## 15 Abstract

The ocean plays a crucial role in the global carbon cycle by absorbing and storing substantial amounts of atmospheric carbon dioxide (CO<sub>2</sub>). It is estimated that the ocean has sequestered approximately 26% of CO<sub>2</sub> emissions over the last decade, resulting in significant changes in the marine carbon system and impacting the marine environment. The sea-surface microlayer (SML) plays a crucial role in these processes, facilitating the transfer of materials and energy between the ocean and the atmosphere. However, most studies on the carbon cycle in the SML have primarily addressed daily variability and overlooked nocturnal processes, which may lead to inaccurate global carbon estimates. We analysed temperature, salinity, pH<sub>T25</sub>, and pCO<sub>2</sub> using data collected over three complete diel cycles during an oceanographic campaign along the Croatian coast near Šibenik in the Middle Adriatic. Our analysis revealed statistically significant differences ( $p < 0.05$ ) between daytime and nighttime measurements of temperature, salinity, and pH<sub>T25</sub>. These differences may be related to the occurrence of buoyancy fluxes, which are typically more pronounced during the day and could enhance CO<sub>2</sub> fluxes, as observed with values of  $1.98 \pm 2.52 \text{ mmol cm}^{-2} \text{ h}^{-1}$  during the day, while at night, they dropped to  $0.01 \pm 0.02 \text{ mmol cm}^{-2} \text{ h}^{-1}$ . These findings emphasise the importance of considering complete diurnal cycles to accurately capture the variability in thermohaline features and carbon exchange processes, thereby improving our understanding of the role of the ocean in climate change.

## 1. Introduction

The ocean is a crucial climate regulator that mitigates the effects of anthropogenic emissions (Gattuso *et al.*, 2015). It absorbs a significant portion of the Earth's excess heat (Hoegh-Guldberg *et al.*, 2014) and captures a substantial amount of anthropogenic carbon dioxide (CO<sub>2</sub>) emissions (Wong *et al.*, 2014). It is well known that CO<sub>2</sub>

35 significantly affects marine chemistry (Doney *et al.*, 2009; Gattuso *et al.*, 2015), and it is estimated that the ocean  
has sequestered approximately 26% of global CO<sub>2</sub> emissions in the last decade (Friedlingstein *et al.*, 2024).  
Consequently, changes in the ocean environment have exceeded the magnitude and rate of natural variation due to  
anthropogenic carbon perturbation over the last millennia (Gattuso *et al.*, 2015). In this context, the marine carbon  
system undergoes substantial modifications, resulting in various effects on the marine environment, including a  
40 decrease in pH levels (Cantoni *et al.*, 2012; Doney *et al.*, 2009). Therefore, understanding the evolving state of  
marine biogeochemistry in the context of climate change is crucial, with a primary focus on the upper layers of  
the water column, which are closely linked to ocean-atmosphere interactions.

In the ocean-atmosphere system, the sea-surface microlayer (SML) plays a vital role in transferring materials and  
energy, such as heat, gases, and particles (Wurl *et al.*, 2019), which must pass through it (Frka *et al.*, 2009; Stolle  
45 *et al.*, 2020). The SML is a distinctive and complex marine environment that represents the interfacial boundary  
layer between the ocean and the atmosphere (Frka *et al.*, 2009; Wurl *et al.*, 2011). Its thickness typically does not  
exceed 1000 µm, and it exhibits distinct biological and physicochemical properties compared with the underlying  
water masses (Cunliffe *et al.*, 2013; Stolle *et al.*, 2020; Wurl *et al.*, 2011). Thus, the SML experiences instantaneous  
meteorological forcing, such as solar radiation, wind, and atmospheric inputs (Wurl *et al.*, 2019; Gassen *et al.*,  
50 2023), which impacts the development of physical and biogeochemical processes occurring in the underlying water  
(Liss & Duce, 1997; Stolle *et al.*, 2020). These characteristics of the SML overlap with the growing interest in  
oceanographic research to study the spatiotemporal variability of the marine carbon system (Cantoni *et al.*, 2016),  
as this layer is essential for understanding global marine biogeochemistry. However, to gain a comprehensive  
spatiotemporal perspective on marine carbon chemistry processes, focusing on underexplored fields, such as the  
55 role of nocturnal processes within the diel cycle, is crucial.

Daily variations force cyclic changes in chemistry (De Montety *et al.*, 2011), which are influenced by processes  
such as photosynthesis, gas exchange between the ocean and atmosphere, and various environmental conditions  
(e.g., light, temperature, and nutrient availability) (Poulson & Sullivan, 2010). These processes directly affect the  
seawater pH by adding or removing CO<sub>2</sub> from seawater (Poulson & Sullivan, 2010; Takahashi *et al.*, 2002). It is  
60 well known that photosynthesis consumes CO<sub>2</sub> during the day, thereby reducing *p*CO<sub>2</sub> levels, and consequently  
causing an increase in pH (Cantoni *et al.*, 2012; Takahashi *et al.*, 2002). At night, the CO<sub>2</sub> produced by respiration  
tends to be more constant and accumulates in the water column, leading to an increase in *p*CO<sub>2</sub> and a decrease in  
pH (Cantoni *et al.*, 2012). Although these processes are significant for seawater chemistry, research has  
predominantly focused on diurnal processes. As a result, the roles of respiration and other nocturnal processes in  
65 the SML remain largely unexplored.

