**Abstract.** We present r.avaflow v4, an enhanced version of the open-source mass flow simulation tool r.avaflow. The updated version includes, among other new functionalities, (i) a layered model, where the individual phases move on top of each other instead of mixing; (ii) a sliding model, supporting the entire range from block sliding to full deformation; (iii) a  
15 slow-flow model, allowing for the simulation of landslides beyond extremely rapid processes, using an equilibrium-of-motion model; and (iv) an interface for 3D and virtual reality visualization of the results. We use four case studies to demonstrate the functionalities introduced to r.avaflow v4 and to discuss the related chances and challenges: (i) a generic planar rock slide with interlayer shearing, and (ii)–(iv) semi-generic representations of the prehistoric Köfels rock slide (Austria), the prehistoric East Fogo landslide and tsunami (Cape Verde), and the Dösen rock glacier (Austria). Our results  
20 clearly reveal the high potential of the additional functionalities to widen the scope of r.avaflow beyond the simulation of extremely rapid and freely deforming mass flows. Combinations of the layered model, the sliding model, and the slow-flow model unlock potentials yet barely explored in the field of GIS-based landslide simulations. In addition, the layered model facilitates a more realistic simulation of landslide-reservoir interactions. We also highlight the limitations regarding the physical basis and the application of the functionalities presented. Our enhancements are particularly useful for improved  
25 process visualization targeting at awareness building and environmental education. They are also suitable to be used for scenario-based predictive simulations in combination with a thorough empirical evaluation campaign.

### 1 Introduction

r.avaflow is a GIS-based open-source simulation framework for mass flows and related process chains. It was first introduced by Mergili et al. (2017), at that time based on the two-phase mass flow model of Pudasaini (2012), with a solid  
30 and a fluid phase. The tool was then continuously extended and equipped with a third, fine-solid, phase (Pudasaini and Mergili, 2019). It was applied to a number of case studies, mainly regarding geomorphic process chains in high-mountain

environments, such as the 2012 Santa Cruz glacial lake outburst flood (GLOF) (Mergili et al., 2018a), the complex  
landslides in 1962 and 1970 at Huascarán (Mergili et al., 2018b), the 2017 Piz Cengalo-Bondo process chain (Mergili et al.,  
2020a), the 1941 Palcacocha GLOF (Mergili et al., 2020b), the 2020 Salkantay GLOF (Vilca et al., 2021), the 2020 Jinwuco  
35 GLOF (Zheng et al., 2021), the 2021 Chamoli process chain (Shugar et al., 2021), and, most recently, the 2023 South  
Lhonak GLOF process chain (Sattar et al., 2024).

The various case studies have highlighted the potentials of the r.avaflow software, but also revealed remaining limitations  
and challenges, which can be summarized as follows:

- 40 (1) Forward simulations remain a particular challenge, especially for complex process chains, since parameters must be  
calibrated with observed and documented mass flow characteristics. Guiding parameter sets for future simulations  
would have to rely on a large number of back-calculations of documented events (Mergili et al., 2018b).
- (2) r.avaflow is only suitable for extremely rapid processes. It was not designed for slower processes dominated by  
viscosity. A prototype of a slow-flow model was implemented recently (Su et al., 2024; Section 2.4).
- 45 (3) r.avaflow is designed for more or less freely deforming flow-type processes. It is unsuitable for slide-type  
movements with limited deformation. However, a prototype for deformation control (Pudasaini and Mergili, 2024a)  
was included recently.
- (4) Each of the phases is clearly associated with a particular rheology, without a lot of flexibility (e.g., the solid, fine-  
solid and fluid phase in Pudasaini and Mergili, 2019). A Voellmy-type rheology (Voellmy, 1955) is only available  
with the single-phase model.
- 50 (5) Even though the tool is able to cope with three phases, there is always a mixture of the phases assumed. E.g., the  
behaviour of a landslide moving and depositing at the bottom of a reservoir without mixing with the water cannot  
be simulated. Computational experiments with large-scale volcanic flank collapses have revealed a strong need to  
revisit and to enhance the concepts of r.avaflow in regard to the simulation of landslide-to-reservoir impacts.
- 55 (6) The user interface basically consists in a start script which has to be written manually, without a capable user  
interface. The software is tightly coupled with GRASS GIS and bound to UNIX systems, with rather unsuccessful  
earlier attempts to create a powerful Windows-based stand-alone version of the tool.
- (7) Raster maps, text files and map and animation plots are provided as output, but there are no direct interfaces to  
more advanced visualization systems.

We do not consider challenge (1) in this work. The issue of guiding parameter sets and forward simulations has to be the  
60 subject of further investigations, e.g., by applying machine learning and artificial intelligence methods (Yildiz et al., 2023).  
Instead, we focus on the challenges (2)–(7), along with some other aspects, to enhance the scope and usability of the  
r.avaflow mass flow simulation framework. In Section 2, we will introduce r.avaflow v4 and its new functionalities,  
compared to the older versions. In Section 3 and Section 4, we will demonstrate the functionalities using a set of generic and  
semi-generic case studies. We will discuss our findings in Section 5 and conclude in Section 6.

## 65 2 The simulation framework r.avaflow

### 2.1 General concept of r.avaflow

r.avaflow is a GIS-based open-source mass flow simulation framework. Basically, it transports mass and momentum of up to three phases through a regular grid. The two-phase model of Pudasaini (2012) was employed in the original version (Mergili et al., 2017). It was later replaced by the three-phase model of Pudasaini and Mergili (2019), with a solid, a fine-solid, and a fluid phase, each associated with pre-defined rheologies: the solid phase is characterized through internal and basal friction, the fine-solid phase additionally through viscosity and yield strength, and the fluid phase through viscosity and yield strength. Interactions between the phases are considered through buoyancy effects, virtual mass, and drag. A Voellmy-type mixture model is available as an alternative. The mass and momentum balance equations in Pudasaini and Mergili (2019) are depth-averaged, and the phases are considered to be mixed over the flow height, even though the vertical distribution of the concentration of the individual phases can be controlled. A TVD-NOC central differencing scheme on a staggered grid is used for mass and momentum transport (Tai et al., 2002). The grid is moved half a cell at each time step (cf. Wang et al., 2004 for details).

Typically, the release mass is defined through raster maps showing the release heights for each cell and each phase, imposed on a digital terrain model. Hydrographs (not only for water, but for all types of material considered in r.avaflow) can be used to input mass and momentum to the system, too. Additional functionalities include entrainment, stopping, non-hydrostatic dispersive motion, spatio-temporal variation of several parameters and controls, and empirical evaluation of the results. They are not relevant for the present work, so that the readers are directed to the r.avaflow web site (Mergili and Pudasaini, 2024) for further information. The output of r.avaflow essentially consists in time series of ascii raster maps and plots of flow height and (optionally) kinetic energy and dynamic pressure, along with text files summarizing the simulation.

### 85 2.2 New features of r.avaflow v4

In contrast to earlier versions of r.avaflow, with pre-defined solid, fine-solid, and fluid phases (Pudasaini, 2012; Mergili et al., 2017; Pudasaini and Mergili, 2019), there is no a-priori distinction between different rheologies in r.avaflow v4. Based on the frame of the Pudasaini and Mergili (2019) model, the governing momentum balance equation

$$F_t + F_x + F_y = \alpha \cdot h \cdot (GA + DF + DR - EC - TF - FF - AD) \quad (1)$$

applies to the x and y directions for each of the (minimum 1, maximum 3) phases. The flux terms  $F_t$ ,  $F_x$ , and  $F_y$  are expressed as the derivatives in time, x, and y direction. Thereby, the time derivative is neglected for simplicity.  $\alpha$  is the volumetric fraction of the considered phase, and  $h$  is the total flow height. Source terms which can act either accelerating or decelerating are gravitational acceleration ( $GA$ ), internal deformation ( $DF$ ), and drag ( $DR$ ). The extended Coulomb term ( $EC$ ), turbulent friction term ( $TF$ ), fluid friction term ( $FF$ ), and ambient drag term ( $AD$ ) can only decelerate motion. This implies that in sum the terms do not induce a change in the direction of motion. If such a change of direction would occur

from a purely mathematical point of view, the flow at the given raster cell would stop. All terms are elaborated in more detail in Table 1. Detailed information on all aspects exceeds the scope of this work and is provided in the referenced publications in Table 1.

The behaviour of the landslide depends on the definition of the parameters associated to each term. All terms can be deactivated by setting the governing input parameters to zero. Where necessary, it is automatically decided whether to consider a material as solid or as fluid: solid material is assumed if the internal friction angle  $\varphi > 0$ . Otherwise, the material is considered fluid. Buoyancy is only considered with respect to fluid phases of lower density. Not all combinations of terms are necessarily physically meaningful, so that the enhanced flexibility for users also implies an increased responsibility to combine terms in a meaningful way.

