Abstract. Coastal cross-shelf transport drives the redistribution of sediment, nutrients and pollutants on continental shelves. Here, the cross-shelf volume flux is quantified from in situ measurements at two coastal sites on the Bay of Biscay (BoB) shelf. At both sites, a semidiurnal internal tide propagates onshore, and mode 1 nonlinear internal wave packets are observed. The Eulerian and Stokes drift contributions to the subtidal cross-shelf transport are estimated along density layers from ADCP, temperature sensors, and CTD measurements at 62 m water depth on the Landes plateau or SE-BoB (44°N) and 47 m water depth on the Armorican shelf or N-BoB (47°N). The Stokes drift transport has possible contributions from the internal tides, nonlinear internal waves and the surface waves and tide. At both sites, the vertical profile of the month-long averaged Stokes drift volume flux matches the shape of the semi-analytical Stokes drift volume flux due to a linear mode-1 internal tide. We demonstrate that nonlinear internal wave events can also contribute to the Stokes drift volume flux. We thereby attribute the Stokes drift volume flux at the study sites to internal wave pumping (IWP). At both sites, the IWP is responsible for a near-seabed onshore volume flux during stratified conditions and spring internal tides that is equivalent to an wind-driven upwelling event generated by a 4 m/s wind. At N-BoB (47°N), IWP is the main contributor to the total cross-shelf volume flux under stratified conditions and a spring internal tide. At SE-BoB (44°N), IWP augments the near-seabed onshore volume flux during upwelling events and maintains a near-seabed onshore volume flux even during downwelling events.

1 Introduction

Transport across continental shelves is a key driver of nutrient, sediment, pollutant and physical properties of water masses. Offshore transport from the shelf to the sea can also impact the global circulation and represents one of the CO₂ pumps from the atmosphere towards the deep ocean (Huthnance et al., 2009). Cross-shelf transport may be driven by processes of various temporal and spatial scales such as eddies, fronts, Ekman transport, tidal pumping, surface waves, internal tides and their Stokes drift and nonlinear internal waves (Huthnance, 1995; Bowden, 1983). The contribution of internal wave cross-shelf transport remains poorly quantified due to the challenge of observing this process.

Observations of both nonlinear internal waves and internal tides have demonstrated a net volume transport from the open ocean to the shelf seas (Inall et al., 2001; Zhang et al., 2015). In theory, steady linear internal waves are not expected to

generate net transport because their Eulerian and Stokes transport cancel in an inviscid ocean under rotation or in the presence of a sloping seabed connected to a land boundary (Spingys et al., 2020). However, the two flows may not exactly cancel and transport can occur for unsteady waves (when there is a temporal evolution of the currents) or when diapycnal mixing occurs (Spingys et al., 2020), which is common for internal waves propagating upslope (Henderson, 2016). The theoretical Stokes drift vertical profile is made of three layers. It can be divided into a bolus transport, in the wave direction in the surface and bottom layers and an opposite shear transport in the intermediate layer (Henderson, 2016; Spingys et al., 2020). A net transport due to internal tide Stokes drift has been computed from observations at three different shelves (New Zealand, European Malin and Celtic shelves) (Spingys et al., 2020). Close to the Bay of Biscay, in the Celtic Sea, internal tide Stokes transport by internal waves on the Celtic shelf was estimated at $0.33 \text{ m}^2 \cdot \text{s}^{-1}$ in the bottom layer, $-0.43 \text{ m}^2 \cdot \text{s}^{-1}$ in the interior, and $0.15 \text{ m}^2 \cdot \text{s}^{-1}$ in the surface layer (Huthnance et al., 2022).

Nonlinear internal waves range from steepened internal tides to packets of high frequency waves. Alongshore observations on Dongsha Atoll have demonstrated the upslope transport of cold water by a combination of tidal bores and nonlinear internal waves (Davis et al., 2020). Observations at Monterey Bay (Californian shelf) demonstrate the transport of cold, hypoxic deep water by tidal bores that is modulated by wind-driven upwelling events (Walter et al., 2014). Evidence of internal tide bore transportation of planktonic larvae at the Southern Californian Bight were observed by Pineda (1991). NLIW of elevation, or bolus', trap water masses within their core and transport these masses appreciable distances (Gil and Fringer, 2016). Net transport due to NLIW of depression has been quantified on the Washington shelf, where regular NLIW of different types generate onshore mass transport equivalent to Ekman transport ($1 \text{ m}^2 \cdot \text{s}^{-1}$) (Zhang et al., 2015); the New Jersey Shelf, where the average daily NLIW onshore transport was estimated as ($0.3 \text{ m}^2 \cdot \text{s}^{-1}$) (Shroyer et al., 2010) and the Malin Shelf, where the summertime sustained transport was estimated as $0.3 \text{ m}^2 \cdot \text{s}^{-1}$ (Inall et al., 2001).

In the Bay of Biscay (BoB), mass transport over the shelf has previously been attributed to along-shore regional circulation, wind forcing and thermohaline circulation induced by strong river inputs (mainly the Loire, Gironde and Adour rivers). Over the shelf, the barotropic tidal currents increase from south ($10 \text{ cm} \cdot \text{s}^{-1}$ for M2 tidal current) to north ($70 \text{ cm} \cdot \text{s}^{-1}$ at 48°N) (Le Cann, 1990). Surface waves induce transport through Stokes drift, but their effect remains constrained to near the surface and quickly decreases with depth, with a reduction of 1/23 of the wave motion at a depth of half a wavelength below the surface in deep water (Bowden, 1983). Long-term (subtidal) transport due to internal waves has not previously been assessed at the Bay of Biscay shelf. Transport in the BoB is mainly wind driven and seasonally fluctuates (Le Boyer et al., 2013). On the south-eastern part of the BoB, cross-shelf transport is dominated by wind and bottom Ekman transport (Huthnance et al., 2009). Internal waves are expected to be numerous and highly energetic in summer on the Armorican shelf as the BoB shelf break is a hot spot for internal waves (Baines, 1982; Pingree and New, 1991; Gerkema, 2001; Xie et al., 2015; Barbot et al., 2021). The southern shelf of the BoB presents the smallest barotropic tide of the shelf. However, currents associated with internal waves up to 3 times the barotropic current were observed during summer on the southern shelf of the BoB (Moncuquet et al., 2025). NLIW packets were a common feature with a variety of wave responses depending on the vertical stratification. On the Bay of Biscay shelf the transport induced by internal waves is currently unknown.

In this paper, we quantify the Stokes drift cross-shelf subtidal volume flux using isopycnal coordinates at the two Bay of Biscay locations during the summer period. Here we define the Stokes drift transport as the difference between the total subtidal volume transport and the subtidal Eulerian transport; it can include contributions from the surface tide, surface waves, internal tide and nonlinear internal waves. We first describe the measurements at each site and the method used to compute both the Stokes drift and Eulerian subtidal volume transport. In the results section, we describe the observed dynamics at each site. We then present the monthly-averaged transport at each site. We compare the results at each site with the semi-analytical formulation for Stokes transport by a linear M2 internal tide (Franks et al., 2020). In the final section, we describe the time evolution of the fluxes at each site and link it to the observed dynamics.

2 Methods

The two observation sites were on the Armorican shelf over the northern part of the BoB (N-BoB) and on the Aquitaine shelf over the southeastern part of the Bay (SE-BoB) (Figure 1). The data sets are from two distinct campaigns (2017 and 2022) that were executed during northern hemisphere summer periods. We applied identical cross-shelf transport analysis at both sites.

2.1 Mooring sites

The Bay of Biscay is an open bay with a steep shelf break, located on the western part of the European margin. The BoB extends from the Celtic Sea to the Iberian Peninsula. The BoB shelf can be divided into three shelves of decreasing width towards the south (Figure 1). The Armorican shelf is between 100-150 km wide and is located in the north. The Aquitaine shelf is between 46°N and the Capbreton canyon (Figure 1a). The narrow Spanish shelf is perpendicular to the Aquitaine shelf and spreads along the Spanish coast (Figure 1a). Along the shelves, currents and stratification are forced by different mechanisms (Koutsikopoulos and Cann, 1996). The surface tide is mainly semi-diurnal and its intensity decreases towards the south (Le Cann, 1990). The two main freshwater inputs are from the Loire and the Gironde rivers and are reduced during the summer months (Puillat et al., 2004). The wind is the main driver of the currents over the shelf (Le Boyer et al., 2013) and on average the regional circulation is less than 2.5 cm.s^{-1} during summer and increases in winter.

