Supplemental Information

Carbon and Nitrogen Concentration Methods

Total carbon (C) and nitrogen (N) of the solid samples were measured on an elemental analyzer (ECS 8020; NC technologies, Italy). Leachate aqueous phase dissolved organic carbon (DOC) and total dissolved nitrogen (TDN) were determined on a Shimadzu TOC-L Total Organic Carbon Analyzer.

NMR Methodology

Solution ³¹P nuclear magnetic resonance (NMR) experiments were run at the Environmental Molecular Science Laboratory (Pacific Northwest National Laboratory Richland Campus) on an Agilent DD2 spectrometer operated at a field strength of 14.1 T (600.18 MHz ¹H, 242.95 MHz ³¹P) using a Varian 5 mm direct detect probe. A standard one-dimensional (1D) pulse and acquire experiment was employed using a 90° hard pulse (calibrated using the orthophosphate naturally present in each sample), an acquisition time of 0.6 s (6,098 complex points), a spectral width of 42 ppm (10.2 kHz), and relaxation delay equal to 5 times the measured T₁ relaxation constant minus the acquisition time. Each experiment was acquired for approximately 16 hours and the number of transients co-added for each spectrum was dependent on the T₁ for each individual sample.

Post-acquisition processing included setting the orthophosphate peak to 6.0 ppm, phasing, baseline correction, and line-broadening of 10 Hz using MNova 14.0.1 (Mestrelab Research, Spain). Chemical shifts of P species were compared to published literature for identification and assignments were confirmed via spiking experiments.(Cade-Menun, 2015; Doolette et al., 2009) Spiking experiments were conducted by sequentially adding solutions containing known compounds from commercial sources (Figure S2). These known P compounds were dissolved in the reconstitution buffer at concentrations of approximately 60 mM and added in 5–10 μ L amounts to samples after initial sample NMR measurements. Spiked compounds, along with their chemical shifts and standard deviations, included DL- α -glycerophosphate (4.92 ± 0.05 ppm), β -glycerophosphate (4.58 ± 0.03 ppm), RNA (4.50 ± 0.06 ppm, 4.33 ± 0.03 ppm; mononucleotide degradation products), glucose-6-phosphate (5.15 ± 0.01 ppm), glucose-1-phosphate (3.27 ppm), phytate (5.58 ± 0.02 ppm, 4.60 ± 0.02 ppm, 4.30 ± 0.20 ppm, 3.89 ± 0.02 ppm), phosphocholine (3.90 ± 0.01 ppm), and adenosine monophosphate (4.42 ± 0.05 ppm).

Organic P moieties were grouped into orthophosphate monoester (monoester) or orthophosphate diester (diester) regions (Figure S2). The monoester region relative percent was calculated by integrating from 10.0 to 2.5 ppm and subtracting the orthophosphate (6 ppm) peak area. The diester region was integrated from 2.5 to -2.2. Degradation of diesters (RNA and phospholipids) to monoesters occurs in the highly alkaline extraction and reconstitution solutions and may continue during the duration of the NMR experiment.(Doolette et al., 2009; Turner et al., 2003) As a result, we corrected for this by shifting the deconvoluted areas of α -glycerophosphate, β -glycerophosphate, and mononucleotide peaks from the monoester to diester region.(Cade-Menun, 2015; Recena et al., 2018) Specific P moieties were identified and quantified with the peak picking function and any missing peaks were added by hand.

XANES Methodology

Finely ground unburned solid and char samples and reference compounds were smeared to form a homogeneous thin film on P-free tape and then mounted to an aluminum sample holder. Bulk spectra were collected in a helium gas environment at room temperature until adequate signal to noise ratio was achieved (between 2 to 16 scans). A monochromator consisting of double crystal Si (III) and spectra were recorded in fluorescence mode using a 7 element Vortex detector.

Multiple internal reference compounds were used; spectra were energy shifted for the white line of hydroxyapatite to occur at 2152.3 eV, sodium phosphate monobasic at 2152.7, and sodium pyrophosphate at 2152.5. Spectral scans were averaged in SixPack(Webb, 2005), followed by energy calibration and normalization using the Athena Software Program.(Ravel and Newville, 2005) Phosphorus speciation was estimated first with the fit_athena function in the R package 'LCF'(Werner F, 2017) using all reference compounds ($n = 46$) and samples ($n = 64$) in Grieger et al.(Grieger et al., 2022) to identify a subset of likely compounds solid samples are composed of ($n = 26$; Table S3). This subset of reference compounds was used to perform linear combination fits in Athena (Figure S3).

