Dear editor and referees,

We appreciate all your detailed and valuable comments on our manuscript (egusphere-2025-2154). We have carefully considered the comments and revised the manuscript accordingly. Please see the point-by-point response below and changes are marked blue in the revised manuscript.

Thank you very much!

Most sincerely,

Yujue Wang and Min Hu

Point-by-point response to review comments

Note: *Review comments are in 12 point italicized font*. Our responses are indented and in 12 point normal font. The revised text is in quotes and in 10 point blue font.

Referee #2

In this manuscript, the authors present a thorough study on atmospheric organosulfates (OSs) in the East Asian marginal seas, focusing on seasonal variability, chemical composition, and the impact of biogenic marine emissions and transported anthropogenic pollutants. The study utilizes observational cruises across three seasons (spring, summer, and autumn) and integrates high-resolution chemical analysis, principal component analysis (PCA), and back-trajectory assessments to attribute sources and mechanisms of OSs formation. The authors highlight the underestimated importance of OSs in the oceanic sulfur cycle and their possible role in the climate system alongside traditional species like methanesulfonic acid (MSA). The study is well-structured and results are well discussed. Below are the comments for consideration:

General Comments:

The manuscript has a focus comparing OSs levels to MSA, implying both as sulfur-containing organic species and potential CCN. However, they may not necessarily have similar hygroscopicity and CCN activity and therefore climate impact. It is recommended to clarify distinction between MSA and OSs first (regarding precursor, formation pathways and chemical structure), improve transitions between discussing secondary OSs vs MSA, and later on discuss with literature supporting the physicochemical properties of the identified OSs.

> **Response**: Thanks very much for the suggestions. We have added the descriptions on the distinction between MSA and OSs, including precursors, formation pathways, hygroscopicity and CCN activity, in the introduction section (lines 32–35, 43–53 and 61–67) and section 3.2 (lines 258–264).

> **Lines 32–35:**

> Marine phytoplankton could generate abundant dimethylsulfide (DMS), which further be oxidized in the atmosphere, forms methane sulphonic acid (MSA) or sulfate aerosols and then regulates the cloud condensation nuclei (CCN) formation and climate in the marine boundary layer (Andreae and Rosenfeld, 2008; Kettle and Andreae, 2000; Kloster et al., 2006).

> **Lines 43–53:**

> Another important SOA formation pathway from isoprene and monoterpene oxidation is facilitated by acidic sulfate particles under high humidity conditions, resulting in the formation of organosulfates (OSs) (Brüggemann et al., 2020). In the marine boundary layer, sulfate aerosols could largely be formed

via the oxidation of DMS emitted by marine phytoplankton (Andreae, 1990; Li et al., 2018; Yan et al., 2024). Sulfate aerosols are generally abundant over various marine environments (Li et al., 2018; Shank et al., 2012), which serve as a key precursor for the OSs formation and provide an ideal condition for the reactive uptake of VOCs oxidation products. Laboratory studies suggested that the reactive uptake of isoprene epoxydiols (IEPOX) or monoterpene oxides onto aerosol particles and ring-opening epoxide reactions could be catalyzed by acidic sulfate aerosols, resulting in the formation of IEPOX-OS and monoterpene-derived OSs (Surratt et al., 2010; Schindelka et al., 2013; Riva et al., 2016). Biogenic organosulfur formation via the acidic sulfate-catalyzed aqueous reactions with VOCs has been proved to represent an important source of atmospheric organic aerosols (Riva et al., 2019).

Lines 61–67:

Different from MSA, organosulfates are generally with larger molecular weights and weakly hygroscopic taking up water even at subsaturated humidity conditions (Brüggemann et al., 2020; Peng et al., 2021; Hansen et al., 2015). The OSs molecules have the hydrophilic sulfate group and the hydrophobic organic group, making them surface-active compounds. It has been suggested that OSs could lower the surface tension of particles, affect the particles' ability to absorb water, and to act as CCN (Brüggemann et al., 2020; Hansen et al., 2015). The roles of OSs in regulating the CCN formation and climate may be different from MSA, which needs further elaboration via field observations and laboratory studies.

Lines 258–264:

Previous studies have suggested that atmospheric MSA formed via the oxidation of DMS contributes to the CCN formation in the marine boundary layer, which is a vital species relevant to the CLAW hypothesis of oceanic phytoplankton-controlled climate regulation (Ayers et al., 1997; Charlson et al., 1987; Quinn and Bates, 2011). Atmospheric OSs could modify the aerosol morphology, suppress the surface tension and might play roles in altering the cloud formation (Estillore et al., 2016; Riva et al., 2019). The relevance of MSA and OSs in climate regulation and the CLAW hypothesis should be assessed considering their abundance in the atmosphere as well as their distinct physicochemical properties.