105

**Table 1: x-directional flux and source terms governing flow dynamics in r.avafLOW v4, for any of the maximum of three phases. Terms in y direction are formulated in an analogous way.  $u_x$  and  $u_y$  = depth-averaged velocities in x and y direction;  $uu_{vm}$  and  $uv_{vm}$  = virtual mass contributions (Pudasaini and Mergili, 2019);  $DT$  = dispersion term (Pudasaini, 2023);  $g_x$  = effective downslope component of gravity in x direction;  $f_d$  = deformation coefficient (Pudasaini and Mergili, 2024a);  $k_x$  = x-directional earth pressure coefficient;  $g_z^+$  and  $g_z^-$  = effective slope-normal components of gravity, including the different buoyancy effects (Pudasaini and Mergili, 2019);  $g_z^*$  = effective slope-normal components of gravity, including buoyancy and curvature effects;  $c_{DRAG}$  = drag coefficient (Pudasaini and Mergili, 2019);  $\delta$  = basal friction angle;  $c$  = cohesion;  $E_v$  = energy loss through shearing coefficient (Pudasaini and Mergili, 2024b);  $\varphi$  = internal friction angle;  $F_{ml}$  = fragmentation number (Pudasaini et al., 2024);  $\zeta$  = turbulent friction number;  $n$  = Manning number; and  $c_{AD}$  = ambient drag coefficient. Green colour denotes input parameters, blue colour denotes derived parameters.**

115

Term	Equation	Remarks
Flux in x direction	$F_x = \frac{\partial}{\partial x} \cdot \alpha \cdot h \cdot (u_x^2 - uu_{vm}) + DT$	
Flux in y direction	$F_y = \frac{\partial}{\partial y} \cdot \alpha \cdot h \cdot (u_x \cdot u_y - uv_{vm})$	
Gravitational acceleration	$SL = g_x^*$	Global component included with enhanced deformation control (Section 2.4)
Internal deformation (solid)	$DF = -f_d \cdot k_x \cdot g_z^+ \cdot \frac{\partial h}{\partial x} \left[ -g_z^- \cdot \frac{\partial h}{\partial x} \right]$	Buoyancy effects in square brackets
Internal deformation (fluid)	$DF = -g_z^+ \cdot \frac{\partial h}{\partial x} \left[ + \frac{g_z^-}{2} \cdot \frac{h}{\alpha} \cdot \frac{\partial \alpha}{\partial x} \right]$	Buoyancy effects in square brackets
Drag	$DR = \pm c_{DRAG} \cdot \Delta u_x \cdot  \Delta  u  ^{j-1}$	One drag term with respect to each other phase, if fluid; see Pudasaini and Mergili (2019) for details; not

		valid for layered model (Section 2.3)
Extended Coulomb term	$EC = \frac{u_x}{ u } \cdot \tan \delta \cdot g_z^* + \frac{c}{\alpha \cdot h}$ $+ E_{sp} \cdot \tan \varphi \cdot f_d \cdot \frac{\partial u_x}{\partial x} \cdot \frac{\partial h}{\partial x} + F_{ml} \cdot u_x$	Includes energy loss through shearing and fragmentation (Table 2)
Turbulent friction	$TF = \frac{u_x \cdot  u }{\alpha \cdot h \cdot \zeta}$	Voellmy-type model: Coulomb term and turbulent friction
Fluid friction	$FF = \frac{n^2}{h^{4/3}} \cdot u_x \cdot  u $	Simplified application of the Manning equation
Ambient drag	$AD = c_{AD} \cdot u_x \cdot  u $	Can be used to account for fluid/air resistance

120 The Voellmy-type model is available for each phase, by combining the Coulomb term with the turbulent friction term. Apart from rethinking the general concept of the phases, some additional functionalities have been introduced (some of them as prototypes already in the previous version r.avaflow v3). They are summarized in Table 2.

**Table 2: Additional functionalities available in r.avaflow v4. Those functionalities considered in detail in this study are written in bold letters.**

Functionality	Description	References
<b>Layer model</b>	The phases are arranged on top of each other, instead of mixed together.	
<b>Deformation control</b>	Internal deformation of the moving mass is mechanically controlled, allowing to simulate the whole range between free flow and block sliding.	Pudasaini and Mergili (2024a)
<b>Slow-flow model</b>	An equilibrium-of-motion model is employed to simulate the motion of viscosity-dominated flows which are not extremely rapid.	Su et al. (2024)
Fragmentation model	Fragmentation processes in rock avalanches can be included.	Pudasaini et al. (2024)
Energy loss through shearing model	Energy loss through shearing can be considered in the simulation.	Pudasaini and Mergili (2024b)

Dispersion model	Dispersion processes can be included in the simulation.	Pudasaini (2023)
<b>Virtual reality interface</b>	csv files and Python scripts facilitate the integration of the simulation results in 3D and VR visualization tools.	
Web-based user interface	Manual, data and parameter input, and generation of start scripts and parameter files are enabled through a Web interface.	Mergili and Pudasaini (2024)

125 The models for fragmentation (Pudasaini et al., 2024), energy loss through shearing (Pudasaini and Mergili, 2024b), and  
dispersion (Pudasaini, 2023), which have been introduced earlier, will not be further considered here. The model for  
deformation control has been introduced by Pudasaini and Mergili (2024a), but an enhanced version is considered in the case  
studies introduced in Section 3. We now introduce the layered model, the enhanced deformation control, the slow-flow  
model, and the virtual reality interface. We note that all these models can be combined with each other (Section 3 and  
130 Section 4).

### 2.3 Layered model

When a landside hits a reservoir, simulation with a depth-averaged multi-phase mixture model results in a mixture of solid  
landslide material and fluid water. The solid and fluid column of material is not resolved, and the phases are mixed along the  
vertical or slope-normal profile of the flow mass. For a two-phase model involving a frictional solid phase, this means that  
135 the entire column of material is effectively frictional. The way how the pressure gradients are computed, will prevent the  
fluid phase from behaving independently from the solid phase. If the solid fraction is significant, this means that the original  
water surface will never recover, a behaviour that is not realistic in those cases where the landslide deposits at the bottom of  
the reservoir. This phenomenon is particularly obvious in the results of simulations where large landslides deposit at the  
bottom of deep reservoirs, whereas it is less clearly visible where small landslides interact with rather shallow water bodies.  
140 In many real-world-cases, however, we can assume such a solid-dominated bottom and a fluid-dominated top, connected by  
a mixture layer. In the present work, we simplify this pattern to a maximum of three layers, with phase 1 at the bottom, an  
optional phase 2 in the middle, and phase 3 at the top (Fig. 1a). To achieve this, we control the gravity components, the flow  
height gradients, and the drag:

- Gravity components: with the layered model, the gravity components for phase 2 and phase 3 are not computed  
145 from the slope of the basal surface, but from the slope of the upper surface of the layer below. This means that the  
upper surface of phase 1 is considered the basal surface of phase 2, and the upper surface of phase 2 is considered  
the basal surface of phase 3. Buoyancy effects on the gravity components are not considered for the layered model.
- Flow height gradients: in the standard mixture model introduced in Section 2.1, the effective flow height for internal  
deformation is the total mixture height  $h_c = h$ . In the layered model each phase P1–P3 has its own effective material

150 height,  $h_e = h_{P1}$  for phase 1,  $h_e = h_{P2}$  for phase 2, and  $h_e = h_{P3}$  for phase 3. This ensures that each phase deforms individually.

- Drag: with the standard model, the drag is computed according to Pudasaini and Mergili (2019) for each phase in the mixture. This concept, however, is not applicable to layered movements, for which we introduce the following approximation for the drag coefficient in x direction  $C_{Dx}$ :

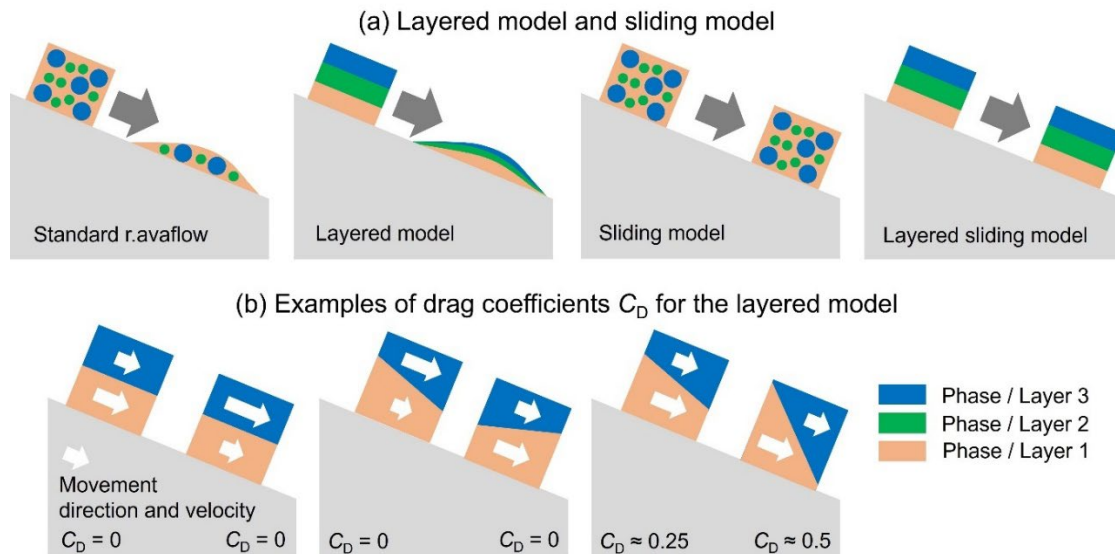

155 if  $\text{sgn} \frac{\partial h_{P1}}{\partial x} = \text{sgn}(u_{x,P2} - u_{x,P1})$  and  $|u_{x,P1}| > |u_{x,P2}|$ :  $C_{Dx} = f_{DR} \cdot \sin\left(\arctan \frac{\partial h_{P1}}{\partial x}\right) \cdot \alpha_{P1}$ , (2)

where P2 is a fluid phase moving on top of a solid phase P1.  $f_{DR}$  is a scaling factor. The drag coefficient in y direction  $C_{Dy}$  is computed in an analogous way. The ideas behind this concept are that (i) drag only acts if the flow height gradient of the solid phase goes into the same direction as the relative velocity difference between the fluid and the solid phase; (ii) drag only acts when the solid moves faster than the fluid; and (iii) the drag coefficient is proportional to the sine of the gradient of solid flow height (i.e., there would be no drag if the surface of the solid part of the flow would run parallel to the terrain slope and, theoretically, the drag coefficient would be 1 in the case of a vertical wall and  $f_{DR} = 1$ ). Fig. 1b illustrates some selected examples of drag coefficients (assuming  $f_{DR} = 1$ ) computed with this approach.

160

We note that the layered model is not only useful for landslide-reservoir interactions, but also for layered landslides (Section 3 and Section 4).

165

170 **Fig. 1:** Schematic sketch illustrating the effects of the new model components of r.avafLOW v4, using profiles along the down-slope direction. (a) Comparison of the standard model used in r.avafLOW, with maximum 3 phases (Pudasaini and Mergili, 2019); the layered model, where the phases are not mixed, but arranged on top of another; the sliding model, where the deformation of the moving mass is controlled; and the combination of the layered model and the sliding model. (b) Examples of drag coefficients computed with the layered model (examples here with two distinct layers) for selected idealized situations.