Previous studies have noted that differentiating reference compound spectra in complex matrices can be challenging, particularly among organic P species.(Kruse et al., 2015) However, lack of inclusion of multiple organic and inorganic compounds of a given metal within the reference compound library can result in erroneous fits and underestimation of the contributions from metal and organic P species.(Prietzl and Klysubun, 2018) Hence, we collected a large reference library of inorganic and organic species associated with Ca, Al, Fe, Mn, K, and Na and then

classified individual reference compounds into groups based on the associated metal for inorganic P (Pi) and kept all organic P (Po) as a separate category regardless of the metal association in the linear combination fit (Figure S3; Table S3).

Method Limitations

NMR and XANES are complimentary techniques that help to gain a better understanding of Po and Pi species in environmental samples. NMR allows for measuring the detailed composition of the organic pool, such as differentiating DNA from phytate, but is only capable of classifying inorganic species as orthophosphate and polyphosphates (such as pyrophosphate). NMR has better resolution for Po when conducted in solution, which requires extracting solid samples and potentially altering them or leaving some P unextracted.(Cade-Menun, 2015) On the other hand, XANES has the advantage of measuring the bonding environment of all P atoms in unaltered solid samples, however there are challenges to identifying organic P species(Kruse et al., 2015) (see discussion in SI XANES Methodology section). Although we used both of these techniques on the solid samples, the NMR extraction efficiencies indicate we are quantifying as low as 41.5 (16.2)% for Douglas fir forest high severity chars (Table S1). Notably, the extraction efficiencies significantly decreased as Ca-Pi (measured by XANES) increased (linear model: $p < 0.001$, $r^2 = 0.46$), which is poorly soluble in alkaline solutions and has been observed in soil studies.(McDowell et al., 2007) Therefore, we are preferentially extracting Po and other non-Ca-containing compounds, which are primarily found in unburned and lower severity char samples. This means we are underestimating Pi in char samples when quantified by NMR relative to XANES.

	Unburned	Low	Moderate	High
Douglas-fir Live				
Douglas-fir Litter				
Big Sagebrush				N/A

Figure S1. Representative photos of Douglas-fir forest (composed of litter and live plant material) and Sagebrush shrubland (composed of big sagebrush) for each burn severity classification. Sagebrush shrubland did not reach high severity in our open-air burn experiments.

Burn Severity	Vegetation	P (%)	n
Unburned	Douglas-fir forest	87.4 (7.0)	2
	Sagebrush shrubland	105.9	1
Low	Douglas-fir forest	44.9 (14.1)	5
	Sagebrush shrubland	74.5 (13.3)	2
Moderate	Douglas-fir forest	43.5 (21.6)	3
	Sagebrush shrubland	61.0 (9.8)	2
High	Douglas-fir forest	41.5 (16.2)	4

Table S1. The P extraction efficiency mean (standard deviation) is reported as the proportion (%) of total P in the NaOH-EDTA extracts from solution ^{31}P NMR analysis relative to the aqua-regia digested solid samples. The number of samples (n) is also reported.