The terms "OS" vs "OSs", "NOS" vs "NOSs", and "VOC" vs "VOCs" should be used more consistently, e.g., Line 250: "OSs concentrations" vs Line 255: "OS concentrations" vs Line 211: "organosulfate".

Response: Thanks for the kind reminding. To be consistent, we now use the terms "OSs", "NOSs", "VOCs", and "organosulfates" throughout the main text.

Language editing is needed for some sentences starting with "While…" (Line 35-37, Line 54-57, Line 125-126, Line 236-238).

Response: We have now revised these sentences to be clear.

Lines 35–37:

However, the following observational evidence and modelling studies indicated that CCN formation in marine atmospheres is far more complex than had been recognized by the CLAW hypothesis (Quinn and Bates, 2011).

Lines 67–69:

We noted that the atmospheric OSs derived from isoprene or monoterpenes were rarely detected in the marine aerosols collected at a remote island site located in the Southern Ocean or the southern Indian Ocean (Claeys et al., 2010; Cui et al., 2019).

Lines 166–167:

The OSs formation may be limited by the low biogenic VOCs emissions or ambient RH in the wintertime inland environments (Wang et al., 2020).

Lines 297–298:

However, during autumn and spring, we observed higher mass ratios of C_2-C_3 OSs versus isoprene-OSs due to the additional sources of C_2-C_3 OSs contributed by anthropogenic sources.

Lines 302–304:

The low-NO conditions in summer favored the IEPOX formation from isoprene oxidation via HO_2 pathway, and the formation of MAE via NO/NO_2 pathway increased under the influence of continental pollutants in autumn and spring.

Lines 318–319:

However, we cannot exclude the potential influence of transported continental air masses, especially over the nYBS.

Specific Comments:

Line 43-46: "Another important SOA formation pathway from isoprene and monoterpene oxidation is facilitated by acidic sulfate particles under high humidity conditions, with organosulfates (OSs) as the products (Brüggemann et al., 2020). Sulfate aerosols could be readily formed via DMS oxidation and are generally abundant over various marine environments (Andreae, 1990; Li et al., 2018; Yan et al., 2024)." More story-telling is needed to clarify why DMS-derived sulfate is discussed here with other biogenic OSs. Also consider citing some mechanism-focused studies here to highlight how aqueous-phase chemistry drives reactive uptake of epoxydiols by sulfate aerosols.

Response: The DMS-derived sulfate is discussed here as sulfate aerosols are an important precursor for the OSs formation via the interactions between acidic sulfate and VOCs precursors. Related explanations have been added in lines 43–48.

As suggested, laboratory studies are now cited to highlight the mechanisms of aqueous-phase chemistry driving the reactive uptake of epoxydiols by the sulfate aerosols (lines 48–53).

Lines 43–53:

Another important SOA formation pathway from isoprene and monoterpene oxidation is facilitated by acidic sulfate particles under high humidity conditions, resulting in the formation of organosulfates (OSs) (Brüggemann et al., 2020). In the marine boundary layer, sulfate aerosols could largely be formed via the oxidation of DMS emitted by marine phytoplankton (Andreae, 1990; Li et al., 2018; Yan et al., 2024). Sulfate aerosols are generally abundant over various marine environments (Li et al., 2018; Shank et al., 2012), which serve as a key precursor for the OSs formation and provide an ideal condition for the reactive uptake of VOCs oxidation products. Laboratory studies suggested that the reactive

uptake of isoprene epoxydiols (IEPOX) or monoterpene oxides onto aerosol particles and ring-opening epoxide reactions could be catalyzed by acidic sulfate aerosols, resulting in the formation of IEPOX-OS and monoterpene-derived OSs (Surratt et al., 2010; Schindelka et al., 2013; Riva et al., 2016). Biogenic organosulfur formation via the acidic sulfate-catalyzed aqueous reactions with VOCs has been proved to represent an important source of atmospheric organic aerosols (Riva et al., 2019).

Section 2.1: Give a brief introduction about the geographical and climate characteristics of Yellow Sea and Bohai Sea (YBS), and state how the measurement here would address current research gap. It will be good to also mention the time resolutions of filter sampling and other measurements including WS, RH, EC, and Chl-a.

Response: As suggested, we have added the descriptions on the geographical and climate characteristics of the YBS (lines 83–87) as well as the time resolutions of filter sampling and other measurements in section 2.1 (lines 90–91, 93–97 and 144–145).