2.1.1 South-eastern BoB site

The SE-BoB has a double shelf break and is defined by the Cap Ferret Canyon in the north and the CapBreton Canyon in the south (Figure 1a). At this location, barotropic tides are small compared to the rest of the Bay and oriented in the cross-shelf direction (Figure 1a). The summer stratification is strong in the region, with surface temperatures that can reach 26°C, whereas bottom temperatures remain around 12°C along the 80 m isobath (Koutsikopoulos and Cann, 1996). The stratification may temporally be affected by upwelling along the Landes coast (Valencia et al., 2004; Froidefond et al., 1996) and by downwelling formed along the Spanish coast (Batifoulier et al., 2012). Due to the coast shape, westerly winds along the Spanish coast induce a pressure gradient along the French coast, generating poleward jets and ultimately increasing the bottom temperature around the 54 m isobath along the Landes shelf (Batifoulier et al., 2012). The cross-shelf circulation in summer is usually sheared

over the vertical and the current inversion corresponds to the pycnocline position (Le Boyer et al., 2013). The Cap Ferret Canyon has been identified as a region with strong internal wave generation (Barbot, 2018). Along 44°N, the internal tide and nonlinear internal waves propagate in the cross-shore direction and generate currents more than 3 times the barotropic tidal current (Moncuquet et al., 2025).

Here we used a near-coastal mooring that observed temperature and velocity in 62 m water depth, hereafter referred to as SE-BoB and 2C in (Moncuquet et al., 2025). The ETOILE campaign was initially designed to study high-frequency internal waves along the SE-BoB shelf (Lazure and Puillat, 2017). Here, we used the co-located measurements of temperature and velocity gathered between 07/09/2017 and 07/30/2017 (2C mooring - 44°00 N / 1°31 W). The mooring line had 6 temperature and pressure sensors with an acquisition frequency of 1 min. The vertical positions of the sensors were regularly spaced every 10 m, between 0.7 meters above the bottom (mab) and 47.5 mab (Figure 1d,e). The accuracy of the temperature sensors was 0.15 °C. Conductivity and temperature vertical profiles were measured using a moving vessel profiler (MVP) between 25-29 July 2017 to compute the density-temperature relationship (Figure A1, A2). A bottom-mounted ADCP (RDI Sentinel 300kHz) was deployed with an acquisition frequency of 0.5 Hz and a vertical bin resolution of 1 m.

2.1.2 Northern BoB site

The second site was located north of Belle-Ile island (Figure 1) at 47.1°N, 4°W on the Armorican shelf. The presence of a homogeneous cold water mass (~ 12 - 13 °C) called a cold pool or "bourrelet froid" is one of the main hydrological features in the northern part of the BoB. This cold water mass, centred around 100 m water depth, extends along the northern coast between 48.5°N to around 46.5°N with low seasonal and inter-annual variability. Its formation depends mainly on the thermal exchange near the surface, the intensity of the barotropic tidal currents, and occasional freshwater inputs that allow strong stratification which isolates the bottom layer and reduces the downward heat diffusion (Puillat et al., 2004). The winds at N-BoB are more intense than at SE-BoB (Koutsikopoulos and Cann, 1996), resulting in the deepening of the surface mixed layer. The surface mixed layer can also be affected by the surface freshwater layer originating from the Loire and Gironde rivers. However, summer salinity anomalies are small, as flows reach their annual minima and plumes are stretched offshore and southwards under the influence of prevailing north-westerly winds (Lazure and Jegou, 1998).

The SOLIBOB campaign was designed to study NLIW close to Belle-Ile (Lazure, 2022). The internal tide is generated along the shelf break, offshore of the mooring site (Barbot et al., 2021; Pairaud et al., 2010; Pichon et al., 2013; Xie et al., 2015). NLIW have frequently been observed along the north Armorican slope (Pingree and Mardell, 1985). This site is also close to the mid-shelf mud belt called the "Grande Vasière". Here we use co-located measurements of temperature and velocity gathered between 08/27/2022 and 09/30/2022 at 47 m water depth (M1 mooring - 47°15.733'N / 03°09.377'W). The mooring line had 6 temperature and pressure sensors with an acquisition period of 2 min. The vertical position of the sensors was on average 5.3, 9.9, 14.9, 20.1, 25.2 and 47.1 m above the bottom (mab) (Figure 1b,c). A bottom-mounted ADCP (Sentinel V50) was deployed with an acquisition frequency of 0.5 Hz and a vertical bin resolution of 0.5 m. The temperature profiles were constructed from the 6 temperature sensors and the ADCP temperature sensor. The accuracy of the temperature sensors was 0.15 °C.

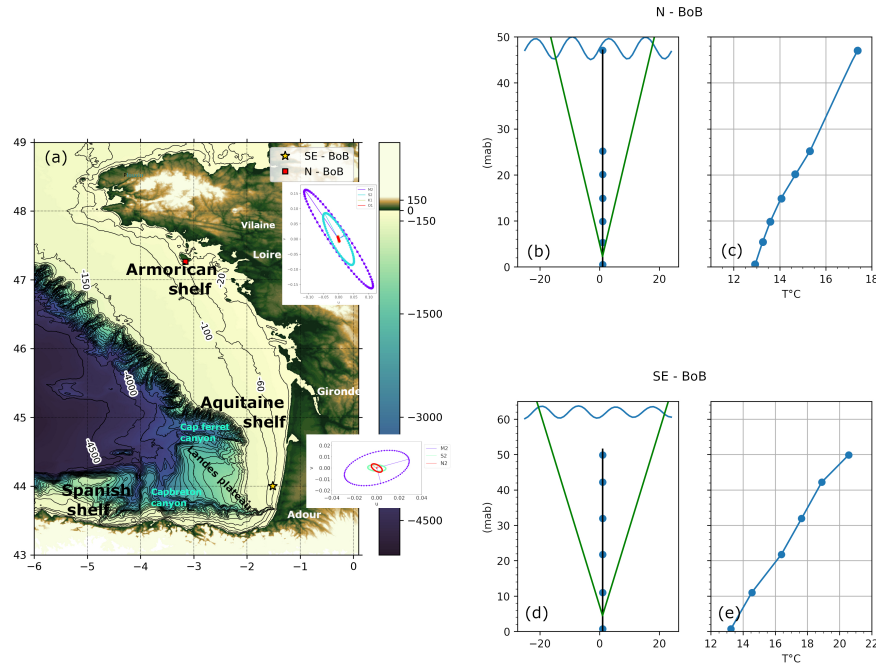

Figure 1. (a) BoB bathymetric map (colours) and mooring positions (the star corresponds to the SE - BoB experiment and the red square to the N - BoB experiment). The tidal ellipses are computed from the barotropic current at the mooring locations and show the contribution of the main tidal frequency at each site. Temperature profiles and mooring schematics are added for NE-BoB (b, c) and SE-BoB (d, e). The mooring schematics (b and d) show the spread of the ADCP beams in green solid lines and the position of the temperature and pressure sensors (blue solid circles). The height of each point is given in meters above the bottom (mab). The temperature profiles (c and e) show the summertime average temperature profiles from the moorings.

2.2 Data analysis for hydrographic conditions

2.2.1 Temperature and velocity fields

125 We linearly interpolated temperature and cross-shore velocity measurements onto a uniform vertical grid with 0.5 m spacing. Velocities were time-averaged on the same temporal resolution as the temperature sensors which varied between sites. The temporal resolution was 1 min for the SE-BoB mooring and 2 min for the N-BoB mooring. The currents for the N-BoB site were rotated counter-clockwise by 60° to align with the shelf slope. Hence, the cross-shore velocity u is positive when directed in the NE direction for this site. At SE-BoB, the eastward velocity corresponds to the cross-shore component; therefore, no
130 rotation was applied.

We defined the background fields as the tidally filtered temperature and velocity fields. To filter the tidal components we used a Butterworth 24 h low pass filter of order 3. The filtered data are denoted $\langle . \rangle$. From the background temperature field, we computed the stratification and the modal profile.

2.2.2 Stratification

135 To define the stratification over the whole water column we set a constant temperature above the highest sensor (i.e. no gradient in the surface layer). We then solved the Sturm-Liouville equation (4) and computed the internal wave vertical modes, propagation speed and amplitude. Salinity and temperature profile measurements were made in the vicinity of the moorings during the deployment or the recovery campaigns. At both locations, the relationship between density and temperature was linear (see Annex : Figure A1 and Figure A2). We hypothesized that the salinity was fairly constant over the whole month so that we
140 could derive density from temperature measurements at each mooring line. To first order, this is reasonable as the influence of freshwater is weak, confined to the surface and is less important at this time of year for both sites (Puillat et al., 2006). Moreover, the main stratification profile uncertainty is expected to come from the low vertical resolution of the temperature measurements (10 m). We used equation (1) to compute the density field at SE-BoB and equation (2) at N-BoB.

$$\rho = -0.31T + 1031.19 \quad (1)$$

145 $\rho = -0.256T + 1030.1 \quad (2)$

The Brunt-Väisälä frequency N^2 was computed without the compressible effect, using the following equation :

$$N^2 = -\frac{g}{\rho} \left(\frac{d\rho}{dz} \right) \quad (3)$$

2.2.3 Modal structure

From N^2 we computed the time evolution of the first vertical mode ϕ_1 and the propagation speed of the semi-diurnal internal
150 tide c_{M2} from the complete Sturm-Liouville equation (4), with the Coriolis coefficient $f = 10^{-4} \cdot s^{-1}$ at SE-BoB (44°N) and at N-BoB (47.2°N).

$$\frac{d^2\phi}{dz^2} + k^2 \frac{N^2 - \omega^2}{\omega^2 - f^2} \phi = 0 \quad (4)$$

We use subscript ϕ_1 to denote the first mode.