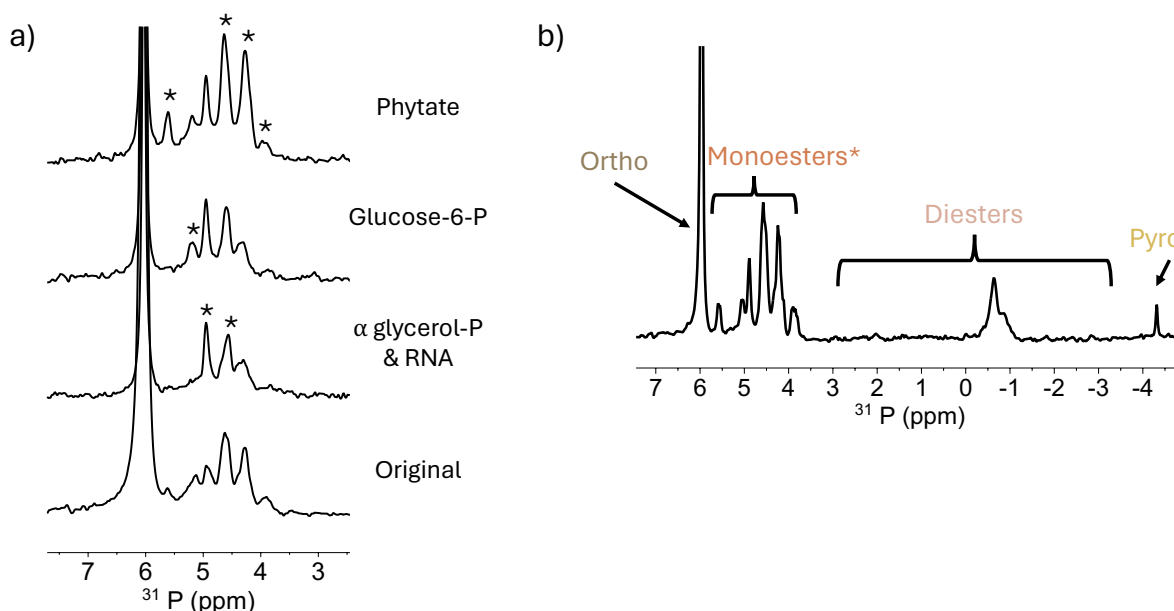

Figure S2. ^{31}P solution NMR a) an example spiking experiment showing the original sample that was subsequently spiked with DL- α -glycerophosphate (4.92 ± 0.05 ppm), RNA (4.50 ± 0.06 ppm, 4.33 ± 0.03 ppm; mononucleotide degradation products), glucose-6-phosphate (5.15 ± 0.01 ppm), and phytate (5.58 ± 0.02 ppm, 4.60 ± 0.02 ppm, 4.30 ± 0.20 ppm, 3.89 ± 0.02 ppm) to identify sample composition of the monoester region; and b) identification of orthophosphate (6 ppm), monoester region (10.0 to 2.5 ppm), diester region (2.5 to -2.2 ppm), and pyrophosphate (-4.2 ± 0.07 ppm). Orthophosphate and pyrophosphate are inorganic species (brown colors) and monoester and diesters are organic species (orange colors). Chemical shifts are reported as the mean (standard deviation) across all samples and spectra are presented with 10 Hz line broadening. *Note the monoester region may contain diester degradation products, which were corrected for. See SI NMR Methods and Method Limitation sections for additional details.