Lines 83–87:

The YBS are marginal seas surrounded by the East Asian continents (Figure 1), where there are active interactions between transported continent outflows (e.g. Asian dust, anthropogenic pollutants) and marine emissions. The atmosphere over the YBS is dominantly influenced by the marine emissions or the continental outflows in different seasons, making it an ideal region to understand the roles of marine emissions and continental pollutants in the marine aerosol formation.

Lines 90–91:

Each aerosol sample was collected for 10−24 hrs, and a field blank sample was collected during each cruise.

Lines 93–97:

During the observation, wind speed (WS), air temperature, and relative humidity (RH) were simultaneously measured by a shipboard meteorological observatory, with a time resolution of 10s. The surface seawater (2−5 m) samples were collected by a conductivity−temperature−depth (CTD) assembly (Seabird 9/11), and the chlorophyll-a (*Chl-a*) concentration in surface seawater was measured using a CE Turner Designs fluorometer. There were 2−12 CTD sites during the sampling period of each filter sample.

Lines 144–145:

The filter samples, with a time resolution of 10−24 hrs, were used for the analysis of organic carbon (OC), elemental carbon (EC), water-soluble ions, and MSA in the marine aerosols.

Line 78: The short form for chlorophyll-a (Chl-a) should be denoted here as the first appearance in the manuscript.

Response: Revised accordingly.

Section 2.2: Do the authors also correct for extraction efficiencies and quantification uncertainties? Some quantitative descriptors (e.g. R^2, S.D., uncertainty range, n-values) can be reported consistently throughout the manuscript.

Response: The quantitative descriptors of OSs quantification, including extraction efficiencies, quantification uncertainties, R^2, S.D., n-values, have been described in lines 126–132, and details are listed in Table S1.

Lines 126–132:

As shown in Table S1, the UHPLC and MS/MS conditions produce highly linear calibration curves for the quantified OSs compounds ($R^2 > 0.99$). The limit of detection (LOD) and limit of quantification (LOQ) of C_2-C_3 OSs range 0.07–0.79 µg L^{-1} and 0.24–2.62 µg L^{-1}. The LOD and LOQ of monoterpene-OSs range 0.73–2.65 µg L^{-1} and 2.42–8.85 µg L^{-1}. The relative standard deviation (RSD) of the quantified OSs is <12.1% based on ten replicate injections of standards. Spike recoveries of the OSs standards on the blank filter are 94%–105%. The measurement uncertainty of OSs concentrations is 5.5–13.2% considering the relative errors in air volume (5%), extraction efficiency (recovery), and instrumental analysis (Hettiyadura et al., 2017).

Newly added Table S1:

Table S1 Synthesized OSs standards used in the HPLC-MS analysis, linearity, coefficient of determination (R^2), limit of detection (LOD), limit of quantification (LOQ), relative standard deviation (RSD) and measurement uncertainty of ten replicate standard injections.

Common name	Formula	[M-H]$^-$	Linear range (µg L^{-1})	R^2	LOD (µg L^{-1})	LOQ (µg L^{-1})	RSD (%)	Measurement uncertainty (%)
Hydroxyacetone sulfate (HAS)	$C_3H_5O_5S^-$	152.99	10-1000	0.995	0.79	2.62	2.79	7.6
Glycolic acid sulfate (GAS)	$C_2H_3O_6S^-$	154.97	10-1000	0.999	0.13	0.43	12.08	13.2
Lactic acid sulfate (LAS)	$C_3H_5O_6S^-$	168.98	10-1000	0.995	0.07	0.24	5.37	7.9
α-Pinene OS			10-1000	0.998	0.78	2.59	2.34	5.5
β-Pinene OS	$C_{10}H_{17}O_5S^-$	249.08	10-1000	0.999	0.76	2.53	4.16	6.3

limonaketone NOS	$C_9H_{14}NO_8S^-$	296.04	10-1000	0.999	2.65	8.85	2.85	5.8

Line 111: "The OA concentration was then calculated by multiplying OC by 1.6." Cite the reference for the estimation.

Response: Related reference Wang et al., *ES&T*, 2023 has been cited in line 147. The selection of the OM/OC conversion factor (1.6) is detailed in the Appendix of Wang et al., (2023).

Line 114: "The concentrations of non-sea-salt potassium ion (nss-K^+) and non-sea-salt sulfate (nss-SO_4^{2-}) were calculated by $[K^+]−0.037×[Na^+]$ and $[SO_4^{2-}]−0.2516×[Na^+]$." Cite the reference for the estimation.

Response: Related reference has been cited in line 150.

Lines 148–150:

The concentrations of non-sea-salt potassium ion (nss-K^+) and non-sea-salt sulfate (nss-SO_4^{2-}) were respectively calculated by $[K^+]−0.037×[Na^+]$ and $[SO_4^{2-}]−0.2516×[Na^+]$ (Millero and Sohn, 1992; Jung et al., 2020; Balasubramanian et al., 2003; Behera et al., 2013).