## 2.4 Enhanced deformation control (sliding model)

We use the controlled deformation model introduced by Pudasaini and Mergili (2024a). This model can be applied to all  
 175 phases with internal friction angle  $\varphi > 0$  and builds on the effective deformation factors  $f_{dx}$  in x direction and  $f_{dy}$  in y  
 direction, both in the range 0–1, where  $f_{dx}, f_{dy} = 0$  completely locks the deformation (as shown in Fig. 1a), and  $f_{dx}, f_{dy} = 1$   
 allows full deformation (identical to the model without deformation control).  $f_{dx}$  and  $f_{dy}$  are no input parameters. The input  
 value is the raw deformation factor  $f_d^*$ , which is enhanced with the earth pressure coefficient  $K$  and the gravity components  
 in z direction  $g_{zx}$  or  $g_{zy}$ , respectively:

$$180 \quad f_{dx} = 1 - \frac{(1-f_d^*)g_z^*}{Kg_{zx}}, \quad f_{dy} = 1 - \frac{(1-f_d^*)g_z^*}{Kg_{zy}}, \quad (3)$$

where  $g_z^*$  is the gravity component in z direction at the steepest raster cell of the release area. In multi-phase applications,  
 the deformation control – also referred to as the sliding model – should only be applied in combination with the layered  
 model (Section 2.3).

In addition, it is possible to consider gravitational acceleration of the entire landslide mass as a rigid block, instead of  
 185 considering each cell individually. For this purpose, the global gravity components  $g_x^g$ ,  $g_y^g$ , and  $g_z^g$  are introduced,  
 representing the mean values of  $g_x$ ,  $g_y$ , and  $g_z$  over the entire sliding mass, weighted for flow height and updated at each time  
 step of the simulation. Global gravity components are optionally applied in the gravitational acceleration term ( $g_x = g_x^g$ ,  
 $g_y = g_y^g$ ) and the deceleration term ( $g_z = g_z^g$ ) for frictional material. For simplicity this function is referred to as global  
 sliding, whereas the conventional way to consider each raster cell individually is referred to as local sliding. Global and local  
 190 sliding can also be combined, with the parameter  $f_g$  denoting the fraction of global sliding.

## 2.5 Slow-flow model

The core functionalities of r.avaflow have been designed to support the simulation of extremely rapid flows (Pudasaini and  
 Mergili, 2019). To extend the applicability to slow landslides (in the range of a few metres per second or even lower, as  
 described by Hungr et al., 2014) an equilibrium-of-motion model has been adopted. This method, outlined by Su et al.  
 195 (2024), is founded on the premise of a viscous downslope mass flow, with the flexibility to include a viscous base layer of  
 minor thickness.

Assuming a planar Couette flow, the viscous forces in x and y direction are counterbalancing the gravitational force, which  
 substitutes the forces exerted by the upper surface. Regarding the properties of individual cells, the mass is proportional to  
 the landslide height  $h$ , while the landslide density  $\rho$  and the surface area  $A$  are normalized:

$$200 \quad F = \mu A \frac{u}{h} \rightarrow ahA\rho = \nu\rho A \frac{u}{h} \rightarrow g_x h = \nu \frac{u_{xe}}{h}, \quad g_y h = \nu \frac{u_{ye}}{h} \rightarrow u_{xe} = \frac{g_x h^2}{\nu}, \quad u_{ye} = \frac{g_y h^2}{\nu}, \quad (4)$$

where  $F$  is the force acting on the landslide mass,  $\mu$  and  $\nu$  are the dynamic and kinematic viscosities,  $u$  is the flow velocity at the upper surface of the landslide,  $a$  is the acceleration of the landslide, and  $g_x$  and  $g_y$  are the downslope gravity components in x and y direction.  $u_{xe}$  and  $u_{ye}$  are the equilibrium velocities in x and y directions.

205 Multiplying  $u$  and  $\nu$  by  $h$ , yields the normalized momenta  $p_x$  and  $p_y$ . Thus, the velocities of the deforming mass ( $u_x$  in x direction and  $u_y$  in y direction) decrease linearly along the vertical profile from top to bottom (base velocities  $u_{xb}$ ,  $u_{yb}$ ). Accordingly,  $u_x$  and  $u_y$  represent the mean velocities within the landslide column of the depth-averaged model, while the surface velocities of the landslide are  $[2(u_x - u_{xb})] + u_{xb}$  and  $[2(u_y - u_{yb})] + u_{yb}$ . The first terms of Eq. (5) thus describe the deformation of the landslide and the second terms represent the basal movement.

$$210 \quad p_x = h \left( \frac{g_{xt}h^2}{2\nu} + \frac{g_{xb}^*}{\xi} \right), p_y = h \left( \frac{g_{yt}h^2}{2\nu} + \frac{g_{yb}^*}{\xi} \right), \quad (5)$$

where  $g_{xt}$  and  $g_{yt}$  are the downslope components of gravity in x and y direction at the top of the landslide (i.e., including gradients of flow height),  $\nu$  is the kinematic viscosity of the mass,  $g_{xb}^*$  and  $g_{yb}^*$  are the downslope components of the effective gravity (Section 2.3) in x and y direction at the bottom of the landslide, and  $\xi$  is the viscosity term for the basal layer. The ratio between the kinematic viscosity and the square of the basal layer thickness is represented by  $\xi$ .

215 Mass and momentum fluxes between cells follow the conventions of traditional flow models (Savage and Hutter, 1989; fluid terms in Pudasaini, 2012; Pudasaini and Mergili, 2019). Calculating momenta from Eq. (5) results in their evolution in equilibrium with accelerating and decelerating forces at the individual grid cells. Hence, those momenta cannot act as source of momentum production or dissipation. Compared to momentum balance models one major advantage is the simple approach to time-scaling. Time-scaling can be directly applied to  $u$  and  $\nu$ , without the necessity to adjust any additional  
220 variables. It is important to emphasize that the outlined method neglects inertial effects and consequently must not be applied for the simulation of extremely rapid mass flows (according to the definitions of Hungr et al., 2014).

## 2.6 Virtual reality interface

r.avaflow v4 includes an interface for 3D and virtual reality (VR) visualization of the model results. For this purpose, a time series of csv files – one for each time step – is automatically produced, describing the geometric information (elevation of  
225 the landslide surface and, optionally, elevation of the terrain surface and individual layers) for each raster cell along with red, green, and blue (RGB) colour values to be used for visualization. The RGB values are composed of the following pieces of information, which can be combined in different ways:

- Landslide heights and composition of phases (updated for each time step);
- shaded relief information (updated for each time step);
- and orthophoto information, if an orthophoto is provided by the user. Optionally, the raster cell values of the  
230 orthophoto can be shifted to follow the motion of the landslide, allowing for a more realistic visualization.

Along with the csv files, Python scripts are automatically generated to facilitate import to the 3D and VR visualization and animation tools Paraview and Blender 3, and to the game engine Unreal Engine 5. This work flow allows for the integration of r.avafLOW v4 simulation results with various levels of virtual reality (Table 3).

235

**Table 3: Levels of virtual reality which can be generated from r.avafLOW v4 simulation results.**

Level	Description	Advantages	Disadvantages
<b>0 Oblique view</b>	Video from bird’s eye perspective, no 3D effect	No special equipment needed	No real 3D impression, fixed path of movement and view direction
<b>1 Anaglyph view</b>	Red-cyan anaglyph video, 3D impression with anaglyph glasses	Anaglyph glasses are very cheap and easy to use	Poor colour representation, fixed path of movement and view direction
<b>2 Stereo 3D view</b>	Two side-by-side videos, 3D impression with VR glasses, e.g., cardboard	VR glasses or cardboards are affordable and easy to use, realistic colours	VR cardboards only usable with Android smart-phones, fixed path
<b>3 VR scene inspection</b>	Immersive VR with headset, free movement possible within the scene	Very realistic VR experience, free movement and rotation of view within scene	Expensive equipment, user cannot interact with environment
<b>4 VR game with precomputed simulations</b>	Immersive VR with headset, free movement and interaction with environment possible within the scene	Very realistic VR experience, user can interact with environment (e.g., trigger landslides)	Expensive equipment
<b>5 VR game with live simulations</b>	Immersive VR with headset, free movement and interaction with environment possible within the scene, different processes can interact	Very realistic VR experience, user can interact with environment, processes can interact among themselves	Expensive equipment, computational time for process simulation

### 3 Test cases and simulation design

#### 3.1 Generic planar rock slide with interlayer shearing

240 A computer-generated simplified landscape with an extent of 5000 x 5000 m is used for the demonstration of a planar rock slide, assuming the involvement of three discrete layers of rock. An inclined slope with a gradient of 0.5 runs out into a horizontal plane in down-slope (x) direction. The three planar sliding planes, with heights of 100 m each, forming the bases of the top, middle, and bottom layers, are aligned parallel to the main slope (Fig. 2).

245 Experiment SD1 uses the equilibrium-of-motion model, assuming an extremely slow movement. Model parameters are calibrated towards a plausible representation of layered sliding, where the motion along the sliding planes clearly dominates over the internal deformation of the individual layers. The settings are detailed in Table 4. All simulations are executed with densities of  $\rho = 2,700 \text{ kg m}^{-3}$ , and at a raster cell size of 10 m. The simulation is run for a process duration of 50,000 years, using a time scaling factor of  $31.536 \cdot 10^9$  ( $1 \text{ s} \rightarrow 1000 \text{ years}$ ).