Within this framework, the Mediterranean Sea presents a unique research opportunity to investigate the  
spatiotemporal variability of the marine carbon system. It is often referred to as a "laboratory basin" (Bergamasco  
& Malanotte-Rizzoli, 2010; Robinson & Golnaraghi, 1994) because it allows us to approximate processes  
occurring on a global scale within a shorter time and space (Álvarez *et al.*, 2014). Despite representing 0.8% of  
70 the global ocean surface (Álvarez-Rodríguez, 2012), the Mediterranean Sea is considered an important  
anthropogenic carbon storage (Álvarez *et al.*, 2014), as it absorbs a disproportionately larger amount of  
anthropogenic carbon compared to the global ocean (Hassoun *et al.*, 2015; Schneider *et al.*, 2010). Higher  
acidification ranges (-0.001 to -0.009 pH unit yr<sup>-1</sup>) (Hassoun *et al.*, 2022) were measured and exceeded those

measured in the Atlantic Ocean ( $-0.001$  to  $-0.0026$  pH unit  $\text{yr}^{-1}$ ) (Takahashi *et al.*, 2014). However, as explored in  
75 this study, the dynamics of biogeochemical processes in coastal regions are more complex than those in the open  
ocean (Borges, 2005). When examining oceanic regions, it is crucial to acknowledge that daily variability  
profoundly affects marine carbon chemistry.

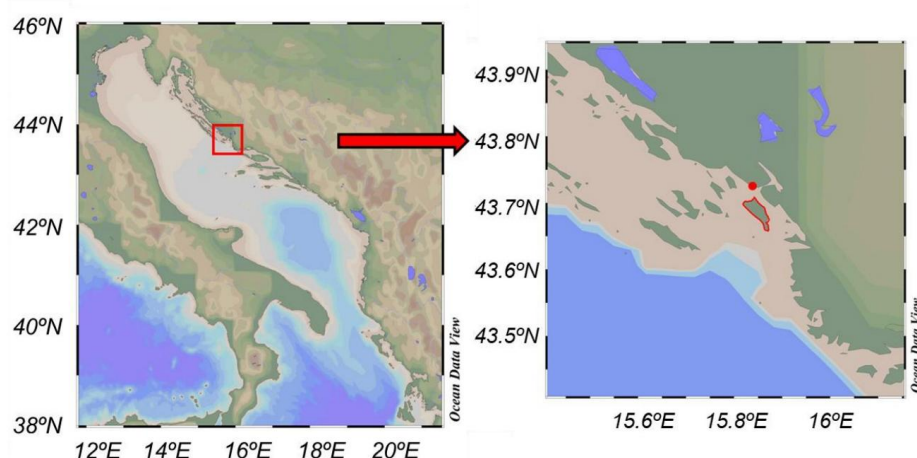

This study emphasises the role of diel variability in thermohaline features and dynamics of the marine inorganic  
carbon cycle in the coastal region of the Mediterranean Sea (Šibenik, Croatia), thereby providing a comprehensive  
80 understanding of the processes that influence the complete diurnal cycle. Therefore, it is essential to incorporate  
nocturnal processes into global estimates of marine carbon cycle dynamics. We present high-resolution data to  
understand biogeochemical processes and their variability in the water column, which complicates predictions of  
coastal marine carbon system variations (Cantoni *et al.*, 2012). We have focused on understanding the nocturnal  
processes that affect the inorganic carbon system, thereby helping to clarify the uncertainties associated with this  
85 system. This study contributes to the identification of anthropogenic influences on the marine environment in the  
context of climate change.

## 2. Materials and Methods

### 2.1. Sampling Strategy and Seawater Analyses

Sampling was conducted in the Middle Adriatic region, specifically **on the Croatian coast near Šibenik** (Figure 1).  
90 Temperature, conductivity, and **pH data** from the SML were collected using sensors integrated in a flow-through  
system on the “Sea Surface Scanner (S<sup>3</sup>)” (Ribas-Ribas *et al.*, 2017) during a six-day campaign in August 2020  
(from 10 to 15 August 2020). Measurements of the underlying water (ULW;  $\sim 1$  m) were performed similarly. Solar  
radiance and wind data were collected from a meteorological station (Davis Instruments, Vantage Pro2 Plus)  
located on Zlarin Island. **This study** collected high-volume samples of approximately 15 L from the SML and ULW  
95 for comprehensive analyses related to the SML. Discrete samples designated for the inorganic carbon parameters  
were collected directly **from the S<sup>3</sup> output** and immediately sealed to prevent atmospheric contamination. These  
measurements were conducted six times per diel cycle, each lasting 30–45 minutes, with a sampling frequency of  
**30 seconds**. Three diurnal cycles were conducted during the study period. In each cycle, the first four  
measurements were taken during periods of **noticeable** solar radiation (diurnal data), whereas the last two occurred  
100 without solar radiation (nocturnal data).

Subsamples from the SML and ULW were collected in high-density polyethylene (HDPE) bottles to determine the  
phosphate ( $\text{PO}_4^{3-}$ ) and silicate [ $\text{Si}(\text{OH})_4$ ] concentrations. To preserve the samples, mercury chloride ( $\text{HgCl}_2$ ) was  
added. The preserved samples were stored at  $+4^\circ\text{C}$  until further analysis in the laboratory. Nutrient concentrations  
were measured using a sequential automatic analyser (SAA, SYSTECA EASYCHEM) according to the standard  
105 protocols described by Laskov *et al.*, (2007) and Fanning & Pilson, (1973).

**Figure 1.** Map of the sampling area in the Middle Adriatic Sea, created using Ocean Data View (Schlitzer, 2022). The red dot indicates the sampling area, whereas Zlarin Island, where the meteorological station is situated, is outlined in red.