2.2.4 Nonlinear internal wave identification

155 We identified the NLIW propagating in the cross-shore direction from the temperature and velocity fields. We interpolated the vertical position of a set of isotherms with 1°C difference from temperature and pressure measurements. We high-pass filtered the vertical position of all the isotherms at 2 h to retain the high-frequency oscillations. We determined the time when the high-frequency oscillations of three isotherms reached an amplitude of 0.1 H , where H is the water depth. This is a strong restriction and we acknowledge we will underestimate of the number of NLIW.

160 An event is noted as an NLIW if the vertical velocity changes sign during the time the three isotherms reach the maximum amplitude and go back to their initial position. To define NLIW polarity we used the horizontal, cross-shore, baroclinic velocity and vertical velocity measurements as defined by Shroyer et al. (2009).

2.3 Quantification of cross-shelf volume flux using temperature coordinates

Volume fluxes were computed over a time-varying vertical section of the water column defined between two isotherms of 1 °C difference. We used the linearly interpolated temperature and velocity field between the ADCP first cell (*i.e.*, 4.5 mab (SE-BoB) and 2.8 mab (N-BoB)) and 10 m below the surface. The vertical section of integration depends on how the isotherms are filtered in time. This method was initially developed under isohaline coordinates to track water masses and to compute estuarine exchange per range of salinity (MacCready, 2011). Flux computation over density layers has been used to quantify transport by internal waves from in situ data (Henderson, 2016; Inall et al., 2001) and numerical and in situ data (Spingys et al., 2020).

In the following, we detail the computation of the total volume flux Q , its Eulerian component Q_{Eu} and the difference, which we term the Stokes drift volume flux Q_r . Finally, we detail the theoretical formulation of the Stokes drift for a mode-1 linear internal tide.

2.3.1 Total flux

175 The total volume flux for a time-varying section h_T was computed using the following equation:

$$Q(t, T) = \left\langle \int_{h_T} u(z, t) dz \right\rangle \quad (5)$$

Here u is the unfiltered cross-shelf velocity and $u > 0$ corresponds to an onshore current. h_T is the time-varying layer for which the unfiltered temperature increases by 1 °C. For example, $Q(t, 13^\circ C)$ is the flux computed between 13 °C (strictly greater) and 14 °C (smaller or equal). Note that computing the flux within 2 °C is equivalent to the sum of 2 fluxes made over 1 °C difference. The fluxes were then filtered using a 24 h low pass filter. Note that the filtering was applied after the flux computation so that Q contains the net contribution of all the dynamics associated with temporal periods captured by the highest sampling time of the measurements, *i.e.*, 1 or 2 min (depending on the mooring, see section 2.1). The method differs to compute the Eulerian flux Q_{Eu} .

2.3.2 Eulerian flux computation

185 The Eulerian flux Q_{Eu} was computed from the 24 h low pass filtered velocity and temperature field, *i.e.*, the background fields. This definition is equivalent to the Eulerian decomposition presented in (MacCready, 2011), as :

$$Q_{Eu}(t) = \int_{h_{<T>}^{Eu}} \langle u(z, t) \rangle dz \quad (6)$$

Here $\langle u \rangle$ is the background velocity and $h_{\langle T \rangle}^{Eu}$ is the layer for which the background (*i.e.*, low pass filtered) temperature $\langle T \rangle$ increases by 1 °C (filtered velocity and temperature field are shown for each site in the next section 3).

190 2.3.3 Stokes drift flux

We term the difference between the total and Eulerian fluxes (Q and Q_{Eu} , respectively) the Stokes drift flux Q_r see equation (7). This Stokes drift flux is the net volume flux resulting from processes such as barotropic tidal asymmetry, density currents, surface wave Stokes drift, internal tide Stokes drift and internal wave nonlinearity.

$$Q_r = Q - Q_{Eu} \quad (7)$$

195 2.3.4 Theoretical Stokes volume flux of a linear mode-1 internal tide

The expression for the Stokes drift velocity for a mode-1 linear internal wave with a vertical structure of the vertical velocity $\phi_1(z)$ that propagates at a speed c_{M2} is derived in (Franks et al., 2020). The derivation provided in this paper is recommended to the reader for its clarity. The Stokes drift velocity is:

$$u_S = \frac{A^2}{2} c_{M2} \left[\left(\frac{\partial \phi_1}{\partial z} \right)^2 + \phi_1 \frac{\partial^2 \phi_1}{\partial z^2} \right] \quad (8)$$

200 We denote the analytical Stokes volume flux Q_A and compute it over a layer derived from the background temperature field $h_{\langle T \rangle}^{Eu}$ as in (Spingys et al., 2020) :

$$Q_A(t) = \int_{h_{\langle T \rangle}^{Eu}} u_S dz \quad (9)$$

2.3.5 Internal tide amplitude

We computed the internal tide amplitude A from the envelope of the band-pass filtered isotherm excursions (see next section for
205 example). The envelope was taken as between the maximum and minimum excursion reached between the selected isotherms. The amplitude corresponds to half the distance between the minimum and the maximum of the envelope at each point in time. We selected isotherms from the mid water column, that continuously existed for the whole time record and we considered a 1°C difference between the isotherms.

Because the stratification and depth were different at each site, the number of isotherms used varied. At N-BoB, the internal
210 tide amplitude was computed using 2 isotherms and 3 isotherms for the SE-BoB experiment. We used a band-pass filter to retain semi-diurnal oscillations. The low-pass filter at 2 h removed the NLIW signature whereas the high-pass filter at 14h removed the inertial oscillation. In the following, these filtered isotherms are referred to as tidal isotherms. The values of c_{M2} and ϕ_1 evolved in time and were computed following the methodology described in section 2.2.3.

3 Oceanographic conditions

215 Here, we focus on the temperature and velocity conditions at both sites to provide context for the analyses of the subtidal volume flux, the total cross-shelf volume flux and the analytical Stokes volume flux. We present the background field (low-pass filtered field), the amplitude, the vertical structure and the propagation speed of the mode 1 internal tide.

3.1 N-BoB

3.1.1 Current and temperature fields

220 Compared to SE-BoB, velocity and temperature measurements at N-BoB were longer (1.5 months vs 1 month for SE-BoB) and later in Summer. Before September 28, the bottom temperature was below 13°C and the near-surface temperature was above 17°C most of the time. Before September 28, the strongest background currents were in the middle of the water column (onshore) around 25 mab and near the surface (offshore) (Figure 2b). Near the seabed, the background currents were below 0.1 m/s for most of the record (Figure 2b).

225 From September 07 to 12 the temperature was homogenized close to the seabed and close to the surface so that the stratification was slightly reduced while the barotropic tide increased from neap to spring tide (Figure 2a). From September 12 to 29, during the neap tide (Figure 2a), the temperatures and the cross-shore currents were mostly constant (Figure 2b). Around September 29, a strong, nearly barotropic offshore current was observed, coinciding with ongoing homogenization of the water column (Figure 2b). After August 10, the temperature was almost constant in the whole water column (Figure 2b). The raw
230 (i.e. unfiltered) currents were much stronger, highlighting the role of high-frequency processes such as the tide and NLIW (e.g., Figure 2c). The near-surface current reached up to 0.45 m/s, more than twice the maximum background velocity (Figure 2b.c). We regularly observed internal tidal bores, NLIW of elevation near the seabed and NLIW of depression near the surface (Figure 2c).

3.1.2 Stratification and mode 1 internal tide

235 At N-BoB, the maximum displacement of isotherms was from -17 m to 7 m (Figure 3a). The associated internal tide amplitude was around 12 m. At both sites, the internal tide displacements were not centred around 0.

During the first spring tide, between August 28 and September 01, the stratification was almost continuous with a slightly stronger vertical gradient close to the surface down to 15 mab which tends to favour NLIW of depression (Figure 3b). The stratification changed from September 12 to 24, the warm surface layer thickened and the thermocline was between 20-15 mab.
240 After September 17 the water destratified near the surface and a pycnocline formed around 15 mab. The associated vertical structure of ϕ was maximum below the middle of the water column, favouring elevation NLIW (Figure 3c.d).