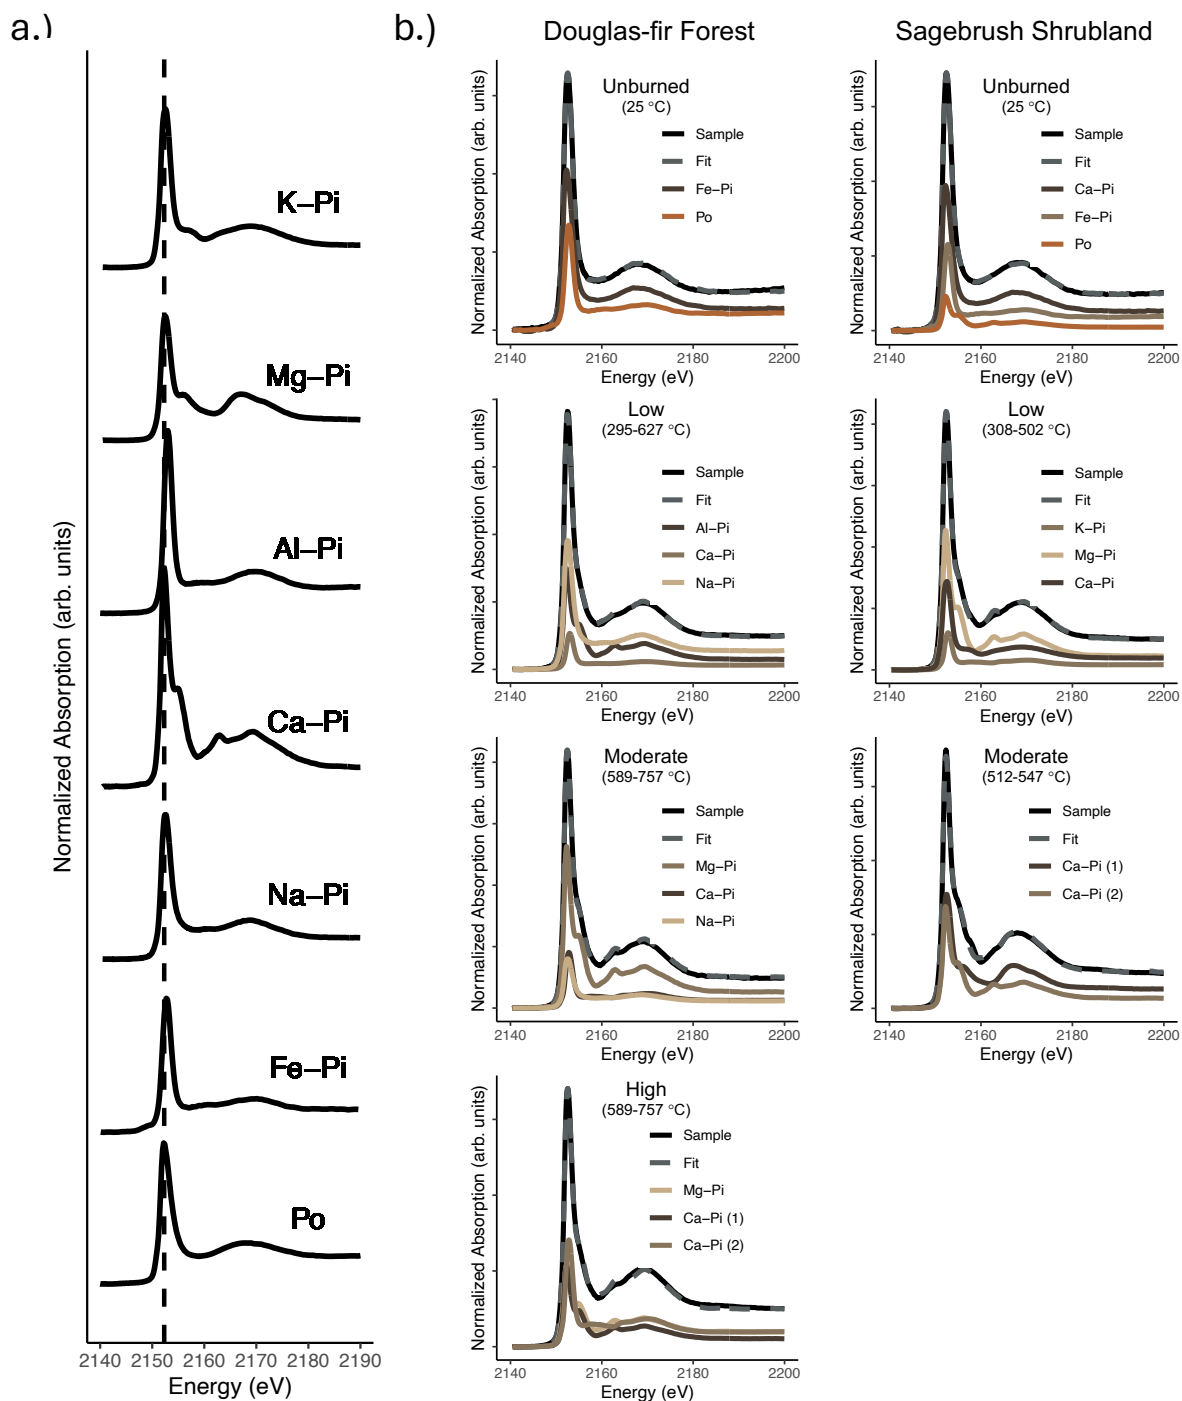

Figure S3. Phosphorus K-edge XANES (a) reference compounds representing K, Mg, Al, Ca, Na, and Fe inorganic P (Pi) along with an organic P species (Po). The vertical dashed line represents the white line of hydroxyapatite at 2152.3 eV, which was used as an internal reference compound; and (b) example linear combination fits for each burn severity experienced by Douglas-fir forest and Sagebrush shrubland. Data (black line), linear combination best fit (dashed gray line), and spectral deconvolution of the reference compounds (colored lines) are presented.