250 **Fig. 2: Oblique view of the generic landscape with a three-layer release mass, used for the experiment SD1 on a planar rock slide. The main bodies of all layers are of equal thickness (100 m), and the surfaces of the two lower layers (not visible in this view) are arranged parallel to the surface of the upper layer.**

#### 3.2 Semi-generic Köfels rock slide

255 The Köfels rock slide has been thoroughly examined for more than a century (cf. Mergili and Prager, 2022 and references therein). The most recent reconstruction by Zangerl et al. (2021) builds the foundation for this case study. According to <sup>14</sup>C-dating the event occurred 9527–9498 years before present (Nicolussi et al., 2015). The process originated from a head scarp

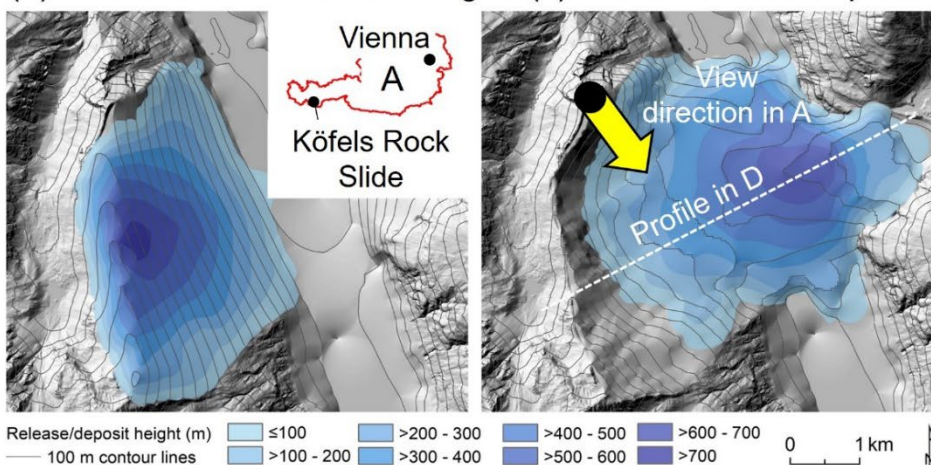

at the western slope of the central Ötz Valley, where the steep terrain exhibits a dip angle of 40 to 80°. The centre of the mass was displaced 2.6 km downslope (Sørensen and Bauer, 2003). Erismann et al. (1977) suggested a movement velocity of 50 m/s.

(a) Oblique view of the Köfels rock slide from NW

(b) Reconstructed release height (c) Reconstructed deposit

(d) Longitudinal profile

260 Fig. 3: The prehistoric Köfels rock slide. (a) Oblique view from NW direction – author: M. Mergili, 3 August 2015; (b) and (c) reconstructed release and deposition masses – modified after Zangerl et al. (2021); (d) longitudinal profile through the rock slide area.

265 The moved volume amounts to 3–4 km<sup>3</sup> and rock mass fragmentation and fracturing induced an increase by a factor of 1.26  
(Zangerl et al., 2021). The sliding rock mass reached the entrance of the tributary Horlach Valley on the opposite side of the  
slope, where massive bedrock forced a halt. Down to the present day, the deposit is blocking the main valley. The sliding  
rock mass possibly split up, as proposed by Erismann and Abele (2001): The lower part might have stopped and deposited  
after the collision with the opposite slope, whereas the upper part moved one kilometre farther. Preuss (1986) reported about  
some evidence of a potential internal shear zone. This finding, however, has not yet been supported by field evidence. An  
270 alternative more likely scenario is the emergence of several internal shear zones facilitating the adaption to the terrain  
surface over the course of the substantial deformation of the rock mass. The rock slide deposit is extremely heterogenous,  
with characteristics ranging from completely disintegrated and crushed material to almost solid fractured rock. The  
pronounced vertical and horizontal variability in the degree of cataclasis and fracturing indicates complex internal  
deformation phenomena during the rock slide.

275 We consider this case study semi-generic, as there are considerable uncertainties in regard to the pre-event topography and  
the characteristics of the rock slide and its internal deformation. Three computational experiments are performed (Table 4),  
using the standard flow model of r.avaflow (experiment KF1), the one-layer sliding model (KF2), and the multi-layer sliding  
model with two layers (KF3). For the multi-layer model, we assume a release mass composed of two layers of equal height  
distribution. All simulations only consider the released rock mass whereas, for simplicity, possibly entrained valley fill is  
280 neglected. The model parameters are optimized against the observed travel distance and deposit using an iterative trial-and-  
error procedure. Thereby, a time dependency of the deformation control and the fraction of global sliding is considered, in  
order to account for effects of increasing crushing and loss of coherence, related to the dynamic stresses the sliding mass is  
exposed to. All simulations are run with a density of  $\rho = 2,700 \text{ kg m}^{-3}$  and at a raster cell size of 15 m, considering a process  
duration of 120 s.

### 285 3.3 Semi-generic East Fogo landslide and tsunami

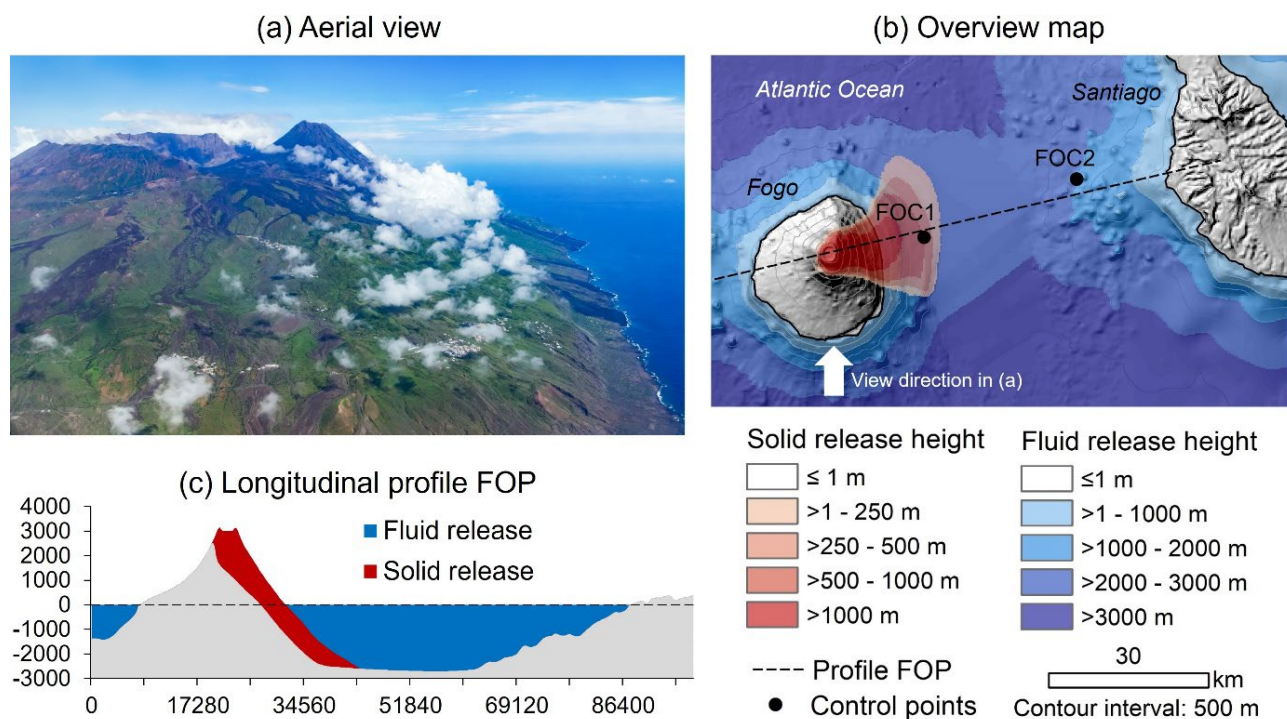

Fogo is an active volcanic island, forming part the archipelago of Cape Verde in the Atlantic Ocean off the coast of Senegal,  
West Africa. Its highest peak is the stratovolcano Pico do Fogo (2829 m asl.), which sits at the bottom of a cauldron,  
bordered by a semi-circular, up to 1000 m high escarpment on the western, south-western, and north-western sides, and  
merging with the outer slope of the island on the eastern side (Fig. 4a). Various studies have investigated the volcanic and  
290 geomorphological history of the island, and there is broad agreement upon the fact that the cauldron was formed by giant  
landsliding, probably in various stages, and today's Pico do Fogo formed afterwards (e.g., Day et al., 1999; Marques et al.,  
2019; Barrett et al., 2020; Cornu et al., 2021). This has led to considerations of future risk. Possible tsunami deposits were  
found on the neighbouring island of Santiago, but their real origin is disputed, and so are the number and total volume of  
landslides, ranging from 20–300 km<sup>3</sup>, depending on the interpretation of the available evidence and the way of  
295 reconstructing the pre-event terrain.

The aim of the present work is not to reconstruct the landsliding – often referred to as the East Fogo volcanic flank collapse(s) – in all detail, but we use this case for demonstrating the effects of layering and controlled deformation for a very large phenomenon. Our terrain reconstruction builds on the hypothesis of the existence of a former volcanic summit, named Monte Amarelo (Cornu et al., 2021), which collapsed in one single event, the sliding surface reaching down to the basis of the volcanic edifice in the deep sea (worst-case assumption). Though based on the available topographic evidence, using the SRTM V4 (Jarvis et al., 2008) and the GEBCO\_2021 Grid (GEBCO Compilation Group, 2021) digital terrain models, our reconstruction largely relies on the subjective reconstruction of the former terrain surface and the basal sliding surface, so that we characterize the outcome as a semi-generic data set (Fig. 4b and 4c). The derived collapse volume would be approx. 250 km<sup>3</sup>, which comes close to the maximum estimate of Day et al. (1999) (300 km<sup>3</sup>) and is much higher than more recent estimates of maximum 160 km<sup>3</sup> (Martínez-Moreno et al., 2018).

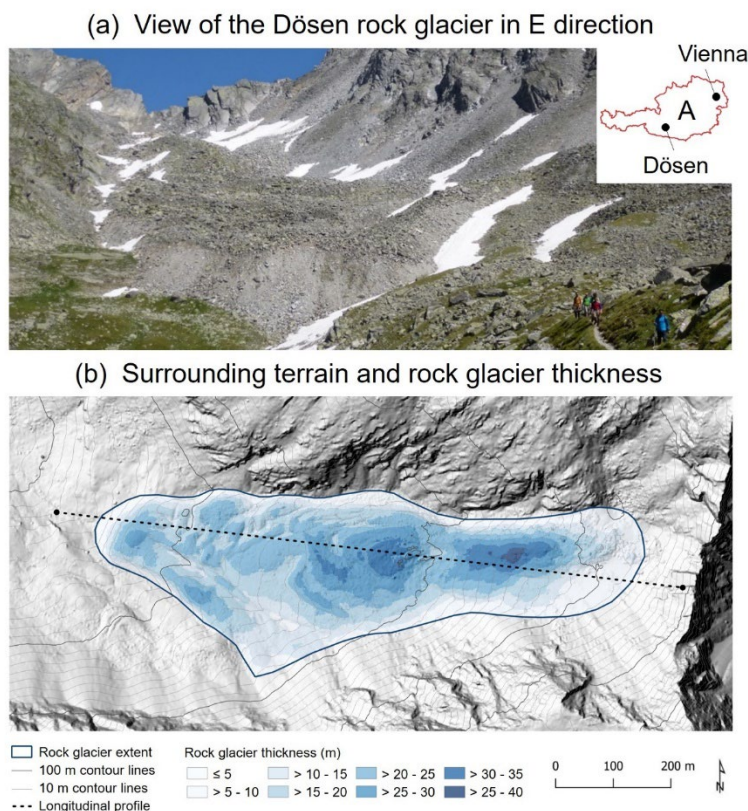

Three computational experiments are applied to the semi-generic East Fogo event, FO1–FO3. They are computed at a raster cell size of 270 m cell size and for a duration of 900 s. The key parameters for each of the experiments are summarized in Table 4. For comparison, all simulations are repeated with the landslide material only, neglecting the ocean water.