Line 124: "…under high RH conditions in coastal areas, which favored the aqueous-phase formation of OSs in the atmosphere." What are the chemical pathways? Cite the references to support the argument.

Response: The chemical pathways and related references are now added in the revised version (lines 163–166).

Lines 163–166:

Acid sulfate-catalyzed reactions with isoprene-derived epoxide are widely adopted as the most important pathway for atmospheric OSs formation (Liao et al., 2015; Surratt et al., 2008; Schindelka et al., 2013; Brüggemann et al., 2020). Under the high-humidity conditions, OSs could also be formed via the heterogeneous reactions between SO_2 and monoterpene ozonolysis intermediates or organic peroxides (Ye et al., 2018).

Line 166: "The IEPOX-OS, a typical low-NO oxidation product of isoprene, was one of the dominant compounds during the summer cruise…" Critical citations on mechanistic and observational studies are needed to support further discussion in this paragraph.

Response: The critical references on mechanistic and observational studies have been cited in lines 205–209 to support further discussion.

Lines 205–209:

The IEPOX-OS was one of the dominant OSs compounds during the summer cruise (Fig. 1), which is a typical low-NO oxidation product of isoprene formed via the acid-catalyzed ring opening of isoprene epoxydiols and subsequent nucleophilic addition of inorganic sulfate (Surratt et al., 2010; Lin et al., 2012). The dominance of IEPOX-OS among the biogenic OSs observed here is consistent with previous field observations under low-NO and high-RH conditions (Cooke et al., 2022; Lam et al., 2019; Liao et al., 2015).

Line 190: "The higher seawater Chlorophyll-a (Chl-a) during summer indicated elevated isoprene production by phytoplankton, and higher temperature favored the sea-to-air transfer process of isoprene (Fig. S3)." It is noted from Fig S3 and S6 that the median do not differ much from other seasons. Please mention the number of measurements and comment on the range of Chl-a measured during summer and whether this elevation is significant.

Response: Thanks for reminding us that the median values in summer, shown in Figures S3 and S6, do not differ much from other seasons. Yes, the median values of *Chl-a* concentrations in summer did not show a significant difference from those in other seasons (p>0.1). We revised the related explanations in lines 236–240. As suggested, the number of measurements and the range of seawater *Chl-a* are also added here in the revised version.

Lines 236–240:

The filter-sampling-averaged *Chl-a* concentrations were 0.6−5.3 mg/m³ (n=7, 2.1±1.7 mg/m³ on average) during summer, 1.0−2.4 mg/m³ (n=8, 1.7±0.5 mg/m³ on average) during spring and 0.5−2.2 mg/m³ (n=11, 1.4±0.6 mg/m³ on average) during autumn. High seawater *Chl-a* conditions (5.3 and 3.6

mg/m³) were observed during the summer cruise. In addition, the air temperature in summer was significantly (p< 0.001) higher than that in other seasons (Fig. S3), and the summertime high temperature favored the sea-to-air transfer process of isoprene.

Line 209: "This suggested that the atmospheric OSs and MSA formation was limited by the same environmental factors in autumn," Whereas MSA has often served as an indicator for marine biological activity, do the author also have plausible explanations for the weaker correlation during summer?

Response: The possible reasons for the weaker correlation between OSs and MSA during summer have been explained in lines 267–273.

Lines 267–273:

The increase of marine phytoplankton emissions (e.g., DMS) may drive the formation and elevation of OSs during autumn over the YBS. Atmospheric OSs and MSA did not show an obvious correlation in summer. The seawater *Chl-a* and SST were higher during the summer cruise than during the other cruises (Fig. S3), indicating abundant marine biogenic emissions and sea-to-air exchange processes in summer. We proposed that the marine biogenic emitted precursors (e.g., DMS, isoprene) were abundant and in excess for the MSA and OSs formation in summer. The formation of MSA or OSs might be limited by different atmospheric oxidation or subsequent reaction processes of these precursors, and the environmental conditions driving their formation in summer need further investigation.

Section 3.5: Consider reporting how many samples and variables were input into PCA in the maintext.

Response: A total of 26 aerosol samples and 18 variables were input into the PCA analysis. Related information has been added in lines 347–349.

Lines 347–349:

Principal Component Analysis (PCA) was performed using 26 aerosol samples to further understand the sources of atmospheric OSs over the YBS (Fig. 6, Table S3). A total of 18 particulate components, including OSs, water-soluble ions, EC, and MSA, were chosen to carry out the statistics.