From September 25 to the end of the record, the water column stratification decreased continuously. Around September 28, the internal tide amplitude was maintained between 5 m and 10 m. Before September 28 the isotherms 15°C and 16°C carried the highest amplitude internal tide. Just after September 28, the 14°C isotherm fell by 12 m and rose by 8 m (Figure

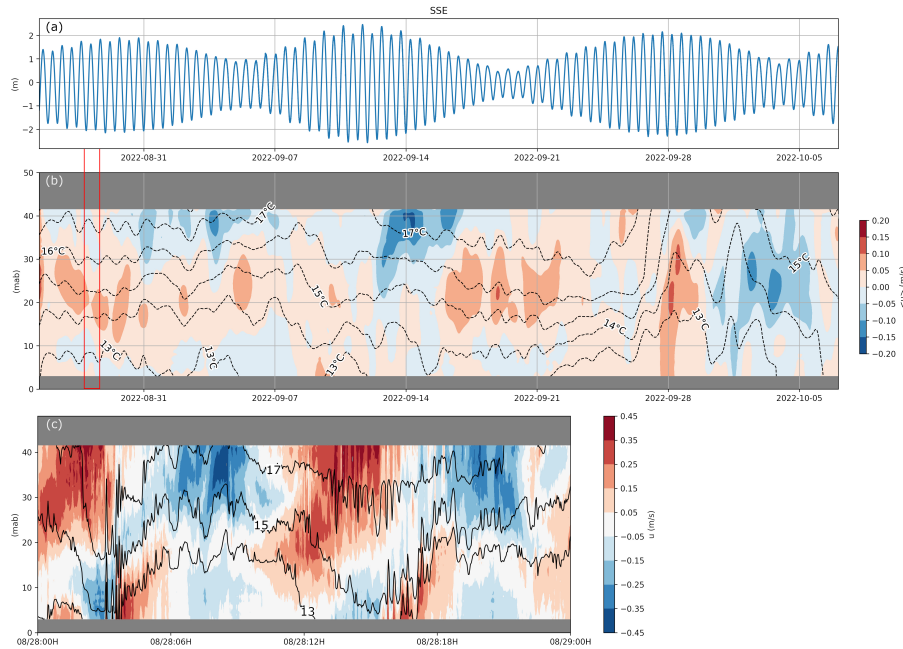

Figure 2. Oceanographic conditions at N-BoB, in 48 m of water depth. (a) Sea surface elevation anomaly over two months. (b) Background fields over two months. The colours are the 24h low pass filtered cross-shore velocity field $\langle u \rangle$. The black dotted lines represent the 24-hour low pass filtered temperature evolution $\langle T \rangle$. The definition of $\langle . \rangle$ is given in 2.3.2. (c) Raw velocity and temperature field (labeled 14, 16, 18, 20°C) for one day during August 25 (correspond to the red rectangle in (a) and (b)). Red is positive, onshore velocity. Blue is negative, offshore velocity.

245 3a). Simultaneously, on the low-frequency signal, the 14°C isotherm rose with a steep slope (Figure 2b). This observation suggested the superposition of an internal tide on a thermal front. After September 29, the stratification was weak (below $10^{-4} s^{-2}$) and c_{M2} dropped to $0.26 m.s^{-1}$ (Figure 3b c). Around October 01 the internal tide displacement first decreased below 5 m, then amplified.

The internal tide amplitude decreased between September 04-11 and between September 21-28 (Figure 3a). We note the
 250 asymmetry of the internal tide amplitude with a mean value below 0 despite the filtering. The isotherms displacements were larger during "low" internal tide (deepening of the isotherms) than during high internal tide. Two main reasons explain the asymmetric internal tide: first, the nonlinearity of the internal tide under asymmetrical stratification with a pycnocline close to the surface is expected to drive larger depression of isotherms compared with elevation. Second, packets of high-frequency negative spikes due to NLIW may have also impacted the results of the filtering and led to a negative mean value of the filtered
 255 isotherm oscillations. Moreover, we observed steep slopes on the 16 and 15°C isotherms around September 28 (Figure 2b) which suggest that the front may coincide with nonlinear internal waves. The asymmetry in isotherm displacement is expected to affect the vertical asymmetry of the transport. As discussed later, transport is enhanced close to the surface when isotherm depression is larger than elevation.

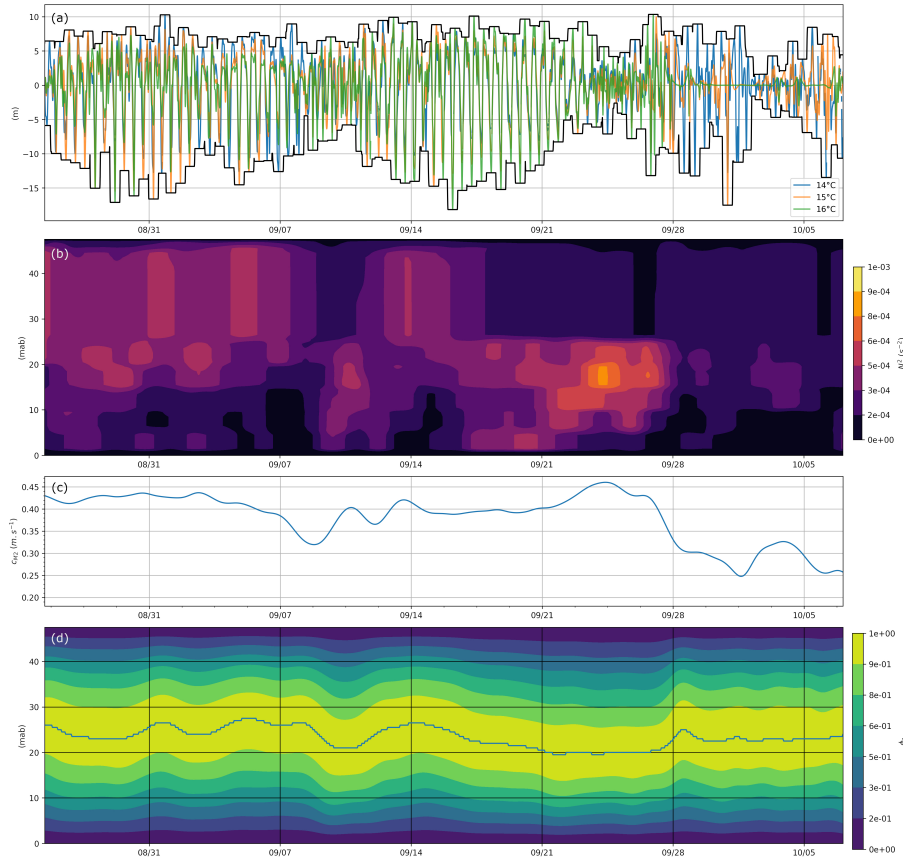

Figure 3. Internal tide characteristics at N-BoB. (a) 14°C, 15°C and 16°C isotherms, band-pass filtered between 2h and 14h. The black lines give the envelope and correspond to the internal tide amplitude A as defined in 2.3.4. (b) Brunt Väisälä frequency defined in section 2.2.2 from 24 h low pass filtered data. (c) Mode 1 propagation speed c_{M2} evolution. (d) 1st vertical mode ϕ_1 time evolution from equation (4). The continuous line indicates the position of maximal ϕ_1 .

3.2 SE-BoB

260 3.2.1 Current and temperature fields

The subtidal and total velocity did not show the same characteristics near the seabed. For most of the record, the subtidal current associated with temperatures below 14 °C (around 5 mab) was offshore (Figure 4b). Evidence of the high-frequency peaks of onshore current and low temperatures (below 14°C) associated with NLIW and the internal tide were present in the raw velocity record (one day example - Figure 4c).

265 For a detailed description of the dynamics, see (Moncuquet et al., 2025). At SE-BoB, the structure of the subtidal flow during the first spring tide was characteristic of upwelling (offshore surface layer flow and onshore bottom layer flow) (Lentz and Chapman, 2004) (from July 12 - Figure 4a,b). During the first spring tide, under upwelling conditions, the near-seabed

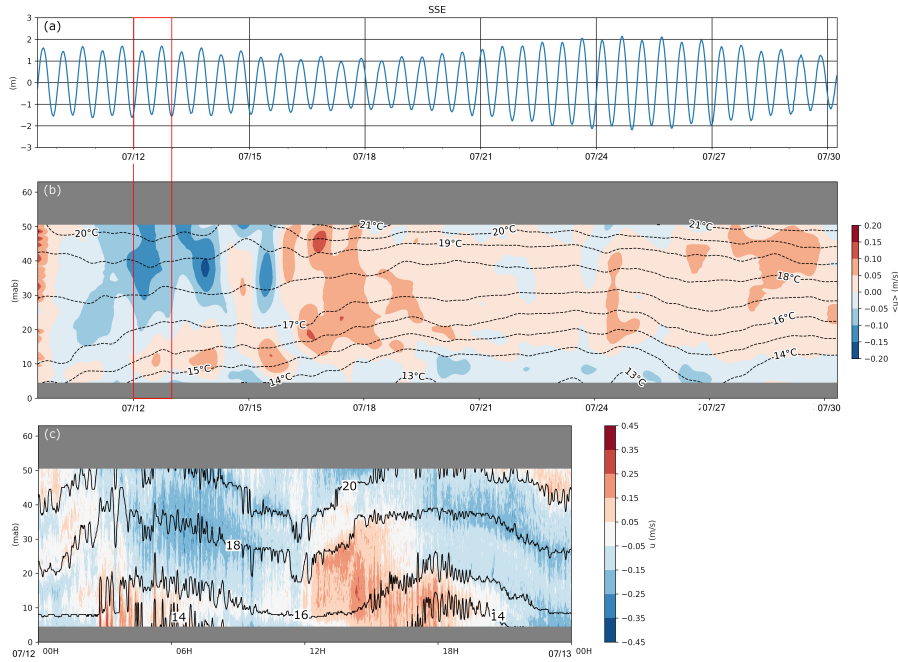

Figure 4. Oceanographic conditions at SE-BoB in 62 m water depth. (a) Sea surface elevation. (b) Background fields over one month. The colours are the 24 h low pass filtered cross-shore velocity field $\langle u \rangle$. The black dotted lines represent the 24 h low pass filtered temperature evolution $\langle T \rangle$. The definition of $\langle . \rangle$ is given in 2.3.2. (c) Raw velocity and temperature field for the day of July 12 (corresponding to the red rectangle in (a) and (b)). Positive (onshore) velocity is indicated in red. Negative (offshore) velocity is indicated in blue.