## 2.2. Marine Carbon System Determination

DIC samples (20 mL) were analysed by coulometric titration (CM 5014, UIC, USA) with an excess of 10% phosphoric acid. Total Alkalinity (TA) samples (100 mL) were measured via potentiometric titration (916 Ti-Touch, Metrohm, Switzerland) and calculated using a modified Gran plot approach implemented in Calculate (version 1.8.0) (Humphreys *et al.*, 2022). Calibration was performed with certified reference material (Batch 187) obtained from A. G. Dickson at the Scripps Institution of Oceanography. The  $1\sigma$  measurement precision was  $\pm 3 \mu\text{mol kg}^{-1}$  for DIC and  $\pm 2 \mu\text{mol kg}^{-1}$  for TA.

To eliminate the effects of temperature variation on the results, the pH values measured in the seawater samples were adjusted to the average temperature value of 25.43 °C, hereafter referred to as  $\text{pH}_{T25}$ . The normalisation utilised an adjustment factor of 0.018 pH units per °C, which is widely accepted for the range of pH and TA conditions typical of seawater (Eq. 1) (Dickson *et al.*, 2007; Dickson & Millero, 1987; Zeebe & Wolf-Gladrow, 2001):

$$\text{pH}_{T25} = \text{pH} + (T - 25.43) \cdot 0.018 \quad (1)$$

To evaluate the marine carbon system, the partial pressure of  $\text{CO}_2$  ( $p\text{CO}_2$ ) was calculated with the CO2SYS program (Version v3.2.0, MATLAB) (Sharp *et al.*, 2020; Van Heuven *et al.*, 2011) using as input parameters: DIC; TA,  $\text{PO}_4^{3-}$ , and  $\text{Si(OH)}_4$ ; salinity (S); temperature (T), and pressure. The respective dissociation constants were used for carbon (Mehrbach *et al.*, 1973), sulfate ( $\text{KSO}_4$ ) (Dickson & Millero, 1987), fluorine (KF) (Perez & Fraga, 1987), and the borate-salinity ratio (Lee *et al.*, 2010). Missing  $p\text{CO}_2$  values were due to erroneous DIC and/or TA measurements. Consequently, standard deviations could not be calculated when the number of reliable data points was less than three. Once the  $p\text{CO}_2$  values were calculated, the  $\text{CO}_2$  flux through the ocean-atmosphere interface in the monitoring area was estimated using the following equation:

130

$$F = \Delta pCO_2 \cdot k \cdot \alpha \quad (2)$$

where  $F$  is the  $CO_2$  flux ( $mmol\ m^{-2}\ d^{-1}$ ),  $\Delta pCO_2$  is equal to the difference in the partial pressures of the gas between the surface water and the atmosphere,  $k$  is the gas transfer coefficient ( $cm\ h^{-1}$ ) from Wanninkhof, (2014), and  $\alpha$  is the solubility of  $CO_2$  in seawater ( $mol\ L^{-1}\ atm^{-1}$ ). To calculate the partial pressure gradient of  $CO_2$ , atmospheric  $pCO_2$  data were sourced from the Mauna Loa Observatory dataset of monthly means for August 2020 (Lan et al., 2023). The percentage error associated with excluding nocturnal fluxes in the daily average calculation was determined by comparing the mean fluxes calculated with and without nocturnal data, expressed as the relative difference between the two values.

To ensure high-quality data, a correction factor (CF) was applied to the continuous salinity and  $pH_{T25}$  data. Discrete salinity values obtained from laboratory analyses served as reference points and were compared to the average continuous values recorded by the  $S^3$  (Ribas-Ribas et al., 2017). This process resulted in the derivation of distinct CFs, which were applied at each depth and during each time interval of the  $S^3$  measurements (Ribas-Ribas et al., 2017). Once the salinity values were corrected, the pH was calculated using the CO2Sys program (Version v3.2.0, MATLAB) (Sharp et al., 2020; Van Heuven et al., 2011). These calculated  $pH_{T25}$  values were then utilised as reference points for comparison with the average continuous values obtained from the  $S^3$  measurements (Ribas-Ribas et al., 2017). After correcting for salinity, the density ( $\rho$ ) was calculated using the TEOS-10 (<https://www.teos-10.org/index.htm>) equation of state in RStudio based on the observed temperature and salinity values. From this calculation, sigma- $t$  was defined as the density at a given temperature and salinity minus  $1,000\ kg\ m^{-3}$ .

### 2.3. Evaporation rate calculation

The evaporation rate ( $E$ ) (Gill, 1982) was estimated using the following formula, which relates the latent heat flux ( $Q_E$ ) (Brutsaert, 2013), the latent heat of vaporisation ( $L_v$ ) (Kittel & Kroemer, 1980), and the calculated density of seawater ( $\rho$ ):

$$E = \frac{Q_E}{L_v \cdot \rho} \quad (3)$$

### 2.4. Statistical Analysis

Since the assumptions of normality and homoscedasticity were not met for the collected data, the Kruskal-Wallis test was chosen as a nonparametric alternative to ANOVA. This test identified significant differences between the data collected during the day and night, between the SML and ULW, and among the medians of the cycles studied. A significance level ( $\alpha$ ) of 0.05 was established to determine whether the groups differed significantly. All statistical analyses were performed using RStudio. In addition, to carry out a complete analysis of the variability of the marine carbon system during the study period, the anomalies in temperature, salinity,  $pH_{T25}$ , and  $pCO_2$  data were calculated using the following expression:  $\Delta$  (SML – ULW). These differences were calculated for diurnal and nocturnal data for each cycle.