Line 307: "Elevated OS concentrations were observed as the increasing of air temperature in summer or as the increasing of wind speed in spring (Fig. 7)." Some language editing may benefit, e.g., OSs concentrations elevated with increasing air temperature in summer and increasing wind speed in spring.

Response: Revised accordingly.

Line 327-329: "The results highlight the abundant formation of airborne OSs in summer, which is promoted by the elevated biogenic VOC emissions from surface ocean. During high biological activity periods, atmospheric OS levels could surpass the MSA concentrations in marine aerosols, which is a vital species in the well-known climate regulation via oceanic phytoplankton sulphur emissions (CLAW hypothesis)." For broader implication, the authors may also discuss the potential of different organic sulfur species (particularly MSA vs biogenic like isoprene-derived OSs) as alternative molecular tracers for phytoplankton-

derived aerosol, in which the inclusion of these tracers may offer greater sensitivity under certain seasons or atmospheric regimes.

Response: Thanks for the suggestion on the broad implications of our study. We have now added in lines 396–398.

Lines 396–398:

In the future studies, isoprene-derived OSs are suggested to be included as the molecular tracers of marine SOA related to phytoplankton emissions, especially during summer or over oceanic regions with high phytoplankton activities and high SST.

Atmospheric Organosulfate Formation Regulated by Continental Outflows and Marine Emissions over East Asian Marginal Seas

Abstract. Organosulfates (OSs) represent an unrecognized fraction and a potentially important source of marine organic aerosols. Based on shipboard observations over East Asian marginal seas, we characterized OSs in marine aerosols during spring, summer, and autumn. The C_2–C_3 OSs and isoprene-/monoterpenes-derived OSs were quantified using synthesized standards. The total quantified OSs concentrations ranged from 4.5 to 109.1 ng/m³, contributing 0.1%−3.2% of the mass concentration of marine organic aerosols. The highest OSs concentrations, dominated by C_2–C_3 OSs and isoprene-OSs, were observed in summer, which surpassed the abundance of methane sulfonic acid, a key component in climate regulation by oceanic phytoplankton sulphur emissions. Abundant OSs formation in summer was mainly attributed to the increased isoprene emissions from the ocean. During the spring and autumn cruises, transported continental pollutants resulted in the higher fraction of monoterpene-derived (nitrooxy-)OSs, as well as the elevated OSs concentrations over regions surrounded by the continent. This work highlights the joint effects of marine emissions and continental outflows on the formation and distribution of atmospheric OSs over marginal seas.

1 Introduction

Marine atmospheric aerosols play a vital role in climate change through influencing cloud formation and solar radiative balance(Li et al., 2022). Marine phytoplankton could generate abundant dimethylsulfide (DMS), which further be oxidized in

the atmosphere, forms methane sulphonic acid (MSA) or sulfate aerosols and then regulates the cloud condensation nuclei (CCN) formation and climate in the marine boundary layer (Andreae and Rosenfeld, 2008; Kettle and Andreae, 2000; Kloster et al., 2006). This is named the CLAW hypothesis, proposed by Charlson et al. (1987) and Ayers et al. (1991). However, the following observational evidence and modelling studies indicated that CCN formation in marine atmospheres is far more complex than had been recognized by the CLAW hypothesis (Quinn and Bates, 2011). This is mainly attributed to the unknown organic fractions in marine aerosols, including those primarily emitted by sea spray and secondarily formed organic aerosols (SOA) via the oxidation of volatile organic compounds (VOCs).

Traditional SOA tracers, including those from the oxidation of isoprene and monoterpene, etc., could explain only <10% of marine organic aerosols (Fu et al., 2011; Guo et al., 2020). The majority of the marine SOA components remain unknown till now. Abundant isoprene could be emitted from the ocean, and isoprene SOA has been proved to be one of the most important fractions in marine organic aerosols (Hu et al., 2013). Another important SOA formation pathway from isoprene and monoterpene oxidation is facilitated by acidic sulfate particles under high humidity conditions, resulting in the formation of organosulfates (OSs) (Brüggemann et al., 2020). In the marine boundary layer, sulfate aerosols could largely be formed via the oxidation of DMS emitted by marine phytoplankton (Andreae, 1990; Li et al., 2018; Yan et al., 2024). Sulfate aerosols are generally abundant over various marine environments (Li et al., 2018; Shank et al., 2012), which serve as a key precursor for the OSs formation and provide an ideal condition for the reactive uptake of VOCs oxidation products. Laboratory studies suggested that the reactive uptake of isoprene epoxydiols (IEPOX) or monoterpene oxides onto aerosol particles and ring-opening epoxide reactions could be catalyzed by acidic sulfate aerosols, resulting in the formation of IEPOX-OS and monoterpene-derived OSs (Surratt et al., 2010; Schindelka et al., 2013; Riva et al., 2016). Biogenic organosulfur formation via the acidic sulfate-catalyzed aqueous reactions with VOCs has been proved to represent an important source of atmospheric organic aerosols (Riva et al., 2019). Recent studies also indicated the existence and importance of organic sulfur compounds, including OSs, in marine aerosols (Bao et al., 2018; Ye et al., 2021).