(below 10 mab) temperature decreased. After July 15, during the neap tide, the near-seabed temperature kept decreasing and water masses of 13 °C were measured (Figure 4b). On July 27, downwelling dynamics (offshore bottom layer flow and increase of the temperature near the seabed) generated a warming of the near seabed temperature during spring tides (Figure 4a,b).

3.2.2 Stratification and mode 1 internal tide

The conditions of stratification were suitable for both internal tide and NLIW propagation. An internal tide was observed for the whole record with an amplitude ranging from 4 m during neap tides to 8 m during spring tides (Figure 5a). The background stratification was maintained during the whole record. Two pycnoclines whose intensity varied with time were separated by a region of lower stratification (Figure 5b). Initially, the stronger pycnocline was below 10 mab. It then rose around July 17 and weakened over time. On July 18 the near-surface pycnocline was the strongest. It is worth noting that the vertical resolution of our temperature sensors did not allow a precise description of the pycnocline position and width. The internal tide phase speed c_{M2} increased from 0.40 m/s to 0.70 m/s, associated with the increase of the vertical averaged stratification later in the record (Figure 5c). The position where $\frac{d\phi}{dz} = 0$ was mostly around the middle of the water column and varied only slightly in time (Figure 5d).

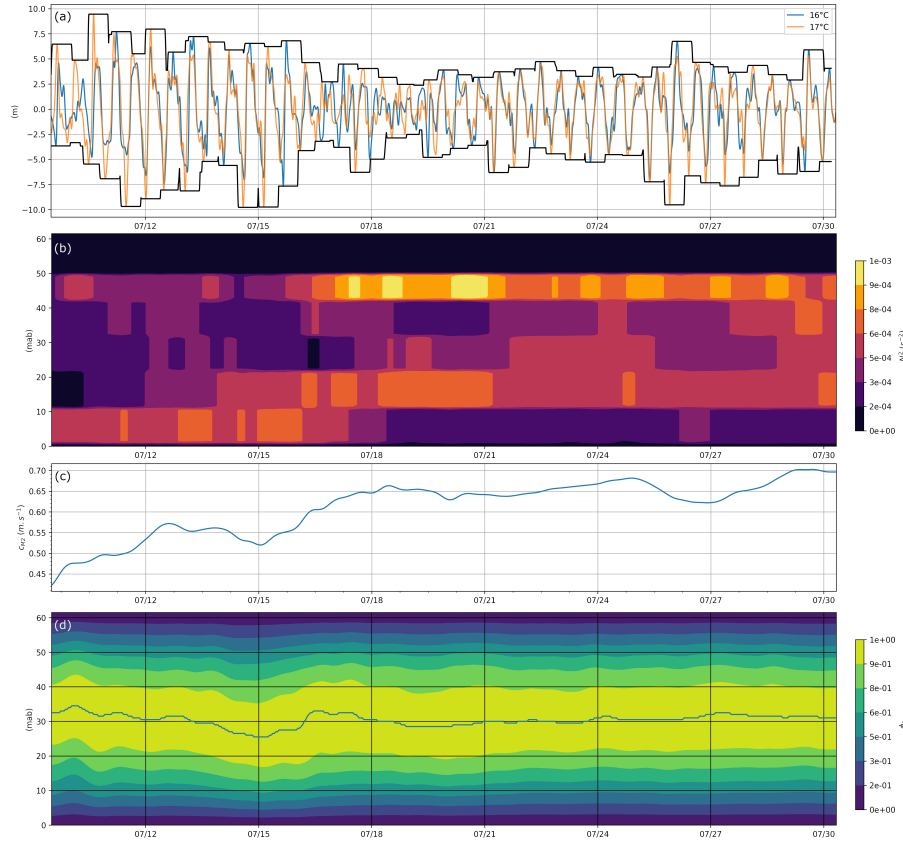

Figure 5. Internal tide characteristics at SE-BoB. (a) 16°C and 17°C tidal isotherms, band pass filtered between 2h and 14h. Only two isotherms are shown as we only selected isotherms measured for the whole period. The black lines give the envelope and correspond to the internal tide amplitude A as defined in 2.3.4. (b) Brünt Väisälä frequency from 24 h low pass filtered data (from section 2.2.2) (c) Mode 1 propagation speed c_{M2} . (d) 1st vertical mode ϕ_1 from equation (4). The continuous line indicates the position of maximum ϕ_1 .

A vertical mode maxima in the middle of the water column corresponds to a symmetrical stratification. Under symmetrical stratification, the usual KdV soliton is not expected. However, two pycnoclines (observed from July 18) can allow the formation of NLIW of higher nonlinearity than the KdV soliton (Lamb, 2023). Moreover, the position and strength of the pycnocline are expected to modify the evolution of the internal tide along the shelf and the generation of NLIW (Dauhajre et al., 2021).

285 4 Cross-shelf transport diagnosed from moorings

In this section, we describe the cross-shelf volume fluxes per range of temperature at both SE-BoB and N-BoB. We compared the estimated Stokes drift volume flux Q_r to the analytical Stokes volume flux Q_A to determine the contribution of the linear internal tide Stokes drift to the observed Stokes drift volume flux. To determine which fluxes contribute to the total transport, we compared Q , Q_{Eu} and Q_r . We first present the monthly averaged vertical profile of the fluxes. Then, we present the time series of the fluxes at both sites and investigate the impact of the background stratification variability.

4.1 Vertical profile of monthly averaged cross-shelf volume flux

For each layer, whose thickness is delimited by isotherms 1 °C apart, we calculated the total flux Q , the Eulerian flux Q_{Eu} , the Stokes drift flux Q_r and the theoretical Stokes drift flux for linear internal waves Q_A , according to the formulas in section 2.3. The fluxes were computed for each temperature range and monthly averaged (Figure 6). The three-layer profiles of Q_r were qualitatively similar for both sites and compared well with the Stokes drift flux expected for the linear internal tide Q_A (Figures 6b,d). This result suggests that the time-averaged total Stokes drift flux was approximated to first order by the linear internal tide Stokes drift at both locations in summer over a month, suggesting the linear internal tide was the dominate contributor to the Stokes drift flux. It should be noted that the internal tide amplitude modulated the vertical profile of Q_A homogeneously but not its vertical asymmetry which will be discussed in the following sections.

The main oceanographic processes that can significantly contribute to the Stokes drift flux are processes with periods below 24 h which include surface tides, internal tides, internal waves solitons, surfaces waves, density currents, storm surges (Huthnance, 1995; Huthnance et al., 2022). However, most of these processes are not expected to affect the results we present in this study. Storm surges are not expected to have a significant contribution at our sites during the summertime. The continental shelf slope is too small (10^{-3}) for density currents to be significant. Stokes drift due to surface waves is limited to the near surface, and we removed the measurements down to 10 m below the surface to limits their influence on the results. Moreover surface wave height are small in the BoB during summer with mean significant wave height below 2 m and mean period wave around 7 s (Charles et al., 2012). The barotropic tidal current is expected to generate a vertically homogeneous transport, except near the bottom boundary layer where the velocity decreases. Therefore the enhanced Stokes drift flux observed near the seabed is expected to be mainly driven by the internal tide and nonlinear internal waves.