## 3. Results

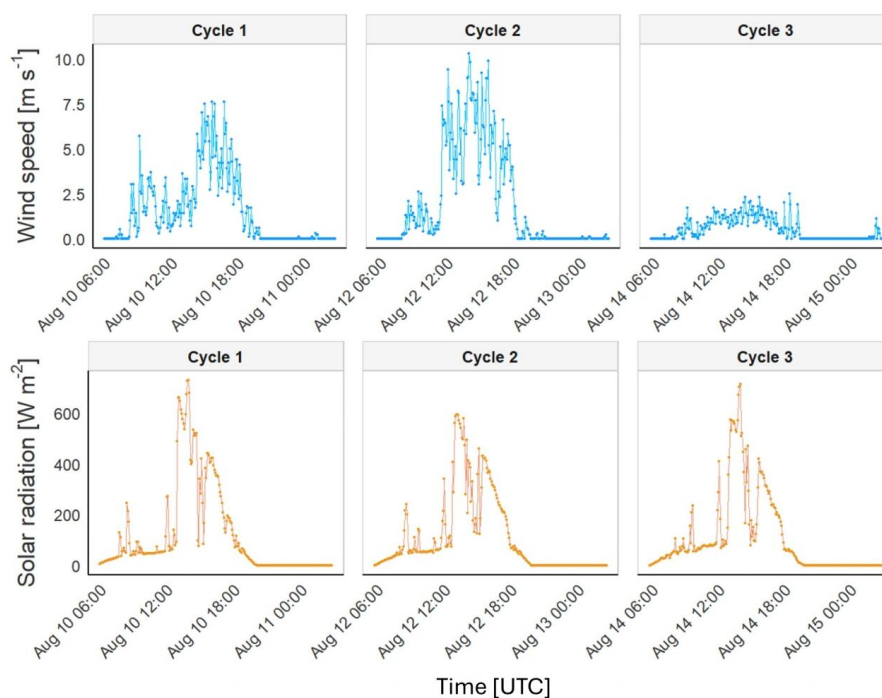

The primary objective of this study was to understand the global patterns of diurnal variability and depth-related differences in marine biogeochemistry during the observed cycles. Temperature, salinity,  $pH_{T25}$ , and  $pCO_2$  were

165 used to perform a statistical analysis of the similarity between the data collected during the diel cycle and to  
calculate the differences between the values measured in the SML and ULW. Additionally, we examined the  
temporal distribution using box-and-whisker plots and calculated the air-sea CO<sub>2</sub> exchange across the SML.

### 3.1. Meteorological conditions

170 To study the potential variance in the meteorological forcing observed during the observations, time-series graphs  
were plotted for solar radiation and wind speed (Figure 2). A consistent pattern of solar radiation was observed  
during all three cycles, with peaks of 525, 404, and 420 W m<sup>-2</sup> observed at 14:00 UTC. Relatively low wind speeds  
were recorded during the day in all three cycles, averaging  $1.26 \pm 1.46$  m s<sup>-1</sup>. Maximum wind speeds were  
observed at 14:00 and 18:00 UTC, higher for Cycles 1 and 2 (2.14 m s<sup>-1</sup> and 5.22 m s<sup>-1</sup>) than during Cycle 3  
(0.95 m s<sup>-1</sup>). Additionally, a decrease in wind speed was observed throughout the night, approaching near-zero  
175 values, except during Cycle 3 when the wind speed remained consistently close to zero.

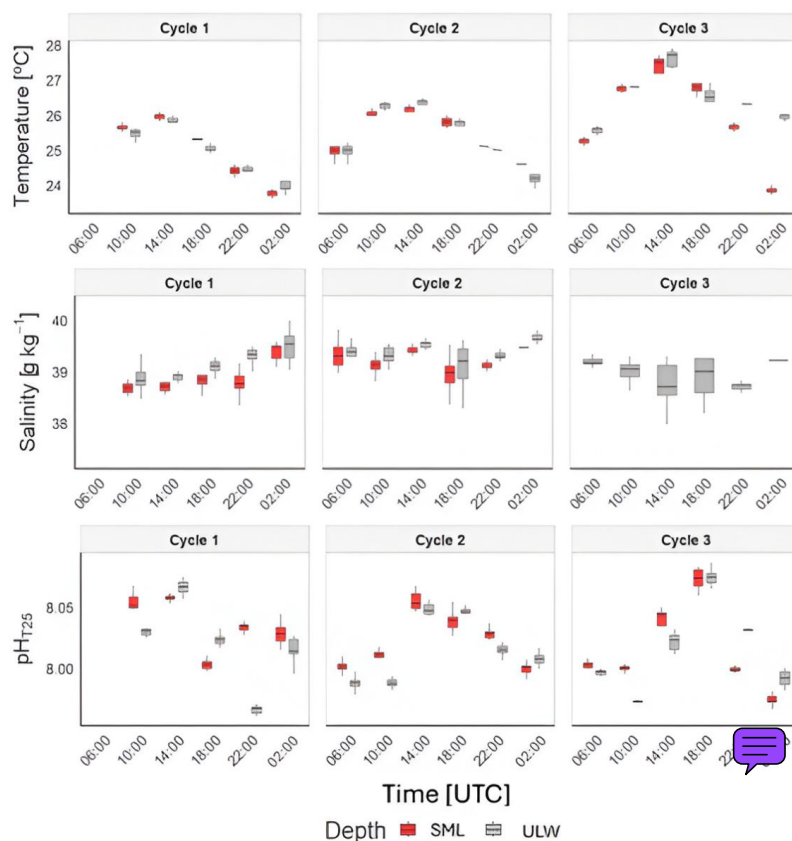

**Figure 2.** Time series showing wind speed and solar radiation on Zlarin Island (Figure 1) during the three studied cycles.