Atmospheric OSs constitute a large portion of organic aerosols (OA) in the environments with substantial interactions of biogenic and anthropogenic emissions (Hettiyadura et al., 2019; Meade et al., 2016; Surratt et al., 2008; Wang et al., 2018). A recent cruise observation over Asian marginal seas suggested that OSs derived from isoprene and monoterpenes could contribute about 7% of the OA mass concentration (Wang et al., 2023b). Wang et al (2023) also indicated that isoprene/monoterpene-derived OSs could surpass the traditionally identified SOA tracers generated from isoprene or monoterpene oxidation (e.g., methylglyceric acid, alkene triols, hydroxyglutaric acid, pinic acid etc.). Besides sulfate and MSA, atmospheric OSs could be a potential key species in the sulfur cycle in the marine boundary layer. Different from MSA, organosulfates are generally with larger molecular weights and weakly hygroscopic taking up water even at subsaturated

humidity conditions (Brüggemann et al., 2020; Peng et al., 2021; Hansen et al., 2015). The OSs molecules have the hydrophilic sulfate group and the hydrophobic organic group, making them surface-active compounds. It has been suggested that OSs could lower the surface tension of particles, affect the particles' ability to absorb water, and to act as CCN (Brüggemann et al., 2020; Hansen et al., 2015). The roles of OSs in regulating the CCN formation and climate may be different from MSA, which needs further elaboration via field observations and laboratory studies. We noted that the atmospheric OSs derived from isoprene or monoterpenes were rarely detected in the marine aerosols collected at a remote island site located in the Southern Ocean or the southern Indian Ocean (Claeys et al., 2010; Cui et al., 2019). These could be attributed to the low biogenic VOCs emission/flux or the degradation of OSs over long-term storage (Claeys et al., 2010; Cui et al., 2019).

The existence or abundance of atmospheric OSs in marine aerosols have not been well evaluated or quantified till now (Hawkins et al., 2010; Wang et al., 2023b; Ye et al., 2021), which limited the understanding on their formation processes or their roles in the sulfur cycle and aerosol climate effects in marine atmospheres. In this study, atmospheric OSs over East Asian marginal seas were quantified using synthesized OSs standards. We characterized the particulate OSs derived from isoprene and monoterpenes, and investigated their spatial distributions, seasonal variations, as well as the dominant environmental factors of OSs formation. Our results suggested that, over marginal seas, the spatiotemporal distribution of OSs abundance and composition was dependent on the relative importance of marine emissions and continental outflows. This work highlights the vital roles of OSs in altering the sulfur cycle in marine boundary layer, and further studies in open ocean are needed to understand the influence of OSs on the climate effects of marine aerosols.

2 Methods

2.1 Cruise observation and sample collection

Marine aerosol samples were collected during summer (16 July–26 July) and autumn (21 October–2 November) in 2021, and during spring (14 April–25 April) in 2022 over the Yellow Sea and Bohai Sea (YBS). The YBS are marginal seas surrounded by the East Asian continents (Figure 1), where there are active interactions between transported continent outflows (e.g. Asian dust, anthropogenic pollutants) and marine emissions. The atmosphere over the YBS is dominantly influenced by the marine emissions or the continental outflows in different seasons, making it an ideal region to understand the roles of marine emissions and continental pollutants in the marine aerosol formation. The fine particle ($PM_{2.5}$) and total suspended particulate (TSP) samples were collected using high-volume aerosol samplers (KB-1000, Qingdao Genstar Electronic Technology, China). The quartz fiber filters were pre-baked at 500 °C for 4.5 hours and wrapped in pre-baked aluminum foil after sampling. Aerosol samplers were placed on the top deck of the vessel "Lanhai 101", approximately 8 m above the sea surface. Each aerosol sample was collected for 10−24 hrs, and a field blank sample was collected during each cruise. The field blank sample was

92 used to correct the potential sampling artifacts for the quantified OSs and other species in the marine aerosol samples.