Burn Severity	Vegetation	#	Al-GibbSorb (Al-Pi)	Apatite-CaDefHydroxy (Ca-Pi)	Apatite-Carbonate (Ca-Pi)	Ca-Octa (Ca-Pi)	Ca-Tri (Ca-Pi)	Fe-FerriSorb (Fe-Pi)	Fe-GoethSorb (Fe-Pi)	K-Di (K-Pi)	K-Pyro (K-Pi)	Mg-Di (Mg-Pi)	Mg-Tri (Mg-Pi)	NH4-Mg (Mg-Pi)	Na-Tri (Na-Pi)	Ca-Lecit (Po)	Na-AMP (Po)	Sum	R Factor

Table S2. XANES linear combination fit results for solid samples. Samples are grouped by their burn severity, vegetation type, and sample number (as used in data packages.(Grieger et al., 2022) Only reference compounds identified in the samples are reported. See Table S3 for reference compound details, including the molecular composition. The groupings (i.e., Al-Pi, Ca-Pi, Fe-Pi, K-Pi, Mg-Pi, Na-Pi, and Po) are reported next to the reference compound name. The relative percentage (%), sum of all components, and R Factor (goodness of fit measurement) are reported for each sample individually.

Table S3. X-ray absorption near edge structure (XANES) reference compounds list used for linear combination fitting in Athena. Inorganic P species (Pi) were grouped based on metal association, whereas organic P (Po) species were grouped together regardless of the metal association (see XANES methodology in SI for additional details). Additional information includes file names, the full compound name, the supplier, CAS number, molecular formula, beamline data was collected on, collection mode, and citation spectra was acquired from. Additional reference compounds were used for initial linear combination fits and can be found in Grieger et al.(Grieger et al., 2022)

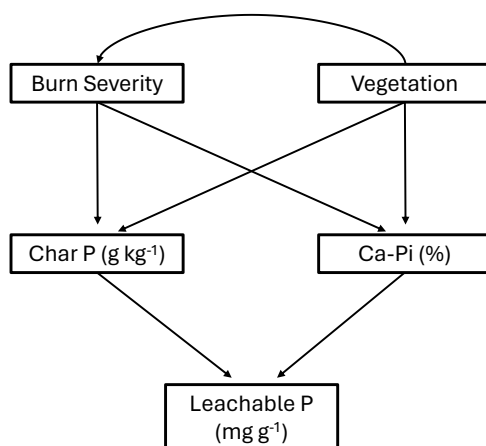

Figure S4. Path analysis conceptual model of hypothesized relationships between burn severity, vegetation type, and leachable P.

Burn Severity	Vegetation	Burn Duration (Minutes)	Lowest Max Temp (°C)	Highest Max Temp (°C)	n
Unburned	Douglas-fir forest	NA	25	25	2
	Sagebrush shrubland	NA	25	25	1
Low	Douglas-fir forest	342 (403)	295	627	5
	Sagebrush shrubland	131 (104)	308	512	2
Moderate	Douglas-fir forest	456 (303)	589	757	3
	Sagebrush shrubland	202 (3)	512	547	2
High	Douglas-fir forest	783 (195)	589	757	4

Table S4. Burn characteristics for severity classifications for each vegetation type including mean (standard deviation) duration, mean (standard deviation) maximum temperature reached, low and high range of maximum temperature, and sample count.