310 Fig. 4: Prehistoric East Fogo event. (a) Aerial view of today's situation with Pico do Fogo – author: M. Mergili, 10 September 2022; (b) Overview map with reconstructed release height distribution; (c) profile along the dashed line in (b).

### 3.4 Semi-generic Dösen rock glacier

Since the 1990s, the Dösen rock glacier has been an important site for interdisciplinary permafrost and periglacial research in the eastern Austrian Alps (Kellerer-Pirklbauer et al., 2018). Located at the valley head, this rock glacier extends over roughly 1 km in length with a maximum width of approx. 340 m, resulting in an area of approx. 0.2 km<sup>2</sup> (Fig. 5). The landform covers a span of 300 m in elevation (terminus at approx. 2500 m) with a mean slope angle of 24° (Wagner et al., 2020). The Dösen rock glacier is talus-derived and tongue-shaped with distinct longitudinal and transverse furrows and ridges and a steep front of up to 40 m in height (Kellerer-Pirklbauer et al., 2022). A 10 to 40 m thick permafrost body exists below an active layer of several metres. The geomorphic setting and results of Schmidt-hammer exposure-age dating suggest that rock glacier formation started after the retreat of the younger Dryas glaciation about 8400 years before present (Kellerer-Pirklbauer et al., 2018). Long-term records of pluriannual (1954 to 1995) and interannual (1995 until 2024) movement rates are complemented with climate and ground climate datasets (Kaufmann et al. 2007, Kellerer-Pirklbauer & Kaufmann, 2012; Kaufmann et al., 2016). For the period between 1995 and 2022, starting with the establishment of annual geodetic surveys, these records amount to a mean annual displacement rate of roughly 35 centimetres per year.

325

**Fig. 5: Dösen rock glacier. (a) Location of the rock glacier in Austria and view from the front towards the rooting zone – author: G. K. Lieb; (b) Rock glacier extent and simulation release height (to be understood as the reconstructed thickness of the rock glacier body, based on geophysical evidence).**

330 The computational experiment DO1 is applied to a simplified (therefore referred to as semi-generic) representation of the  
 Dösen rock glacier (Fig. 5), using the slow-flow model. The simulation is executed at a raster cell size of 1 m for a duration  
 of 300 years. Table 4 discloses the key parameters, which were calibrated in order to reach plausible velocities and  
 movement patterns, related to the measurements. Visualization is performed with and without draping of the dynamically  
 adapted orthophoto, in order to additionally analyse the visual effects of the draping.

335 **Table 4: Summary of the key parameter settings applied to the simulations on the generic slope deformation (SD1), the prehistoric  
 Köfels rock slide (KF1–KF3), the prehistoric East Fogo event (FO1–FO3), and the semi-generic Dösen rock glacier (DO1). L =  
 layered model.**

## 4 Results

### 4.1 Generic planar rock slide with interlayer shearing

340 The equilibrium-of-motion model provides the expected results for the generic planar rock slide, including the formation of  
 back-scarps characteristic for this type of process (Fig. 6). We note that the simulation outcomes are very sensitive to the  
 parameterization, with plausibility strongly depending on the balance between time scaling, internal viscosity, and basal  
 viscosity in the equilibrium-of-motion model. Preliminary tests have shown that the result also strongly depends on the raster

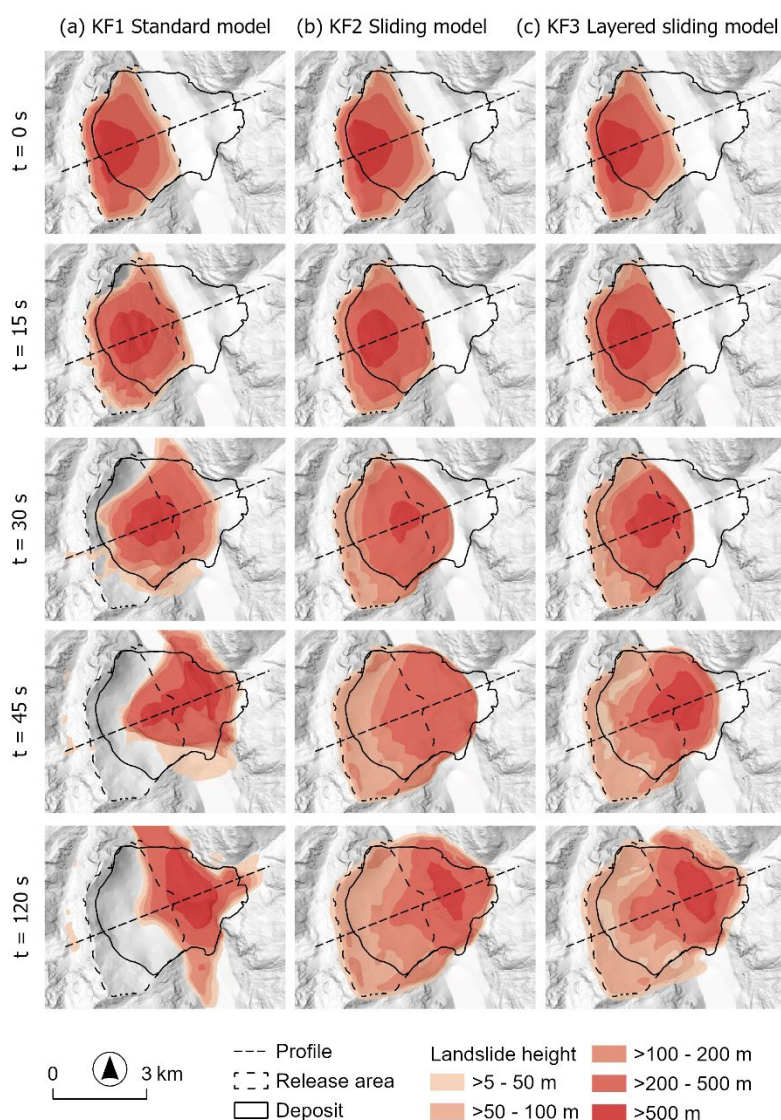

345 cell size applied to the simulation. With coarser cell size, numerical diffusion strongly blurs the layer heads, leading to a smoother deformation pattern.

**Fig. 6:** Flow height evolution for the experiment SD1 along a longitudinal profile in down-slope (x) direction, assuming an extremely slow movement.

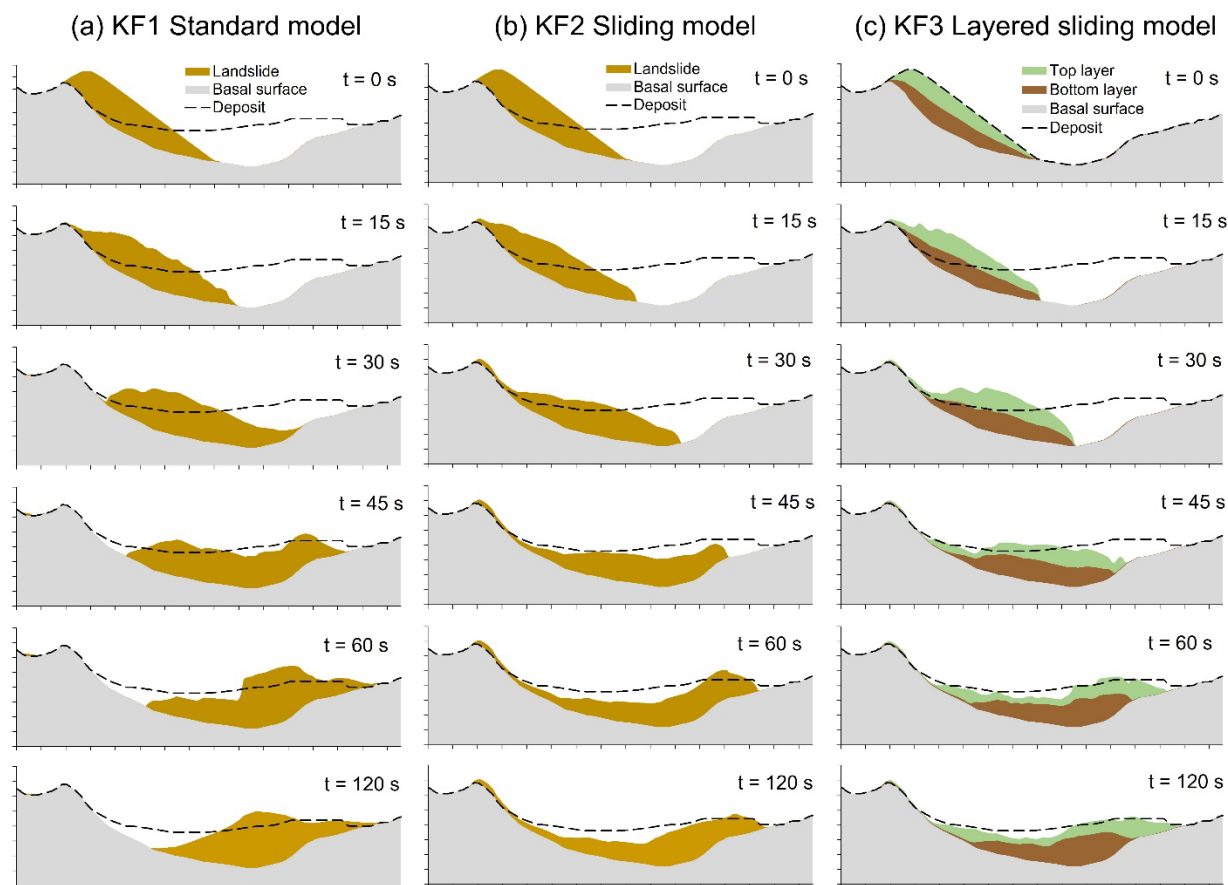

#### 4.2 Semi-generic Köfels rock slide

350 Fig. 7 and Fig. 8 illustrate the differences between the standard r.avaflow model (with one solid phase and full deformation), the one-layer sliding model (with limited deformation), and the two-layer sliding model. The lower density and therefore larger volume and height of the heavily fractured to crushed rock mass, compared to the release mass, is considered in Fig. 7 and Fig. 8: simulated heights are multiplied with a factor up to 1.26, following Zangerl et al. (2021), since the models used in r.avaflow assume a constant density of the material throughout the entire duration of the process.