93 During the observation, wind speed (WS), air temperature, and relative humidity (RH) were simultaneously measured by a

94 shipboard meteorological observatory, with a time resolution of 10s. The surface seawater (2−5 m) samples were collected by

95 a conductivity−temperature−depth (CTD) assembly (Seabird 9/11), and the chlorophyll-a (*Chl-a*) concentration in surface

96 seawater was measured using a CE Turner Designs fluorometer. There were 2−12 CTD sites during the sampling period of

97 each filter sample. Concentrations of seawater isoprene were then estimated by empirical formulas based on previous studies

98 (Ooki et al., 2015; Wang et al., 2023b). The 72 h backward trajectories of air masses from an altitude of 500 m above ground

99 level were calculated using the HYSPLIT model (Version 5.2.1, NOAA), starting every 6 h (Fig. S1). Trajectories at the center

100 site of the observation region were calculated to represent the air masses during each cruise over the YBS.

101 **2.2 HPLC-MS analysis and OSs quantification**

102 An aliquot of each filter sample was extracted by methanol. The solutions were filtered using PTFE syringe filter (0.22 μm),

103 and evaporated to dryness under a gentle stream of N_2 gas. The dried residues were redissolved in methanol containing 0.1%

104 formic acid (100 μL). Organosulfates compounds were quantified using a QTRAP 4500 mass spectrometer (AB Sciex) coupled

105 with an UHPLC system (Ultimate 3000, Thermo Scientific, DE) for the low-molecular-weight OSs, and an Exactive Plus-

106 Orbitrap mass spectrometer (Thermo Scientific Inc.) with an UHPLC system (Ultimate 3000) for monoterpene-derived

107 compounds. Mass spectrometry was operated using a negative-mode electrospray ionization. The monoterpene NOSs

108 ($C_{10}H_{16}NO_7S^-$ and $C_9H_{14}NO_8S^-$) were identified in the extracted ion chromatogram mode, and other OSs compounds were

109 quantified in multiple-reaction monitoring (MRM) mode. In this work, C_2-C_3 OSs (HAS, GAS, and LAS), isoprene-OSs

110 (IEPOX-OS, MAE-OS, and $C_5H_7O_7S^-$), monoterpene-OSs, and nitrooxy-OSs (NOSs) were quantified using synthesized OSs

111 standards (Tables S1, S2) (Wang et al., 2018).

112 Chromatographic separation of the low-molecular-weight OSs, including C_2-C_3 OSs and isoprene-OSs/NOSs, was optimized

113 using an ethylene bridged hybrid (BEH) Amide column (2.1 mm×100 mm, 1.7 μm, Waters, USA) equipped with a pre-column.

114 Hydrophilic interaction liquid chromatography (HILIC) separation is an accurate analytical method for quantifying the low-

115 molecular-weight OSs (Hettiyadura et al., 2015). The injection volume was 2.0 μL. The column was maintained at 35°C.

116 Mobile eluents were solvent A: ammonium acetate buffer (10 mM, pH 9) in ultrapure water and solvent B: 10 mM ammonium

117 acetate buffer (10 mM, pH 9) in acetonitrile/water (95:5). The flow rate was 0.4 mL/min at 0–2.5 min, then decreased to 0.35

118 mL/min from 2.5 to 11.5 min, and increased back to 0.4 mL/min from 11.5 to 18 min. The gradient elution was set as follows:

119 100% B at 0–0.4 min; reduced to 88% B at 0.4–2.4 min and maintained until 11 min; increased to 100% B at 11–11.5 min, and

120 maintained at 100% B until 18 min to re-equilibrate the column. Monoterpene OSs/NOSs were analyzed using an Acquity

121 UPLC HSS T3 column (2.1 mm×100 mm, 1.8 μm, Waters, USA) with a pre-column. The mobile eluents were solvent A (0.1%

122 acetic acid in ultrapure water) and solvent B (0.1% acetic acid in methanol) at a flow rate of 0.3 mL/min. The gradient elution

123 procedure was performed as follows: 5% B at 0−1.5 min; increased to 54% B over 13.7 min and held for 1.0 min; then increased

124 to 90% B over 1.8 min and held for 5 min; decreased to 5% B over 0.5 min and held for 1.5 min to re-equilibrate the column

125 for next injection. The column temperature was maintained at 45°C, and the injection volume was 5.0 μL.

126 As shown in Table S1, the UHPLC and MS/MS conditions produce highly linear calibration curves for the quantified OSs

127 compounds ($R^2 > 0.99$). The limit of detection (LOD) and limit of quantification (LOQ) of C_2-C_3 OSs range 0.07–0.79 μg L^{-1}

128 and 0.24–2.62 μg L^{-1}. The LOD and LOQ of monoterpene-OSs range 0.73–2.65 μg L^{-1} and 2.42–8.85 μg L^{-1}. The relative

129 standard deviation (RSD) of the quantified OSs is <12.1% based on ten replicate injections of standards. Spike recoveries of

130 the OSs standards on the blank filter are 94%–105%. The measurement uncertainty of OSs concentrations is 5.5–13.2%

131 considering the relative errors in air volume (5%), extraction efficiency (recovery), and instrumental analysis (Hettiyadura et

132 al., 2017). Organosulfates are primarily present in the particle phase under ambient conditions due to their low volatilities.