310 4.1.1 Contribution of Stokes drift flux on the total volume flux

At N-BoB, the total flux Q (Figure 6a) had a similar vertical profile to Q_r , *i.e.*, onshore flux for minimum and maximum temperatures and offshore flux for medium temperatures (14 °C-16 °C). The Eulerian flux was weak and opposed the total flux, except for the coolest temperature class ($T < 13$ °C) where both Q and Q_{Eu} were onshore. We observed the maximum Eulerian flux ($0.1 \text{ m}^2 \cdot \text{s}^{-1}$) for medium temperatures, around 15 °C which was small compared to the maximum Q_r . The absolute values of Q_r were larger than Q_{Eu} . At N-BoB, the onshore flux by Q_r integrated from 12°C to 14°C was around 0.25

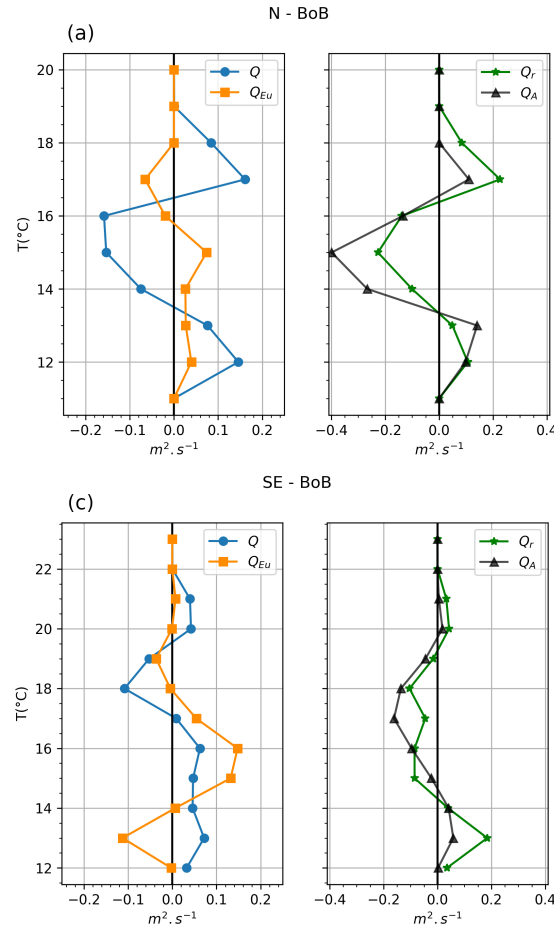

Figure 6. Monthly averaged cross-shore volume flux ($m^2.s^{-1}$) per temperature range. (a,b) N-BoB mooring. (c,d) SE-BoB mooring. Positive values are onshore, negative values are offshore. (a,c) Q is the total flux (blue circles), Q_{Eu} is the subtidal flux (orange rectangles) computed from the fields shown in Figure 2. (b,d) Q_r is the difference between Q and Q_{Eu} (green stars). Q_A is the Stokes drift for a linear internal tide (blue triangles).

$m^2.s^{-1}$. Hence, at N-BoB, the Eulerian flux was not the main contributor to the total flux Q (Figure 6a). Instead, at N-BoB, the total cross-shore flux seemed to be mainly driven by the internal tide Stokes drift.

At SE-BoB, Q also had a three-layer structure, well described by Q_{Eu} , apart for the coolest temperatures where it was similar to Q_r (Figure 6c.d). Q_{Eu} had a similar trend to Q for $22^{\circ}C \geq T > 14^{\circ}C$ with negligible values close to the surface (Figure 6c). In the interior, for temperatures between $19^{\circ}C$ and $15^{\circ}C$, the total transport Q changed signs and followed Q_{Eu} . Near the seabed, Q and Q_r were positive (onshore) for $T > 15^{\circ}C$ which suggested a volume flux driven dominantly by internal waves. Near the surface, both Q and Q_r were positive (onshore) for $T > 20^{\circ}C$ and below $0.1 m^2.s^{-1}$ (Figure 6c.d). At SE-BoB, the onshore volume flux of Q_r from $12^{\circ}C$ to $14^{\circ}C$ was $0.25 m^2.s^{-1}$.

At both sites, Q_r close to the seabed was equivalent to the transport q_w induced by weak upwelling forced by an along-shore wind speed w of 4 m.s^{-1} (using formula, $q_w = \frac{\rho_a C_D w^2}{\rho f}$ (Bowden, 1983) with a typical value of air drag coefficient C_D of $1.4 \cdot 10^{-3}$; air density ρ_a of 1.22 kg.m^{-3} and seawater density ρ of 1025 kg.m^{-3}). Our results suggest that during the stratified period, at SE-BoB, the dynamics that drove cold water were induced by internal tides and NLIW and lead to volume fluxes equivalent to a weak upwelling. A similar conclusion can be made at N-BoB for $Q_r(17^\circ\text{C} < T^\circ\text{C})$. However it should be noted that part of the Eulerian fluxes may not have been observed because we removed measurements close to the seabed. Some low-frequency isotherm variability may have been present close to the seabed. The fluxes were exactly 0 for the coldest and warmest temperatures (Figure 6). Owing to the method, a flux that is exactly 0 means that the temperature range was not measured. At SE-BoB, $Q_A(T \leq 12^\circ\text{C}) = 0$ (Figure 6d) because there are no temperatures below 12°C at the subtidal frequency (Figure 4). For the same reason $Q_{Eu}(T \leq 12^\circ\text{C}) = 0$ at SE-BoB (Figure 6c), whereas $Q(T \leq 12^\circ\text{C}) \neq 0$. Therefore, $Q_r(T \leq 12^\circ\text{C}) \neq 0$, which means that 100 % of the onshore cross-shelf transport of water colder (or equal) to 12°C was driven by tidal and high-frequency dynamics. Close to the seabed, Eulerian volume fluxes may partially cancel the near-seabed upslope Stokes drift but they are not expected to be strong enough to change the sign of the total flux. Therefore our results are expected to hold near the seabed and agree with previous studies that estimate net upslope volume fluxes near the seabed due to internal tide and nonlinear internal wave Stokes drift in both a lake and in the ocean (Henderson, 2016; Spingys et al., 2020).

4.1.2 The vertical profile of the Stokes drift volume flux

The Stokes velocity induced by a linear internal wave in a constant or symmetrical stratification profile is vertically symmetrical (Franks et al., 2020). A loss of symmetry in the stratification profile, *i.e.*, a near surface or near-seabed pycnocline, translates into a loss of symmetry of the Stokes drift volume flux. At both sites, the Stokes drift volume flux Q_A displayed non-symmetrical flux as the stratification was asymmetrical.

At both sites, the semi-analytical volume flux Q_A was maximum (positive) near the seabed (*i.e.* low temperature range) (Figure 6b,d). At SE-BoB, the maximum Q_A was $0.06 \text{ m}^2/\text{s}^1$ near the seabed, for temperatures $13^\circ\text{C} \geq T > 12^\circ\text{C}$. At N-BoB, Q_A has a near-seabed maximum of $0.18 \text{ m}^2/\text{s}^1$ for $14^\circ\text{C} \geq T > 13^\circ\text{C}$. The Stokes drift flux Q_r was also asymmetrical but did not always follow the same trend as Q_A . At SE-BoB, both Q_r and Q_A were maximum near the seabed, for temperatures $13^\circ\text{C} \geq T > 12^\circ\text{C}$. Therefore, the asymmetry of the SE-BoB Stokes drift flux can partly be explained by the asymmetric stratification profile (Figure 6d). At N-BoB, the asymmetry of the analytical and computed volume flux were opposite. Q_r was greater near the surface, for a temperature around 17°C , while Q_A was maximum near the seabed for temperatures around 13°C (Figure 6b). The stratification drove Q_A asymmetry, but could not explain the asymmetrical shape of Q_r . Moreover, at both locations, the maximum positive values of Stokes drift flux were more than twice the maximum Q_A .

Nonlinear processes are expected to enhance asymmetry in the vertical profile of the volume flux. NLIW generate enhanced, vertically-asymmetrical flux, therefore they are likely to drive this discrepancy. NLIW generate a net horizontal flux in their direction of propagation under the crest and in the opposite direction through the remainder of the water column (Shroyer et al., 2010; Lamb, 1997; Zhang et al., 2018; Garwood et al., 2020). The loss of symmetry in the Stokes drift volume flux profile may

be a sign of the non-negligible impact of NLIW. Asymmetry can also partly be due to the methodology as discussed previously and high frequency surface waves. We acknowledge this potential contribution which we believe deserves further investigation.

360 The nonlinear internal tide is also expected to enhance vertical asymmetry in the Stokes drift volume flux. This point will be further investigated by examining time series of volume flux.

4.2 Time variability of the Stokes drift cross-shelf volume flux

In this section, we present the time variability of the four different cross-shelf volume flux estimates Q , Q_A , Q_{Eu} and Q_r at both sites.

365 4.2.1 N-BoB - a site where the volume flux is dominantly driven by the Stokes drift flux

At N-BoB, under stratified conditions, the total volume flux Q (Figure 7a) exhibited strong similarities with Q_r (Figure 7c). Both fluxes were positive close to the surface and seabed, and negative for temperatures between 14°C and 16°C.

From August 27 to September 21, the vertical profile of the total flux could not be explained by the low-pass filtered Eulerian transport Q_{Eu} and was therefore attributed to the Stokes drift flux (7a.b.c). Near the surface, for temperatures above 16°C, total

370 subtidal flux was largest, positive and up to $1 \text{ m}^2 \cdot \text{s}^{-1}$ during the second spring tide (7a). The subtidal Eulerian flux did not display any positive values for temperatures above 16°C, partly because of the lack of temperature measurements near the surface (Figure 7b). The Stokes drift flux, was also largest near the surface (Figure 7c). In the middle of the water column, the total flux was negative during the 1st spring tide for the temperature class between 14°C and 16°C, similar to the Stokes drift flux, with the same intensity between $-0.3 \text{ m}^2 \cdot \text{s}^{-1}$ and $-0.7 \text{ m}^2 \cdot \text{s}^{-1}$ (Figure 7a,c). For the same temperature class, Q_A

375 displayed a larger negative flux reaching $-1.1 \text{ m}^2 \cdot \text{s}^{-1}$ (Figure 7d). During the 2nd spring tide the total offshore flux reached $-1.1 \text{ m}^2 \cdot \text{s}^{-1}$ between 14°C and 18°C, which was mostly explained by the Eulerian flux (Figure 7a.c). Near the seabed (i.e for temperatures below 13°C), the total flux increased to $0.5 \text{ m}^2 \cdot \text{s}^{-1}$ during the first spring tide and $0.7 \text{ m}^2 \cdot \text{s}^{-1}$ during the second spring tide (Figure 7a). The subtidal Eulerian flux explained part of the near seabed flux during the first spring tide but was negligible during the second spring tide period.

