organic matter with isotopically enriched nitrogen is evident in all cores and is especially obvious in core 1. There, the highest N content and highest δ¹⁵N values coincided with the peak of eutrophication during the 1980–1990 period (–30 to –40 a BP₁₉₅₀, see Fig. 3, Fig. 7) and decreased simultaneously when the nitrogen load of Danube significantly dropped after the 1990s (Kovacs & Zavadsky 2021).

If our hypothesis is true that the eutrophication of Danube started several centuries before the onset of industrialisation, this would further imply that Danube was not pristine in the sense of the European Water Frame Directive (WFD) since the Middle Ages. The WFD requests from EU member states to manage water bodies at the river basin level to achieve "good status" for all water bodies, which basically requests a condition with no or minimal human impact (European Commission, 2000), including the riverine nutrient load. The outcome of our study indicates that defining good status of a water body based on zero or minimal human impact may not be possible for some systems as such conditions are difficult to reconstruct. In contrast, it may be recommended to base good environmental status on the ecosystem functions of the water body and those ecosystems associated to it.

Ultimately, organic sediment and carbonate shells represent two different carbon pools, which are affected individually by early diagenesis. In our results, carbonate shells appear systematically older than the surrounding organic sediment, while e.g. Hansen et al. (2022) report the opposite situation.

Conclusions

We have sampled the sediment of across the northwestern NW shelf of the Black Sea along a transect gradient from high influence of Danube close to the Danube Delta toward to low influence close to the shelf break, and. We analysed the content of TOC, TIC, total nitrogen and nitrogen stable isotope composition, and the nitrogen content of the sediment to identify nitrogen sources to the primary production on the NW shelf. Our results confirm previous findings indicate that the relative contribution of riverine nitrogen and pelagic N-fixation fluctuated during the past 57,000 years and was largely driven by climate changes. Our sediment samples from the western shelf enable us to estimate that the oxycline descended at the end of the Atlantic climate phase below 60 m water depth before 4.4 ka BP, and below 80 m at 3.7 ka BP. Due to the proximity of our sampling sites to the Danube Delta, which made the sediment record there more susceptible to signals from the Danube, we found that the deposition of isotopically enriched nitrogen started approximately 800 years ago. The 900 years ago. We attribute the isotopically enriched nitrogen to human activities, and the deposition of substantial amounts of nitrogen from anthropogenic activities started surprisingly long before the industrialisation, which is commonly believed to have started induced the current eutrophication in the 20th century. Instead, Danube was not pristine with respect to nutrient loads since the Middle Ages. Our reconstructed DIN loads suggest that Danube was already eutrophicated at 1800 CE at a similar level as present, and that DIN loads gradually increased throughout the 19th and 20th century until 1960 CE, when. Then, eutrophication steeply increased even further and peaked around 1990 CE, due to intensified agriculture, the so-called Green Revolution. After 1990, The substantial reduction in Danube River DIN loads since 1990 due to efficient decreased significantly due to economic collapse in the early 1990s and nutrient reduction policies afterwards in the Danube River catchment, and this reduction of the Danube N-load is already reflected in the western Black Sea coastal sediment record.