### 3.2. Daily trends

180 To investigate the overall distribution of physicochemical parameters throughout the daily sampling period at SML  
and ULW, we show box-and-whisker plots for temperature, salinity, and pH<sub>T25</sub> across different time intervals  
(Figure 3). We also performed the Kruskal-Wallis test to determine statistically significant differences between the  
SML and ULW (Table S1). The analysis revealed no significant temperature differences between the two depths  
during Cycle 1 (SML:  $25.00 \pm 0.85$  °C; ULW:  $24.90 \pm 0.72$  °C) and Cycle 2 (SML:  $25.40 \pm 0.62$  °C; ULW:  $25.40$

185  $\pm 0.83$  °C). However, in Cycle 3, ULW was slightly warmer, with a mean temperature of  $26.60 \pm 0.72$  °C compared to  $26.20 \pm 1.20$  °C in the SML. For salinity, significant differences were detected between SML and ULW during Cycles 1 and 2, with ULW exhibiting higher salinity levels in Cycle 1 (SML:  $38.90 \pm 0.32$  g kg<sup>-1</sup>; ULW:  $39.10 \pm 0.32$  g kg<sup>-1</sup>) and in Cycle 2 (SML:  $39.2 \pm 0.27$  g kg<sup>-1</sup>; ULW:  $39.4 \pm 0.29$  g kg<sup>-1</sup>). Notably, the salinity data showed greater variability, especially in Cycle 2, in the SML, whereas the ULW remained relatively constant. The pH<sub>T25</sub> data collected over the three cycles displayed considerable variability, with fluctuations observed throughout the day. The SML and ULW data showed significant differences during the first two cycles, with slightly higher values in the SML for Cycle 1 (SML:  $8.030 \pm 0.020$ ; ULW:  $8.020 \pm 0.033$ ) and for Cycle 2 (SML:  $8.020 \pm 0.020$ ; ULW:  $8.010 \pm 0.024$ ). No significant differences were observed in Cycle 3 (SML:  $8.020 \pm 0.032$ ; ULW:  $8.020 \pm 0.032$ ).

195

**Figure 3. Box-and-whisker plots for the different time steps at which measurements were obtained at both the SML and ULW for temperature, salinity, and pH<sub>T25</sub>. The horizontal line within each box denotes the mean of the data, whereas the vertical line associated with each box represents the 25<sup>th</sup> and 75<sup>th</sup> percentiles (Q1 and Q3) of the data.**

### 200 3.3. Diel variability and depth-related anomalies

To assess diel variability in the marine carbon system, we statistically compared the thermohaline and key carbon cycle variables,  $\text{pH}_{\text{T25}}$  and  $\text{pCO}_2$ , between day and night in the SML and ULW (Figure 4, Table 1). Additionally, we calculated  $\Delta\text{SML-ULW}$  to evaluate the magnitude of vertical anomalies during diurnal and nocturnal conditions. The analysis of thermohaline variables indicated significant differences between diurnal and nocturnal data at the two depths across the three cycles (Table S2). However, the salinity data from ULW during Cycle 3 did not exhibit significant differences. The observed anomalies between the SML and ULW varied across the three cycles for temperature (Table 1). In Cycle 1, the SML exhibited positive temperature anomalies during the day and negative anomalies at night (Table 1). In contrast, Cycle 2 showed negative diurnal and positive nocturnal temperature anomalies. During Cycle 3, both diurnal and nocturnal temperature anomalies in the SML were negative. Similarly, salinity anomalies in the SML were consistently negative in Cycles 1 and 2 for both day and night measurements (Table 1). These patterns indicate that external forcing may modulate thermohaline properties, contributing to the marked temporal variability observed across the diel cycle.

215 **Figure 4. Frequency distribution of temperature, salinity, and  $\text{pH}_{\text{T25}}$  differences between SML and ULW observed during the day (orange) and at night (blue) across the three cycles studied.**

When comparing the diurnal and nocturnal data for the variables associated with the marine carbon system at each depth (Table S2), we found significant differences in  $\text{pH}_{\text{T}25}$ , except for the ULW data during Cycle 3. However, no significant differences were observed in the  $\text{pCO}_2$  data. The  $\text{pH}_{\text{T}25}$  deltas (Table 1) revealed that during Cycle 1, lower  $\text{pH}_{\text{T}25}$  values were recorded in the SML for diurnal data and higher for nocturnal data ( $-0.006 \pm 0.018$ ;  $0.038 \pm 0.029$ ). During Cycle 2, the SML showed higher diurnal ( $0.011 \pm 0.012$ ) and lower nocturnal ( $-0.002 \pm 0.012$ )  $\text{pH}_{\text{T}25}$  values. Meanwhile, for Cycle 3, the SML indicated higher  $\text{pH}_{\text{T}25}$  values for the diurnal data ( $0.013 \pm 0.012$ ) and lower values for the nocturnal data ( $0.026 \pm 0.009$ ) (Table 1). For the  $\text{pCO}_2$  data during Cycles 1 and 3, lower  $\text{pCO}_2$  values were recorded in the SML during both diurnal ( $-11 \pm 56 \mu\text{atm}$  and  $-22 \pm 22 \mu\text{atm}$ , respectively) and nocturnal periods ( $-4$  and  $-8 \mu\text{atm}$ , respectively) (Table 1). In Cycle 2, lower diurnal and higher nocturnal values were observed in the SML, with values of  $-12 \pm 19 \mu\text{atm}$  and  $7 \mu\text{atm}$ , respectively. The large variability between the nighttime and daytime data distributions at the two depths can be attributed to the complex interaction between biological processes and atmospheric and oceanic forcing, such as heat flux and mixing processes.