380 The theoretical Stokes drift flux model was able to reproduce the vertical profile of Q_r under the stratified conditions described in the previous section but with different intensity (Figure 7c.d). Near the surface, the theoretical Stokes drift flux Q_A was minimal, with values around $0.1 \text{ m}^2 \cdot \text{s}^{-1}$, ten times smaller than the maximum values computed for Q_r . In the interior, Q_A estimated a stronger offshore flux than what was observed in Q_r . Near the seabed, Q_A and Q_r exhibited similar values, reaching up to $0.5 \text{ m}^2 \cdot \text{s}^{-1}$ during the first spring tide and $0.7 \text{ m}^2 \cdot \text{s}^{-1}$ during the second spring tide. Finally, the temporal

385 variability of Q_r was higher than that of Q_A , revealing that the simple model of Stokes drift flux due to a linear internal tide could not capture all of the variability (Figure 7d).

Part of this discrepancy may be attributed nonlinear internal waves. The impact of NLIW was difficult to differentiate but we note that from August 27 to September 21, Q_r reached values twice Q_A for the near-surface temperature (Figure 7c.d). At the same time, the offshore Q_r was also enhanced in the interior (Figure 7c). Both depression and elevation NLIW were regularly

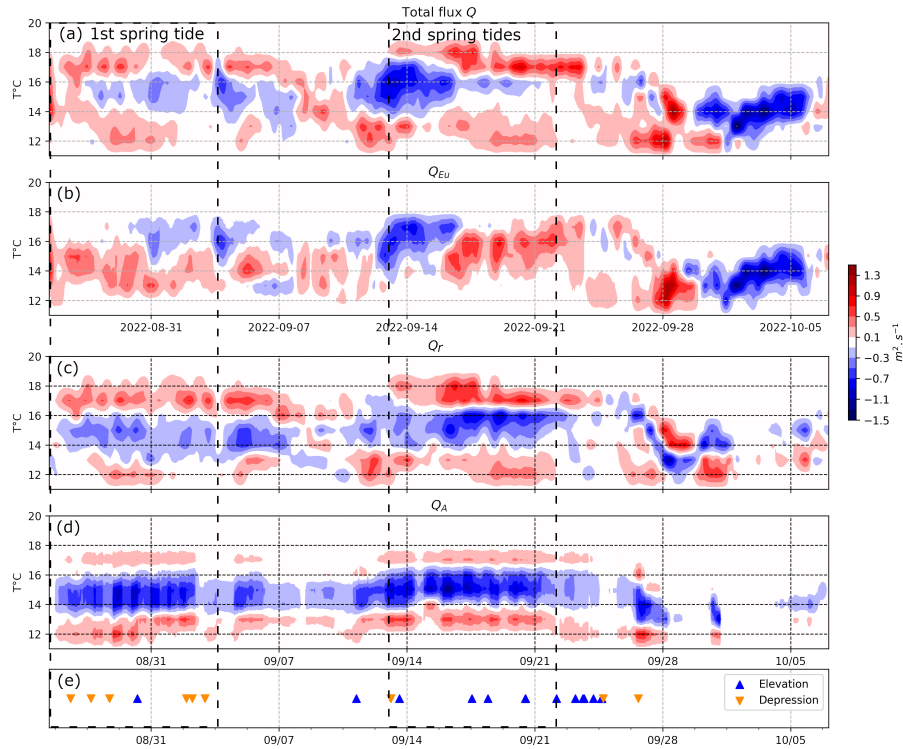

Figure 7. N-BoB fluxes and NLIW from September 28 to October 06. Colors indicate the direction of volume flux. Red is onshore volume flux and blue offshore. (a) Total net cross-shelf volume flux Q . (b) Subtidal volume flux Q_{Eu} . (c) Stokes drift volume flux Q_r (see definition in section 2.3). (d) Theoretical Stokes drift volume flux for a linear, M2, mode 1 internal tide Q_A as defined in section 2.3. (e) NLIW detection, blue triangles correspond to mode 1 NLIW of elevation orange; downward triangles show mode 1 NLIW of depression.

390 observed (Figure 7e). From September 14 to September 21, when the near-seabed Q_r was maximum we also observed a higher number of elevation NLIW (Figure 7c.e).

After September 25, at the end of the record, the stratification was reduced and impacted both the total and Stokes drift subtidal flux (Figure 7). At the end of the record, we measured non-zero Q only over a small range of temperatures as the water column became weakly stratified (Figure 7a). After September 28, the total flux Q was unidirectional over the entire range of
395 temperatures, similar to the Eulerian flux (Figure 7b). At the same time Q_A dropped close to 0 because the amplitude of the internal tide dropped below 5 m. After that, both Q_r and Q_A became negligible (Figure 7c).

4.2.2 SE-BoB - a site where volume flux is mainly driven by subtidal variability

In contrast to N-BoB, the total subtidal volume flux Q at SE-BoB did not have a clear three-layer structure throughout the entire time series (Figure 8a), even though the time-average Q had a three-layer structure (Figure 6). Instead, Q was similar to
400 the subtidal Eulerian volume flux Q_{Eu} (Figure 8b) except close to the seabed, for temperatures below 14 °C. For temperatures

below 14 °C, Q_{Eu} was offshore whereas Q was onshore or nil. The Stokes drift Q_r showed a constant onshore volume flux near the seabed (Figure 8c). The linear internal tide Stokes drift had stronger onshore volume flux near the seabed compared to the surface but the magnitude was small compared to the other fluxes (Figure 8d). Therefore, at SE-BoB, the total volume flux was mainly subtidal except near the seabed where the Stokes drift flux counteracted the Eulerian volume flux, resulting in a weak onshore net volume flux.

The vertical profile of Q_r was complex at the beginning of the record and was not always described as a three-layer profile. For example, during 7/12-13 the volume flux changed sign more than 3 times over the water column. During the time period between July 09 and July 15, we observed trains of NLIW of elevation associated with internal tidal bores (Figure 2a). The linear theoretical Stokes volume flux near the seabed was negligible during this period (Figure 8d). Nonlinearity from the internal tide and NLIW were the likely drivers of Q_r variation during the first spring tide.

After July 17, we no longer observed NLIW trains of elevation; instead, the elevation waves were generated by polarity reversal (Moncuquet et al., 2025). Q_r was still stronger close to the seabed (Figure 8c). The near-absence of NLIW after July 21 was associated with a Stokes drift flux that matched the theoretical linear tide Stokes drift volume flux, suggesting that the M2 mode 1 linear internal tide was driving the Stokes drift flux with enhancement due to internal tide steepening.

4.2.3 SE-BoB - interactions between internal waves and the wind-driven current

At SE-BoB we observed periods of time when a two layer structure Q_{Eu} corresponding with stratified wind-driven upwelling (Batifoulie et al., 2012; Kersalé et al., 2016) coincided with a three-layer Stokes drift volume flux Q_r similar to the theoretical internal tide Stokes drift structure.

During the 1st spring tide, between July 09 and July 16, we observed an offshore total volume flux Q near the surface (warm temperatures) and an onshore flux in the bottom layer (cool temperatures) (Figure 9a), indicative of classical upwelling. However, for temperatures below 14 °C (near the seabed), Q_{Eu} was actually negligible (Figure 9a). Under the stratified conditions, the onshore volume flux was further above the seabed, as described by (Lentz and Chapman, 2004). Lentz and Chapman (2004) presented observations made around the world, which included negative volume flux near the seabed under upwelling on the Peru shelf, a location with a strong internal wave field. Note that the cold water was only present at tidal and higher frequencies and therefore was not retained in the low-pass filtered temperature field (Figure 4). Under the upwelling event, the Stokes drift flux drove the near-seabed onshore flux of cold water instead of the wind-driven upwelling, leading to net onshore near-seabed total flux. The onshore Stokes drift flux Q_r ($13^{\circ}\text{C} < T \leq 14^{\circ}\text{C}$) was up to $0.14 \text{ m}^2 \cdot \text{s}^{-1}$, and equivalent to the onshore subtidal flux Q_{Eu} ($14^{\circ}\text{C} < T \leq 15^{\circ}\text{C}$) (Figure 9a.b).