355

**Fig. 7: Evolution of flow height for the Köfels experiments KF1–KF3. (a) KF1: standard model without deformation control; (b) KF2: sliding model with one layer (deformation control and global sliding); (c) KF3: sliding model with two layers (deformation control and global sliding).**

360 **Fig. 8:** Flow height evolution for the Köfels experiments KF1–KF3 along the longitudinal profile depicted in Fig. 7. (a) KF1: standard model without deformation control; (b) KF2: sliding model with one layer (deformation control and global sliding); (c) KF3: sliding model with two layers (deformation control and global sliding).

With the standard *r.avaflow* model (experiment KF1), the moving mass displays a strong extension in slide-normal direction, flowing up and down the Ötz Valley – a behaviour not corresponding to the shape of the observed deposit. This overestimate  
 365 of lateral spreading is the expected behaviour for a flow model, and therefore underlines the call for an approach more adequately representing sliding behaviour. The one-layer sliding model (experiment KF2) provides a more realistic representation of the rock slide evolution and deposition. The extent of lateral spreading up and down the Ötz Valley is strongly reduced while the travel distance in sliding direction is in correspondence with the observation (calibrated). Control of deformation, however, is applied at the cost of a reduced flexibility of the rock mass to adapt to the funnel shape at the  
 370 outlet of Horlach Valley, so that the front of the simulated rock slide deposit is too wide: the reconstructed impact area is exceeded particularly at the N side (Fig. 7b). Also, the profiles in Fig. 8 reveal that the deposition height is underestimated in the proximal part of the deposition area and overestimated in the distal part. The two-layer sliding model (experiment KF3) has a strong generic component, as the splitting of the release mass into a top and a bottom layer of equal height is done for

375 convenience, as a result of lacking more detailed information (Section 3.2; Zangerl et al., 2021). The main advantage of the  
siding surface between the two layers is that the lower layer can entirely deposit in the Ötz valley, whereas the upper layer  
can slide into the Horlach Valley, to correspond with the observed travel distance of the rock slide. This reduces the need to  
allow for a very strong deformation of the mass, resulting in a slightly more balanced distribution of the deposit along the  
flow path, compared to KF2 (Fig. 7 and Fig. 8).

In all simulations, process velocities and durations are plausible – considering the displacement of the centre of mass of  
380 2.6 km and a velocity of  $50 \text{ m s}^{-1}$  (Erismann et al., 1977), we arrive at a process time of 52 s. Assuming acceleration and  
deceleration phases, this is in line with the observation that, in all experiments, the mass has almost reached its final position  
(corresponding to the position at  $t = 120 \text{ s}$  in Fig. 7 and Fig. 8) after 60 s.

### 4.3 Semi-generic East Fogo landslide and tsunami

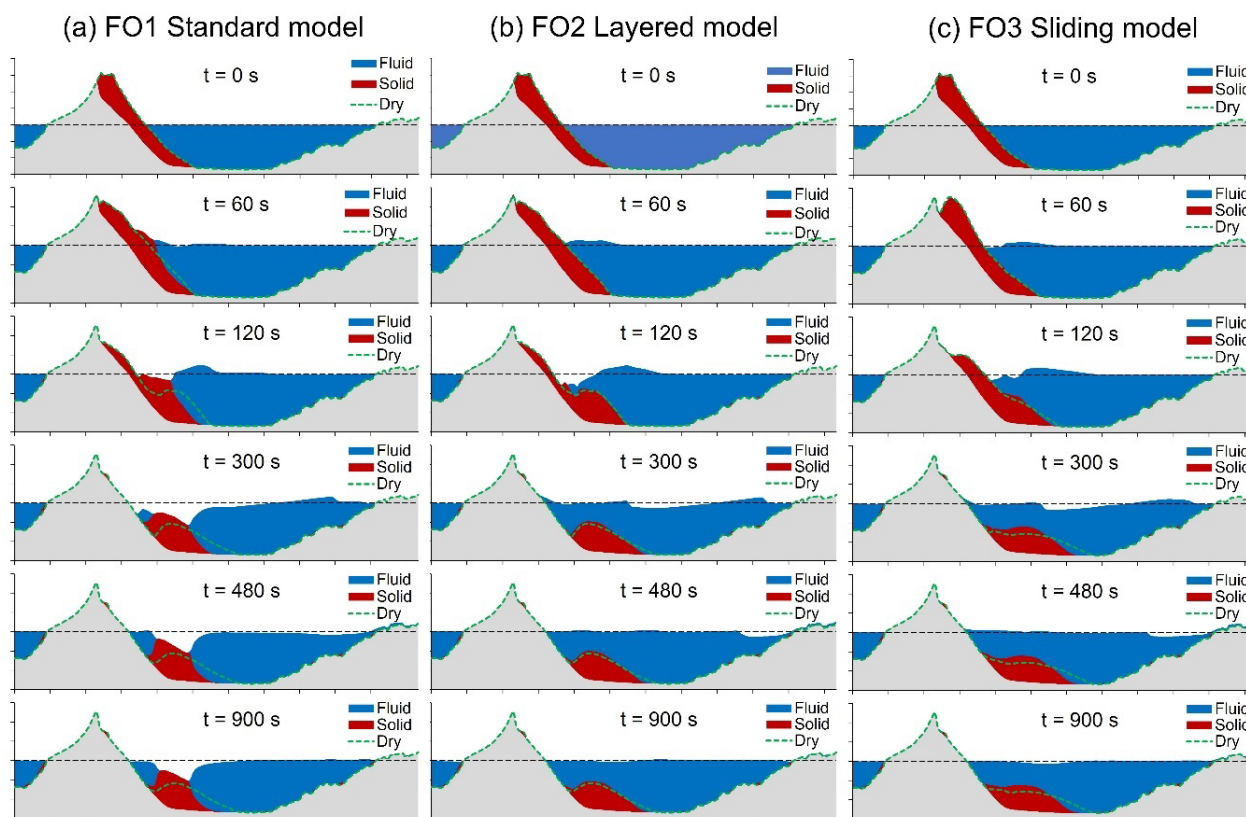

The evolution of the displacement wave triggered by the semi-generic East Fogo volcanic flank collapse is illustrated in  
385 Fig. 9–Fig. 11, with the standard model and the layered model. Without layering (simulation FO1), the deposition area of the  
collapsed solid material remains a massive depression until the end of the simulation at  $t = 900 \text{ s}$ . Whilst it is expected that  
the displacement wave triggered by the impact of the collapse would create such a depression initially, it should be assumed  
that the restitution of the original sea surface starts soon thereafter – a behaviour which is, however, not reflected in the  
simulation results. Fig. 11 also displays this effect very clearly for the simulation FO1, showing a decrease of the sea level  
390 by approx. 980 m for point FOC1 (Fig. 4), only slightly decreasing thereafter, and then stabilizing at a decrease of approx.  
900 m, compared to the initial situation. A much more realistic behaviour of the system is achieved when applying the  
layered model (simulation FO2): after an initial positive anomaly caused by the passing of the solid material, the sea level  
drops to approx. -850 m at the point FOC1 at about the same time when the minimum is reached in FO1. However,  
immediately afterwards, the sea level starts to recover, even though some secondary and tertiary waves prevent it from  
395 exactly reaching its original state until the end of the simulation. In general, the displacement wave has a much lower  
magnitude in the simulation FO2 than in the simulation FO1. This phenomenon is most probably related to the different drag  
concepts used for the standard and layered models and requires some further discussion (Section 5.1). An interesting insight  
is provided by considering the same landslide with the assumption of a dry ocean basin (Fig. 9a and b). Under such dry  
conditions there is, as expected, no difference between the simulation results with the standard model and the layered model.  
400 When including the ocean water, the landslide becomes less mobile with both the standard model (FO1) and the layered  
model (FO2), due to the decelerating effect of the drag.

Fig. 9c depicts the flow heights for selected time steps as derived with the assumption of a slide-type movement (FO3),  
applied together with the layered model, whereas the flow height evolution at the points FOC1 and FOC2 (Fig. 4b) is  
illustrated in Fig. 11. There is less compression of the landslide along the down-slope direction with the sliding model,  
405 compared to the other simulations. In the flow models of FO1 and FO2, the internal deformation of the mass is prescribed by  
its geometry and by topography (Section 3.2; Pudasaini and Mergili, 2024a). With the sliding model employed in FO3, the

mass remains more stretched, mainly because the application of the global gravity components increases acceleration and decreases deceleration in the less steep frontal part, whereas the reverse is the case at the steeper tail. The magnitude of the displacement wave is smaller with FO3, compared to FO2. This phenomenon is most likely a consequence of the higher and steeper front of the flow-type landslide of simulation FO2: both the drag coefficient and the affected fraction of the water column are comparatively smaller in the case of the slide-type movement of simulation FO3 (Figure 1b).