**Table 1. Mean anomalies of temperature, salinity,  $\text{pH}_{\text{T}25}$ , and  $\text{pCO}_2$  between the two depths studied ( $\Delta(\text{SML-ULW})$ ).**

		Temperature [ $^{\circ}\text{C}$ ]		Salinity [ $\text{g kg}^{-1}$ ]		$\text{pH}_{\text{T}25}$		$\text{pCO}_2$ [ $\mu\text{atm}$ ]	
		n	$\Delta$ SML-ULW	n	$\Delta$ SML-ULW	n	$\Delta$ SML-ULW	n	$\Delta$ SML-ULW
Cycle 1	Day	177	$0.19 \pm 0.14$	606	$-0.23 \pm 0.17$	175	$-0.006 \pm 0.018$	3	$-11 \pm 56$
	Night	142	$-0.10 \pm 0.14$	426	$-0.29 \pm 0.30$	140	$0.038 \pm 0.029$	1	$-4$
Cycle 2	Day	312	$-0.13 \pm 0.12$	972	$-0.14 \pm 0.19$	324	$0.011 \pm 0.012$	4	$-12 \pm 19$
	Night	180	$0.28 \pm 0.18$	559	$-0.15 \pm 0.29$	184	$-0.002 \pm 0.012$	2	$7$
Cycle 3	Day	365	$-0.08 \pm 0.24$	-	-	141	$0.013 \pm 0.012$	4	$-22 \pm 22$
	Night	132	$-1.34 \pm 0.77$	-	-	53	$-0.026 \pm 0.009$	2	$-8$

### 3.4. Biogeochemical processes variability across diel cycles

To assess the variability of biogeochemical processes during the diel cycle, we present time series of temperature, salinity, and  $\text{pH}_{\text{T}25}$  (Figure 5). In the time series, large fluctuations were primarily observed in the SML, particularly during the day. This increased variability is consistent with the patterns described in the previous section, although the standard deviations between SML and ULW are similar overall (Table S2). The changes during the day occurred rapidly, with increases and decreases spanning 3- 5-minute intervals for the three parameters. More specifically, during sampling at 18:00 UTC of Cycle 2, we recorded variations over brief intervals, specifically showing changes of approximately  $0.28^{\circ}\text{C}$  in temperature,  $0.30 \text{ g kg}^{-1}$  in salinity, and 0.016 units in  $\text{pH}_{\text{T}25}$ . During the night, fluctuations were less frequent and of smaller magnitude, except for a sudden change at the end of the sampling conducted at 02:00 UTC in Cycle 2. At that point, there was a slight increase in  $\text{pH}_{\text{T}25}$  at both SML and ULW, along with a decrease in salinity at both depths. This observation suggests that daytime surface heating,

evaporation, and production processes likely result in changes in temperature, salinity, and  $\text{pH}_{\text{T25}}$ , which are less pronounced at night.

**Figure 5. Time series data of temperature, salinity, and  $\text{pH}_{\text{T25}}$  collected during Cycle 2: Diurnal (18:00 UTC, August 12) and Nocturnal (02:00 UTC, August 13) measurements.**

To assess the variability observed in the SML, the  $\sigma\text{-}t$  time series for Cycle 2 at 18:00 UTC and 02:00 UTC was plotted (Figure 6), and evaporation rates within the SML were calculated for Cycles 1 and 2 (Table 2), as salinity data required for calculations in Cycle 3 were not available. The  $\sigma\text{-}t$  time series throughout the day exhibits greater variability in the SML compared to nocturnal data, when the density fluctuation decreased. However, this variability trend was not observed in the ULW. The observed patterns of temperature, salinity,  $\text{pH}_{\text{T25}}$ , and  $\sigma\text{-}t$  align with the calculated evaporation rates. In Cycles 1 and 2, the evaporation rates peaked at 14:00 UTC (0.043  $\text{mm h}^{-1}$  and 0.074  $\text{mm h}^{-1}$ , respectively). They remained high during the late afternoon at 18:00 UTC (0.042  $\text{mm h}^{-1}$  and 0.041  $\text{mm h}^{-1}$ , respectively), coinciding with the periods of highest solar radiation and wind speed (Figure 2). In contrast, the evaporation rate was close to zero at night. This behaviour highlights the

influence of meteorological forcing on the SML during the day, highlighting the connection between evaporation and the variability observed.

260 **Figure 6.** Time series during Cycle 2 for diurnal (18:00 UTC on August 12) and nocturnal (02:00 UTC on August 13) sigma-*t* data. Sigma-*t* is defined as the density at a given temperature and salinity minus 1,000 kg m<sup>-3</sup>.