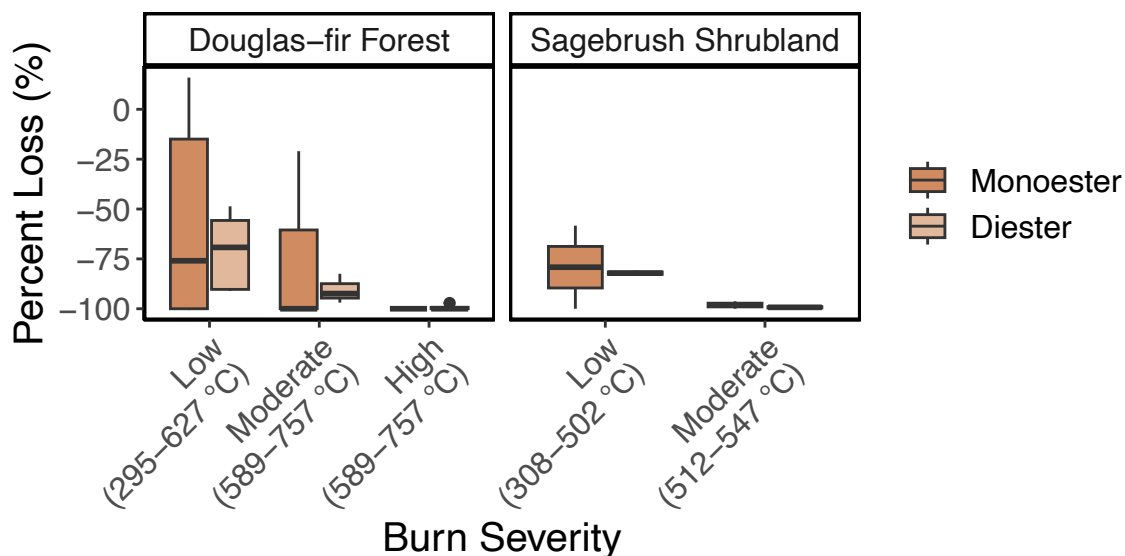

Figure S5. Percent loss of monoester (dark pink) and diester (light pink) species, as identified by ^{31}P NMR. Analysis of variance found no significant difference ($p = 0.97$) between organic classes for the three-factor interaction term. This indicates monoester and diester species are lost at similar proportions within a burn severity classification and vegetation type.

Burn Severity	Vegetation	Ortho	PL	RNA	G6P	Phytate	DNA	Pyro
Percent (%)								
Unburned	Douglas-fir forest	56.8 (2.5)	15.9 (11.2)	9.3 (4.03)	0.7 (NA)	12.4 (NA)	11.3 (0.8)	2.7 (0.8)

Table S7. Molar stoichiometric ratios between Ca, Mg, Fe, Al, Na, K, S, C, and N to P. Mean and standard deviations are reported based on burn severity, vegetation type (Douglas-fir forest or sagebrush shrubland), and sample phase (solid samples, leachate particulate, or leachate aqueous).

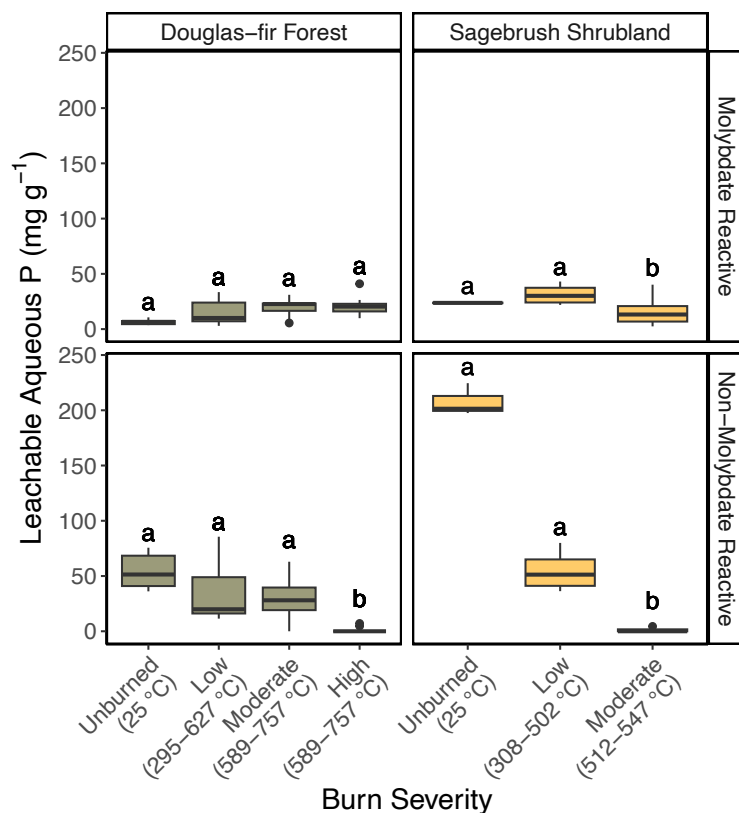

Figure S6. Leachable aqueous molybdate reactive P and non-molybdate reactive P (mg g^{-1}) for Douglas-fir forest (green) and sagebrush shrubland (yellow) based on burn severity classifications. Letters indicate significant differences between burn severities within each vegetation type (mixed effect model post hoc test). Non-molybdate reactive P was calculated as the difference between total P measured on ICP-OES and molybdate reactive P.