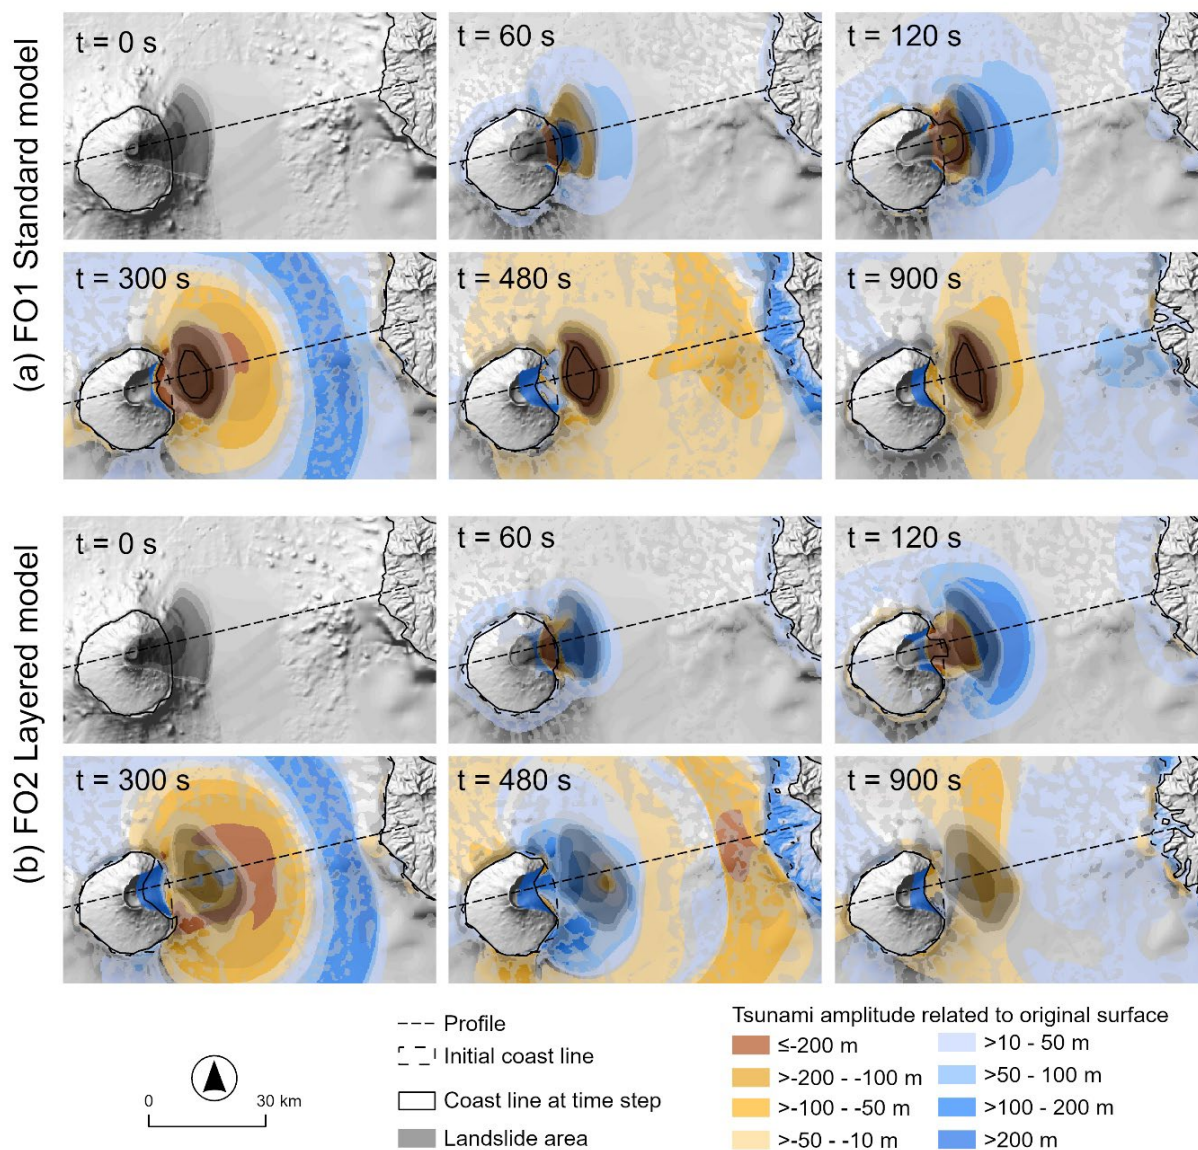

**Fig. 9: Prehistoric East Fogo event, effects of layering and deformation control on the evolution of flow height until  $t = 900$  s. Sections along profile FOP (Fig. 4b) for the simulations (a) FO1 (standard model); (b) FO2 (layered model); and (c) FO3 (sliding model).**

#### 4.4 Semi-generic Dösen rock glacier

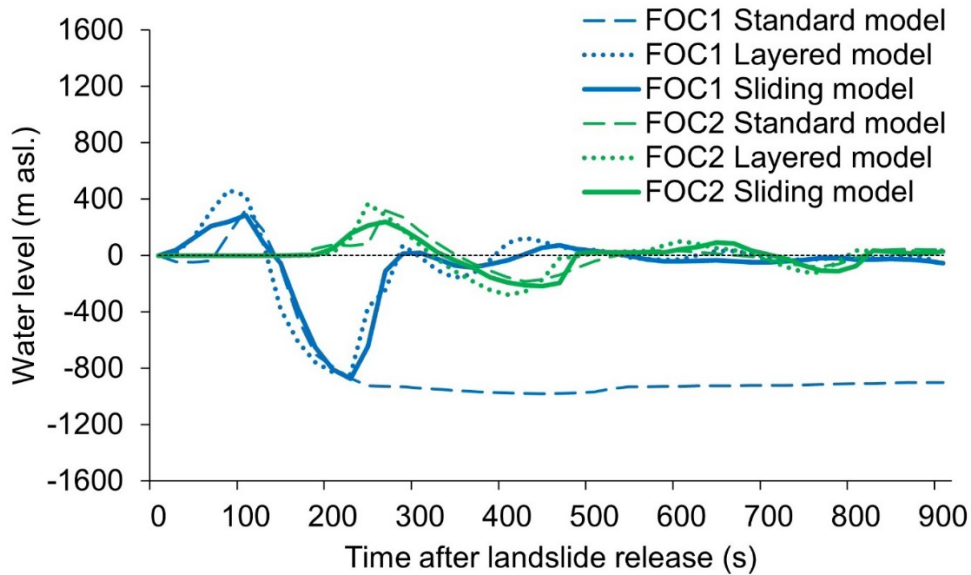

The simulation on the Dösen rock glacier provides plausible results, with a roughly continuous movement of few decimetres per year (Kaufmann et al. 2007, Kellerer-Pirklbauer & Kaufmann 2012; Kaufmann et al., 2016). Fig. 12 summarizes the main patterns obtained with the experiment DO1. Fig. 12b and Fig. 12c clearly reveal the substantial smoothing effect during the simulation, which are most likely associated with the TVD-NOC numerical scheme applied in r.avafLOW (Tai et al., 2002; Wang et al., 2004). This means that the simulation can potentially reproduce or predict the motion of the rock glacier as a whole, whereas the fine-scale movement patterns are lost or at least blurred. In particular, the smaller geomorphological

features typical of rock glaciers, such as ridges and furrows, are lost during the 300-year modelling period. For visualization purposes, particularly in the field of science-to-public communication, such fine-scale patterns, representing the morphological characteristics of rock glaciers, are essential to convey rock glacier dynamics and its geomorphic implication. This can be achieved by draping the distorted orthophoto over the rock glacier – fine-scale patterns are preserved in this way, and motion looks much more realistic than with the draped shaded relief map (Fig. 12d).

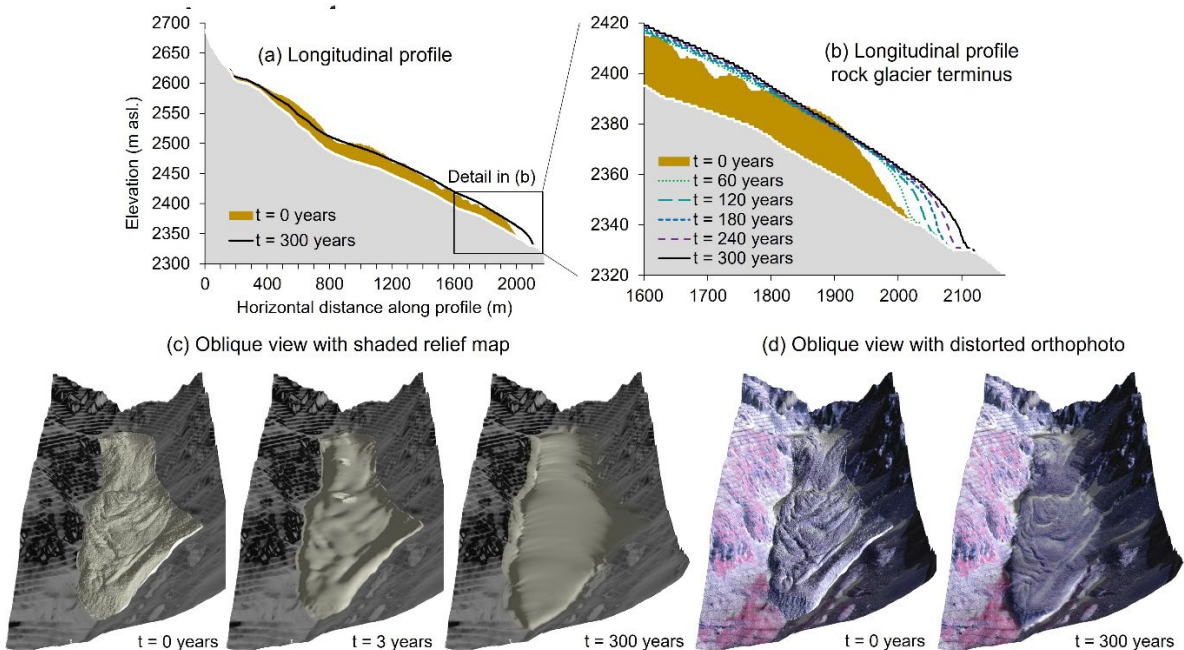

430 **Fig. 10: Prehistoric East Fogo event, effects of layering on the evolution of flow height until  $t = 900$  s. Map plots for (a) FO1 and (b) FO2 for selected time steps.**

**Fig. 11:** Prehistoric East Fogo event, evolution of the sea surface (m asl.) at the control points FOC1 and FOC2 (Fig. 4b) until  $t = 900$  s for the simulations (a) FO1 (standard model), (b) FO2 (layered model), and (c) FO3 (sliding model).