**Table 2.** Estimated evaporation rates (mm h<sup>-1</sup>) based on latent heat flux and seawater density in the SML.

Evaporation rates [mm h <sup>-1</sup> ]				
Cycle	Time (UTC)	Mean	sd	n
Cycle 1	06:00			
	10:00	0.031	$1.261 \cdot 10^{-3}$	41
	14:00	0.043	$4.646 \cdot 10^{-4}$	67

265 To study the gas exchange between the atmosphere and the ocean, we calculated the CO<sub>2</sub> fluxes and *k* values using a wind-based parameterisation (Wanninkhof, 2014) for all three cycles and during both day and night (Figure 7). In Cycle 1, despite the incomplete data, a flux of  $3.68 \pm 1.16$  mmol cm<sup>-2</sup> h<sup>-1</sup> was detected during the day, while the flux was close to zero at night. A similar pattern appeared in Cycles 2 and 3, where the fluxes peaked at approximately 14:00 UTC and declined to near zero thereafter. However, the mean flux was higher in Cycle 2

270  $(2.11 \pm 3.31 \text{ mmol cm}^{-2} \text{ h}^{-1})$  than in Cycle 3  $(0.22 \pm 0.28 \text{ mmol cm}^{-2} \text{ h}^{-1})$ , consistent with stronger winds. The average wind speeds during the day were 1.5, 1.9, and  $0.4 \text{ m s}^{-1}$  for each cycle, respectively, while at night, winds dropped to nearly  $0 \text{ m s}^{-1}$  in the three cycles. The  $k$  values during the day were  $1.12 \pm 0.15$ ,  $2.22 \pm 3.31$ , and  $0.09 \pm 0.11 \text{ cm h}^{-1}$ , whereas at night, they were close to  $0 \text{ cm h}^{-1}$ . In this context, excluding nocturnal fluxes in the daily average calculations introduced local percentage errors of 33%, 50%, and 43% for Cycles 1, 2, and 3, respectively.

275 The increased daytime wind speeds enhanced  $\text{CO}_2$  fluxes, whereas calm nighttime conditions were associated with reduced or nearly zero gas transfer velocities.

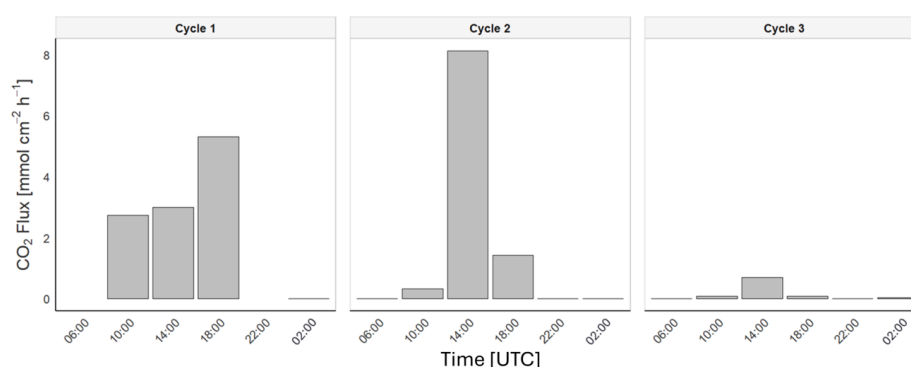

Figure 7.  $\text{CO}_2$  fluxes between the atmosphere and the ocean during the studied cycles.

#### 280 4. Discussion

This study revealed high variability in the SML and ULW during the diel cycle, with significant differences ( $p < 0.05$ ) in temperature, salinity, and  $\text{pH}_{\text{T}25}$  when comparing diurnal and nocturnal data at both depths (Table S1). These results highlight the differences between the meteorological forces that influence the physicochemical properties of seawater during the day and night. For example, during the day, the combined forcing of solar radiation and increased wind speed enhances evaporation rates (Table 2), resulting in the cooling of the SML

285 (Gassen *et al.*, 2023), thus causing changes in temperature, salinity, and  $\text{pH}_{\text{T}25}$  (Figure 4). This means that the SML is subjected to short-time fluctuations that coincide with changes in wind speed. These fluctuations directly influence thermohaline features,  $\text{CO}_2$  system parameters (Acuña *et al.*, 2008), and the kinetics of the metabolic processes occurring in the marine environment (Nimick *et al.*, 2011). Accordingly, in response to the solar

290 photocycle, many marine biogeochemical processes operate on a 24-hour cycle (Nimick *et al.*, 2011), with daily variations comparable in magnitude to the annual variations associated with the amount of solar radiation reaching the ocean surface at different times of the year (Herring *et al.*, 1990; Nimick *et al.*, 2011).

Regarding the variability observed during the day and night, we detected differences in the diurnal temperature data, reaching up to  $+1.89^\circ\text{C}$  in the SML and  $+1.36^\circ\text{C}$  in the ULW. The calculated mean temperature values

295 correspond to the Middle Adriatic Surface Water mass (Table S1). Previous studies have reported mean summertime temperatures in the SML of  $25.1^\circ\text{C}$  (Frka *et al.*, 2009) and  $27.4 \pm 2.9^\circ\text{C}$  (Milinković *et al.*, 2022). Interestingly, the negative diurnal SML anomalies in Cycles 2 and 3 differ from the typical warming pattern in low

wind conditions (Wurl *et al.*, 2019), suggesting that localized mixing or evaporative cooling may have offset surface warming. Similarly, the observed negative salinity anomaly in the SML could also be linked to these processes. While evaporation driven by intense solar radiation tends to increase salinity in the SML (Frka *et al.*, 2009; Wurl *et al.*, 2019), the consistently negative salinity anomalies observed in Cycles 1 and 2 (Table 1) suggest vertical mixing. This explains the daily variability in salinity distribution between the SML and ULW, with mean values of  $39.09 \pm 0.33 \text{ g kg}^{-1}$  and  $39.15 \pm 0.34 \text{ g kg}^{-1}$ , respectively. The Krka River has the highest outflow rates in the region, but it usually has lower discharge during the summer months, which contributes to the increased salinity observed in the SML and ULW (Frka *et al.*, 2009; Marcinek *et al.*, 2020). During dry periods, submarine groundwater discharge contributes only a small amount, between  $0.19\text{--}0.31 \text{ m}^3 \text{ s}^{-1}$  (Liu *et al.*, 2019), compared to its annual mean of  $52.9 \text{ m}^3 \text{ s}^{-1}$  (Bužančić *et al.*, 2016; Marcinek *et al.*, 2020).