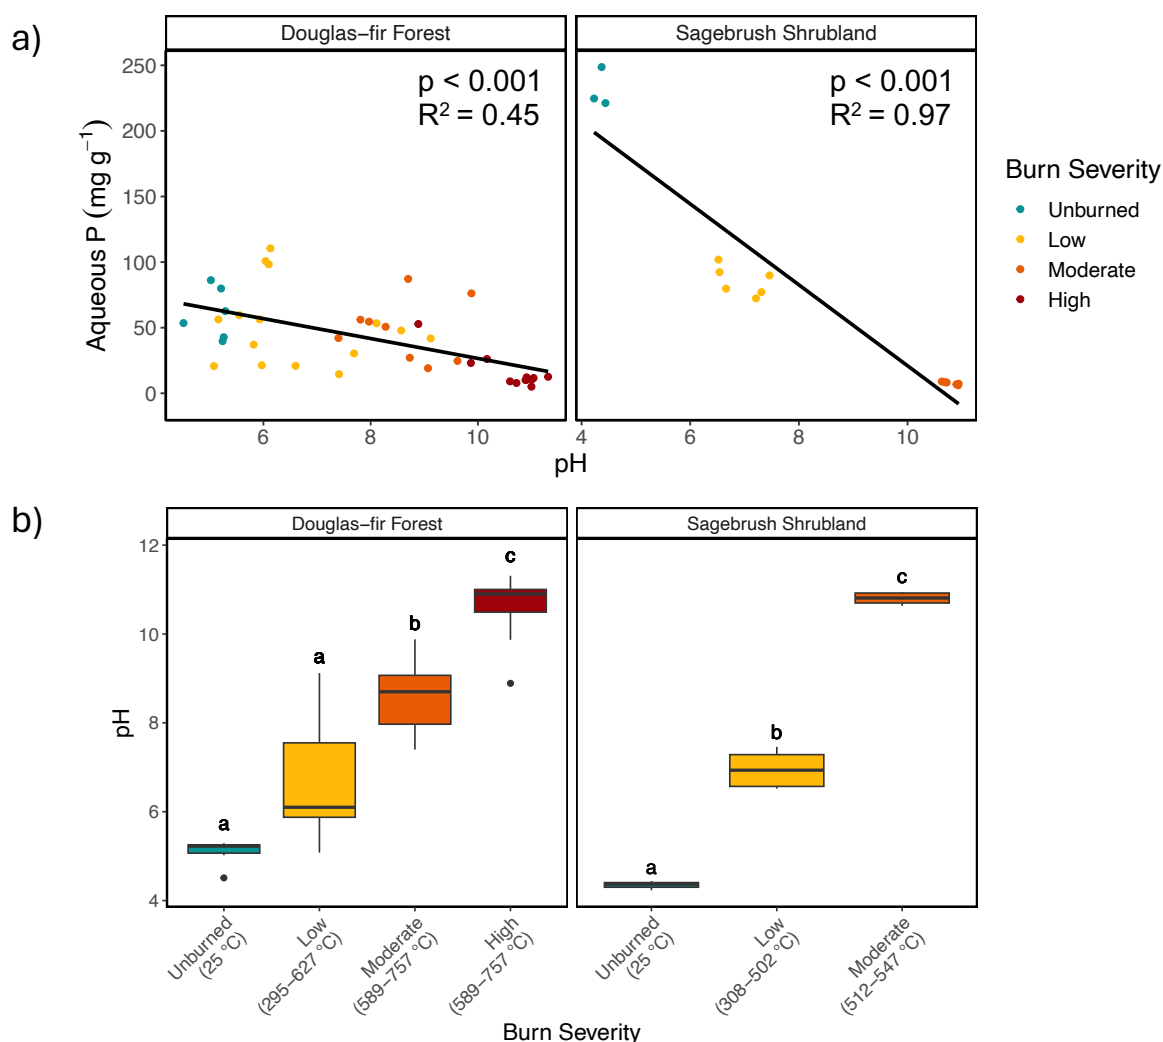

Figure S7. Relationship between a) pH and aqueous P for Douglas-fir forest and Sagebrush shrubland separately, and b) pH and burn severity, with letters representing significant ($\alpha = 0.05$) differences from post hoc test within the respective vegetation types.