435 **Fig. 12:** Simulation results for the semi-generic Dösen rock glacier case. (a) Longitudinal profile along the main flow line for  $t = 0$  and  $t = 300$  years. (b) Longitudinal profile, detail of the rock glacier terminus for six selected time steps. (c) Oblique view against the flow direction, shaded relief map for  $t = 0$ ,  $t = 3$  years, and  $t = 300$  years. (d) Oblique view with distorted orthophoto for  $t = 0$  and  $t = 300$  years.

## 5 Discussion

440 r.avaflow v4 strongly builds on earlier versions of r.avaflow (first introduced by Mergili et al., 2017), but includes some important enhancements presented in the previous sections. We now discuss the potentials and limitations of these enhancements.

Sliding components have already been included in mass flow models by other authors, such as Bout et al. (2022) who used quite a complex approach, or Cicoira et al. (2022) who employed a computationally expensive full 3D model. In order to avoid the introduction of a large number of additional, often unknown, parameters and the need for high-performance computers, we decided to introduce a comparatively simple and straightforward approach, based on a deformation control (Pudasaini and Mergili, 2024a) and on the global gravity components. Fig. 6–Fig. 8 reveal that the sliding model introduced in Section 2 can be used to produce empirically fairly adequate representations of the prehistoric Köfels rock slide, and plausible results for the generic slope deformation. This indicates that this model might be appropriate in regard to the simulation of slide-type movements. However, it involves strong physical, mathematical, and geometric/topographic simplifications, calling for an in-depth discussion of their scope of application and potentials for enhancement and improvement. First, this discussion picks up the complexity vs. simplicity discourse regarding landslide modelling, following the hypothesis that simple models with fewer parameters can be preferable to complex models with many parameters which are often unknown or, even if measurable, have to be calibrated in order to bring the models in line with the observations. In this sense, the deformation coefficient (Pudasaini and Mergili, 2024a), the fraction of global sliding, or the basal viscosity parameter can be considered as empirical parameters with some physical background – a description which would, however, also be appropriate for established material parameters such as basal and internal friction, or viscosity. In contrast to established parameters, where a large pool of experiences can be used to choose plausible starting values for parameter optimization procedures and where, with other software packages, even well-established guiding parameter sets are available, the newly introduced values have to be calibrated from scratch. The deformation coefficient and the fraction of global sliding are intuitive quantities, strongly related to obvious characteristics of landslides. However, the time evolution of the model parameters, which can currently be prescribed based on “hard” time steps, relies on prior knowledge of the event. Coupling parameter evolution to dynamic flow characteristics such as velocity gradients could be an interesting future direction, increasing the physical meaning of the model.

465 The possibility to divide the sliding mass into multiple layers, and therefore to define horizons of shearing, increases the flexibility of the sliding model. Layering, however, is also important in another context: the simulations on the semi-generic East Fogo event clearly reveal that the standard r.avaflow model is not suitable for those simulations of landslide-to-reservoir impacts where a large landslide body comes to rest at the seafloor without substantial mixing with the water body. The explicit consideration of a layered movement (solid beneath fluid) is appropriate to realistically simulate the restitution of the original water surface (Fig. 9–Fig. 11). Technically, layering can be implemented in a relatively straightforward way, largely by the adaptation of the gravity components and pressure gradients. A major difference between the standard model and the

layered model is the drag. The concept of drag applied by Pudasaini and Mergili (2019) is only suitable for mixtures of solid and fluid material, but not for layered landslides. The drag concept for layered movements, introduced in Section 2.3, represents a rough approximation which is supposed to work best in areas of spatially constant gradients of landslide thickness. Therefore, a direct comparison of the results of the corresponding simulations remains problematic. More research is required in this respect.

The slow-flow model proved powerful in plausibly reproducing two fundamentally different processes, a three-layer planar rock slide (Fig. 6) and a rock glacier (Fig. 12). A detailed analysis on the correspondence of the empirically optimized viscosity parameters and parameters measured in comparable real-world cases are out of scope here, but the computational experiments reveal an important general limitation of r.avaflow, related to the TVD-NOC numerical scheme: fine-scale geomorphological patterns such as furrows and ridges are smoothed and blurred. For the Dösen rock glacier, we have shown an approach to visually compensate for this issue by distorting the orthophoto, following the direction of motion. A similar approach was demonstrated for the Köfels rock slide, in order to allow for a more realistic visual impression (Supplementary materials). A solution to the blurring issue would have to rely on the implementation of a different numerical scheme, which should be a major direction for the future.

Another notable limitation in regard to the simulation of large landslides is the application of depth-averaged models, where the height of the landslide should be much lower than the landslide length, and also much lower than the terrain curvature radius. For phenomena such as the Köfels rock slide or the East Fogo event, this condition might be violated, compromising the accuracy of the results. An in-depth benchmark comparison with full 3D models (e.g., Cicoira et al., 2022) would be helpful to learn about the magnitude of those effects. Until more benchmark tests and empirical evaluation efforts will be available, the proposed models are of limited usability when it comes to inform hazard zoning, technical protection measures, evacuation strategies, or other measures of “hard” risk management. The models are, however, useful for those purposes where a plausible representation of processes, achieved within short computational times and at high computational efficiency, is more important than high levels of mathematical, physical, and geometric accuracy.

Through the interfaces of r.avaflow v4 with the 3D visualization and animation software packages Paraview and Blender 3, and with the game engine Unreal Engine 5, simulation results can be converted into ordinary 3D videos, anaglyph videos, or immersive virtual reality experiences in a straightforward way. Such visually realistic representation of one- or multi-layer slide-type movements over a broad range of time scales and velocities without major computational efforts will be important to feed “gamification” (Pfeffer and Mergili, 2024) in order to create awareness and interest towards landslide phenomena within a broader audience at schools, museums, nature parks, universities, and other suitable social environments.

## 6 Conclusions

We have equipped the mass flow simulation tool r.avaflow with a number of additional functions to simulate (i) slide-type landslides with limited deformation, (ii) landslides which are not extremely rapid (Hung et al., 2014), and (iii) layered

landslides. All these enhancements, included in r.avaflow v4, can be combined for the simulation of single- and multi-layer  
505 flow- and slide-type movements which can be extremely rapid to extremely slow. The sliding model builds on a small set of  
empirical parameters with a physical basis and yields plausible results for the test cases of the prehistoric Köfels rock slide  
and a generic three-layer planar rock slide. For landslide-reservoir interactions, when the mixing between the landslide  
material and the water body is insignificant, the consideration of a layered movement results in a much more realistic  
510 restitution of the pre-event water level after alleviation of the primary displacement wave, compared to the standard multi-  
phase model used in r.avaflow that assumes phase mixing. Direct comparison between the standard model and the layered  
model remains a challenge due to different drag concepts to be applied. The slow-flow model proves capable of simulating  
even very slow movements such as a generic planar rock slide or the Dösen rock glacier in a plausible way. Topographic  
details of modelled landforms are lost for numerical reasons but can be visually recreated through draping of a dynamically  
distorted orthophoto.

515 The enhanced flexibility of r.avaflow v4, compared to earlier versions of the software, increases the responsibility of the  
users to combine terms in a meaningful way. All the extensions introduced, and their interconnection, use strong  
simplifications and generalizations, which may lead to the loss of physical detail on the one hand, and a more  
straightforward parameterization on the other hand. Therefore, these models have to be exposed to additional benchmarking  
and empirical evaluation with well-documented real-world cases, in order to learn more about the effects of possible  
520 limitations of the new functionalities and to constrain suitable parameter values, to become ready for predictive applications  
in risk management. Until that point, the proposed models should be handled cautiously when using them in “hard” risk  
management, but will nevertheless represent an important resource for awareness-building and environmental education, in  
combination with the newly implemented 3D animation and virtual reality interfaces of r.avaflow v4.

### **Code availability**

525 r.avaflow 4.0G Revision 6, which was used for the simulations presented in Section 3 and Section 4, is provided in the  
Assets (Mergili, 2024; <https://doi.org/10.5281/zenodo.14005917>). The latest version of the code is available from Mergili  
and Pudasaini (2024). Please see Mergili and Pudasaini (2024) for software requirements and a detailed manual on how to  
run r.avaflow 4.0G.

### **Data availability**

530 All the data and the start scripts required to run the simulations presented in Section 3 and Section 4 with r.avaflow 4.0G are  
provided in the Assets (Mergili, 2024; <https://doi.org/10.5281/zenodo.14005917>). Please consult Mergili and Pudasaini  
(2024) for software requirements and a detailed manual on how to run r.avaflow 4.0G. In addition, 3D animations of all the

experiments SD1, KF1–KF3, FO1–FO3, and DO1 are provided in standard and anaglyph view. These animations were created directly from the simulation results with the software packages Blender 3 and Adobe Premiere Pro.

### 535 **Author contributions**

Martin Mergili (MM), Hanna Pfeffer (HP), Andreas Kellerer-Pirklbauer (AKP), Christian Zangerl (CZ), Shiva P. Pudasaini (SP)

MM has contributed to the conceptualization and methodology of the research, designed the software, performed the formal analysis, visualization, validation, and most of the writing of the original draft. HP, AKP, and CZ have contributed to the data preparation and review & editing of the manuscript. SP has provided input in terms of methodology and review & editing of the manuscript.

### **Competing interests**

The authors declare that they have no conflict of interest.

### **Acknowledgements**

545 This work is part of the project "Moving mountains - landslides as geosystem services in Austrian geoparks" (ESS22-24 - MOVEMONT) funded through the Earth System Sciences programme of the Austrian Academy of Sciences. Shiva P. Pudasaini acknowledges the financial support from the German Research Foundation (DFG) through the research project "Landslide mobility with erosion: Proof-of-concept and application—Part I: Modeling, Simulation and Validation" with the project number 522097187.