The interaction between biological processes and the physicochemical properties of seawater is complex (Álvarez *et al.*, 2014; Cantoni *et al.*, 2012) and has a delicate balance in the marine environment (Cantoni *et al.*, 2012; Takahashi *et al.*, 2002). This interaction directly influences biogeochemical processes typically regulated by production and respiration (Poulson & Sullivan, 2010). These processes significantly affect the pH of seawater through the uptake or removal of  $\text{CO}_2$ . During the day, photosynthesis lowers  $p\text{CO}_2$  levels and increases pH by consuming  $\text{CO}_2$ , whereas at night,  $\text{CO}_2$  from respiration accumulates, increasing  $p\text{CO}_2$  and decreasing pH (Cantoni *et al.*, 2012). However, as we can see in Cycle 3 (Table S2), the observed increase in  $p\text{CO}_2$  ( $525 \pm 47 \text{ } \mu\text{atm}$ ) and  $\text{pH}_{\text{T}25}$  ( $8.042 \pm 0.020$ ) values during the day compared to those measured at night ( $465 \text{ } \mu\text{atm}$ ;  $7.993 \pm 0.026$ ) may be linked to several processes, including increased respiration and various environmental factors that may offset the anticipated effects of photosynthesis or the possibility of photoinhibition caused by excessive solar radiation (Feng *et al.*, 2008), and an accumulation of  $\text{CO}_2$  in the upper layers of the water due to limited mixing (Takahashi *et al.*, 2002).

The complexity of the coupled thermohaline and pH dynamics in seawater is highlighted in the time-series results (Figure 5). The observed fluctuations in the SML for temperature, salinity, and  $\text{pH}_{\text{T}25}$  may be due to buoyancy fluxes. Wind, thermohaline fluctuations, precipitation, and evaporation significantly influence the surface turbulence (Cronin & Sprintall, 2001). The SML absorbs heat from sunlight and cools through radiation and heat loss, leading to changes in temperature and salinity that disrupt buoyancy, cause convective overturning, entrain deeper water from the ULW, and eventually promote mixing (Cronin & Sprintall, 2001). Wind can also enhance this process by creating tangential stress that acts as a vertical momentum flux. Temperature and salinity changes in the SML led to stratification or convection with mixing (Figure 5), depending on oceanic and atmospheric forcing. This process has already been observed in the SML (Wurl *et al.*, 2019) and was found to regulate buoyancy fluxes through evaporative salinisation, playing a crucial role in the exchange of climate-relevant gases and heat between the ocean and the atmosphere.

In this context, the existence of these buoyancy fluxes only during the day could also explain the diel difference in  $\text{CO}_2$  exchange between the atmosphere and the ocean. As observed in this study, the  $\text{CO}_2$  fluxes exhibited differences between daytime ( $1.98 \pm 2.52 \text{ mmol cm}^{-2} \text{ h}^{-1}$ ) and nighttime ( $0.01 \pm 0.02 \text{ mmol cm}^{-2} \text{ h}^{-1}$ ) conditions. Thus, during the day, buoyancy fluxes facilitate the exchange of  $\text{CO}_2$  between the two compartments, accounting for a higher flux than at night. Additionally, the absence of wind at night reduced the calculated flux to nearly zero, suggesting that gas transfer velocity parameterisations without an intercept may not be appropriate (Ribas-Ribas

*et al.*, 2019). Moreover, even without wind, convective airflow driven by temperature gradients can facilitate gas exchange between the surface and atmosphere (Liss & Merlivat, 1986). This study's diel variability aligns with other research findings, suggesting that another main factor affecting this difference is the vertical  $p\text{CO}_2$  gradient in the upper water column, potentially affecting gas transfer estimates (Stolle *et al.*, 2020). Therefore, neglecting nocturnal fluxes may result in overestimation, as in this study, where the three cycles were overvalued by 33%, 50%, and 44%, respectively.

## 5. Conclusions

This study observed a clear diel variability in the distribution of thermohaline features and variables describing the marine inorganic carbon cycle, including temperature, salinity,  $\text{pH}_{\text{T25}}$ , and  $p\text{CO}_2$ . The SML experiences pronounced fluctuations in these parameters throughout the day, influenced by daily changes, like solar radiation, which directly affect the described variables and the environment's metabolic activity. In addition, higher  $\text{CO}_2$  fluxes were observed during the day, coinciding with increased wind speeds and buoyancy fluxes that enhanced the  $\text{CO}_2$  exchange between the two compartments. Thus, by emphasising the study of diel cycles, it has been observed that the daily variability of biogeochemical processes is in a delicate balance, making it challenging to obtain a comprehensive global understanding of marine chemistry. Technological advances have been made in sampling equipment for short temporal and spatial scales in recent decades. However, such progress has not been extended to nighttime observations, which remain significantly more challenging due to greater logistical complexity and heightened safety considerations when operating aboard oceanographic vessels at night. In this context, it is essential to study complete diel cycles, which are crucial for understanding the global carbon budget and its associated uncertainties. Thus, generating a network of diurnal cycle data will identify the drivers of changes in marine chemistry, allowing for assessing the responses of marine ecosystems in the context of climate change.

## Data Availability Statements

The data supporting the findings of this study have been submitted to PANGAEA and are currently undergoing curation and DOI assignment. In the meantime, the data are available for review and use at <https://cloud.uol.de/s/mKHmN3K8MqPnizg>.