During the 2nd spring tide, the Eulerian volume flux at SE-BoB was onshore for warmer temperatures and offshore for colder temperatures (Figure 10a), which corresponded to a wind-driven downwelling structure. The total volume flux Q was onshore over the entire temperature range (Figure 10a). The total near-surface and near-seabed volume flux were not explained

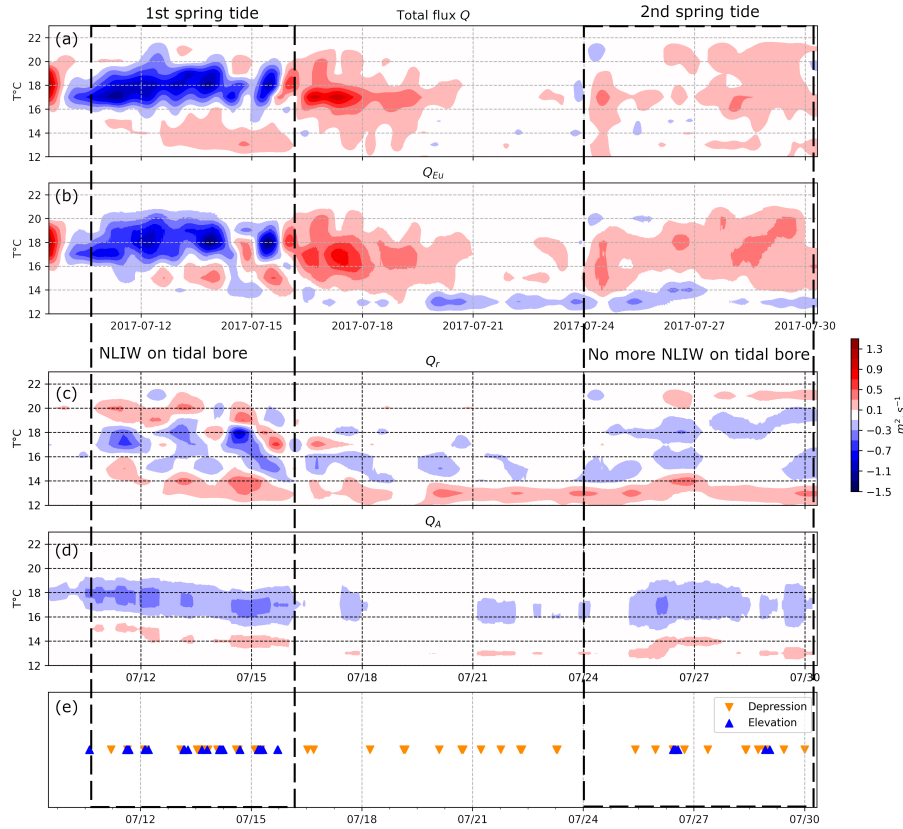

Figure 8. SE-BoB fluxes and NLIW from July 09 to July 30. Colors indicate the direction of volume flux. Red is onshore volume flux and blue offshore. (a) Total net cross-shelf volume flux Q . (b) Subtidal volume flux Q_{Eu} . (c) Stokes drift volume flux Q_r (see definition in section 2.3). (d) Theoretical Stokes volume flux for a linear, M2, mode 1 internal tide Q_A as defined in section 2.3. (e) NLIW, blue triangles correspond to mode 1 NLIW of elevation, orange downward triangles show mode 1 NLIW of depression.

by Q_{Eu} and the near-seabed Q_{Eu} was even offshore, with a maximum of $0.18 \text{ m}^2.\text{s}^{-1}$. This implies that the Stokes drift flux
 435 surpassed the offshore downwelling volume flux and drove onshore total volume flux near the seabed.

5 Discussion and Conclusions

In this study, we quantified the total, Eulerian and Stokes drift cross-shelf subtidal volume flux at two distant coastal sites in the Bay of Biscay. At the two sites, the month-averaged Stokes drift flux (difference between the total and Eulerian fluxes), matched well the theoretical profile of the internal wave Stokes drift for a mode 1 linear internal tide. Therefore, we attributed
 440 the Stokes drift flux at both study sites to be mainly driven by the internal tide. The time series of the Stokes drift fluxes revealed the additional likely important contribution of nonlinear internal waves at these sites, thereby we attribute the Stokes drift flux to internal wave pumping due to the linear internal tide, internal tide steepening and nonlinear internal waves. The IWP was

modulated by background stratification, interaction with wind-driven currents, and the presence of nonlinear processes. At

N-BoB, Eulerian transport was weak and IWP drove the total flux vertical structure. At SE-BoB, the total flux was dominated
445 by wind-driven currents and modulated by IWP, apart from near the seabed where IWP dominated the onshore flux.

Onshore near-seabed volume flux was dominated by IWP at both sites. At N-BoB, the monthly-averaged volume flux due
to IWP was $0.25 \text{ m}^2 \cdot \text{s}^{-1}$ near the seabed, $-0.5 \text{ m}^2 \cdot \text{s}^{-1}$ in the interior and, $0.27 \text{ m}^2 \cdot \text{s}^{-1}$ near the surface which is comparable
to previous values observed in the Celtic Sea by Huthnance et al. (2022). On the Armorican shelf, at N-BoB, the total volume
flux was predominantly driven by the IWP during the stratified period and spring tides. The theoretical Stokes drift internal
450 tide volume flux represented the observed vertical profile of the IWP, but not the magnitude and asymmetry, suggesting the
important impact of nonlinear processes such as internal tide steepening and NLIW on the Stokes drift volume flux. At SE-BoB,
the monthly-averaged volume flux was $0.25 \text{ m}^2 \cdot \text{s}^{-1}$ near the seabed, $-0.33 \text{ m}^2 \cdot \text{s}^{-1}$ in the interior, and below $0.1 \text{ m}^2 \cdot \text{s}^{-1}$ near
the surface. Under both upwelling and downwelling events, the IWP drove an onshore near-seabed volume flux for the entire
record, similar to the $0.3 \text{ m}^2 \cdot \text{s}^{-1}$ sustained near-seabed volume flux by NLIW observed by Inall et al. (2001) on the Malin
455 shelf. Nonlinearity from internal tide steepening, NLIW, and the interaction between internal waves and mesoscale dynamics
likely explain the discrepancy between the IWP vertical profile and the Stokes drift theoretical internal tide profile.

At both sites, nonlinearity modulated the Stokes drift volume flux. The theoretical Stokes drift for a M2 linear mode 1
internal tide explained only part of the Stokes drift flux profile and magnitude throughout much of the time series. NLIWs
were shown to account for some of the discrepancies between the theoretical and observed Stokes drift. Additional moored
460 observations that sample a wider variety of NLIWs are required to more definitively attribute Stokes drift volume flux to
NLIWs. The surface tide and high frequency surface waves could also contribute to the observed Stokes drift. However, we
estimate these contributions should be small during the observation period due to the weak surface tide asymmetry in the region
and the weak high frequency surface waves.

The impact of nonlinear internal tide and NLIW could be further investigated using a realistic high-resolution hydrostatic
465 numerical configuration of the BoB to compare cross-shelf flux under stratified and non-stratified conditions and to further
diagnose the nonlinearity of the internal tide on the shelf. The relative contribution of NLIW and internal tides to the volume
flux should be further investigated using a non-hydrostatic model.

Using a numerical model, Bourgault et al. (2014) demonstrated the role of NLIW in transporting resuspended sediment
shoreward. This led Cheriton et al. (2014) to suggest that midshelf mud belts could be partially controlled by internal waves,
470 via erosion of mud at the outer-shelf being transported towards the midshelf. Similarly, the onshore near-seabed transport
observed at N-BoB could supply the BoB midshelf mud belt (the "Grande Vasière").

A deeper investigation of the internal wave transport on the BoB shelf could help explain the unique sediment distribution
across the shelf. At the SE-BoB, Cirac et al. (2000) observed the absence of sand and unique and unexplainable sedimentary
patterns around 80 m water depth. We suggest that the internal tide and waves could potentially impact the sediment distribution
475 across the SE-BoB by inducing dominant near-seabed onshore transport.

At the Northern Bay of Biscay, close to N-BoB, Laes et al. (2007) made vertical measurements of iron concentration over the
shelf. They observed enhanced values of iron close to the seabed, which could not be explained by wind-driven mechanisms
such as upwelling. Instead, the authors hypothesized that internal waves may drive near-seabed iron transport. This finding

Acknowledgements. We are grateful for the support of the ISblue project, Interdisciplinary graduate school for the blue planet (ANR-17-EURE-0015) and co-funded by a grant from the French government under the program “Investissements d’Avenir” embedded in France 2030 whose efforts made this research possible. We acknowledge Ifremer PhD scholarship program for the additional funding during A. Moncuquet PhD. This study was partly funded by the Laboratory for Ocean Physics and Satellite remote sensing and Ifremer. Jones was supported by the Australian Research Council (Grants IH200100009, and DP210102745). The ETOILE oceanographic campaign has received funding from the European Commission’s Horizon 2020 Research and Innovation program (H2020 JERICO-NEXT). The authors would also like to thank the RV Côte de la Manche crew for their dedicated work as well as the technical team from Ifremer and SHOM for their technical assistance.