133 Laboratory studies suggested that hydrolysis could be an atmospheric removal process for some OSs (Chen et al., 2020; Hu et

134 al., 2011; Lam et al., 2019). The quantified OSs in this study are likely to be chemically stable over the atmospheric time scales

135 (Chen et al., 2020; Hu et al., 2011; Lam et al., 2019). A previous study showed a potential positive bias of atmospheric OSs

136 during the filter sampling and subsequent offline analysis (Kristensen et al., 2016). This sampling artifact is because that the

137 gas-phase epoxides or SO_2 might absorb onto the filter substrates during the sampling. Subsequent on-filter oxidation and

138 sulfation of the absorbed epoxides may form OSs, leading to a positive bias in the sampling and quantification of OSs

139 (Kristensen et al., 2016; Brüggemann et al., 2020). In the present study, the field blanks were analyzed following the same

140 procedures and used to correct the potential sampling artifacts. The mass loadings of the quantified OSs compounds in the

141 field blank samples were < 0.1% of those in the marine aerosol samples. All the reported OSs concentrations have been

142 corrected by subtracting the background values in the corresponding field blank sample.

143 **2.3 Measurements of aerosol chemical composition**

144 The filter samples, with a time resolution of 10−24 hrs, were used for the analysis of organic carbon (OC), elemental carbon

145 (EC), water-soluble ions, and MSA in the marine aerosols. The concentrations of OC and EC were measured using a carbon

146 analyzer (Model RT-3131, Sunset Laboratory, OR). The OA concentration was then calculated by multiplying OC by 1.6

147 (Wang et al., 2023b). Water-soluble cations (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}), anions (Cl^-, NO_3^-, SO_4^{2-}), and MSA were measured

148 using ion chromatography systems (ICS-2100 and ICS-Aquion RFIC, Thermo Scientific). The concentrations of non-sea-salt

149 potassium ion (nss-K^+) and non-sea-salt sulfate (nss-SO_4^{2-}) were respectively calculated by $[K^+]−0.037×[Na^+]$ and

150 $[SO_4^{2-}]−0.2516×[Na^+]$ (Millero and Sohn, 1992; Jung et al., 2020; Balasubramanian et al., 2003; Behera et al., 2013). The

151 mass loadings of OC and sulfate in the field blank samples were < 8% and < 1.3% of those in the collected marine aerosol

152 samples. All the reported concentrations of the aerosol compounds have been corrected by subtracting the background values

153 measured in the corresponding field blank sample. The concentrations of $PM_{2.5}$ or TSP were reconstructed by summing the

154 concentrations of inorganic ions, OA, and EC in each aerosol sample.

3 Results and discussion

3.1 Concentration and composition of marine atmospheric OSs

157 The total quantified OSs and nitrooxy-OSs ranged from 4.5 to 109.1 ng/m³ in marine aerosols during the shipboard

158 observations over the YBS (Fig. 1, Table S2). The eleven quantified OSs and NOSs compounds contributed 0.1%−3.2% of the

159 OA mass concentrations over the YBS. The observed OSs concentrations here were generally higher than the wintertime

160 concentrations at inland sites, and lower than those in coastal regions (Kanellopoulos et al., 2022; Meade et al., 2016; Nguyen

161 et al., 2014; Wang et al., 2020, 2021, 2022b) (Fig. 2). This was due to the active interactions between biogenic VOCs and

162 sulfate aerosols under high RH conditions in coastal areas, which favored the aqueous-phase formation of OSs in the

163 atmosphere. Acid sulfate-catalyzed reactions with isoprene-derived epoxide are widely adopted as the most important pathway

164 for atmospheric OSs formation (Liao et al., 2015; Surratt et al., 2008; Schindelka et al., 2013; Brüggemann et al., 2020). Under

165 the high-humidity conditions, OSs could also be formed via the heterogeneous reactions between SO_2 and monoterpene

166 ozonolysis intermediates or organic peroxides (Ye et al., 2018). The OSs formation may be limited by the low biogenic

167 VOCs emissions or ambient RH in the wintertime inland environments (Wang et al., 2020). It is noted that, taking the autumn

168 observation as an example, we compared the OSs concentrations in the $PM_{2.5}$ and the TSP samples simultaneously collected

169 during the cruise (Fig. S2). The majority of the data points fall along the 1:1 line (Fig. S2). The presence of OSs is dominant

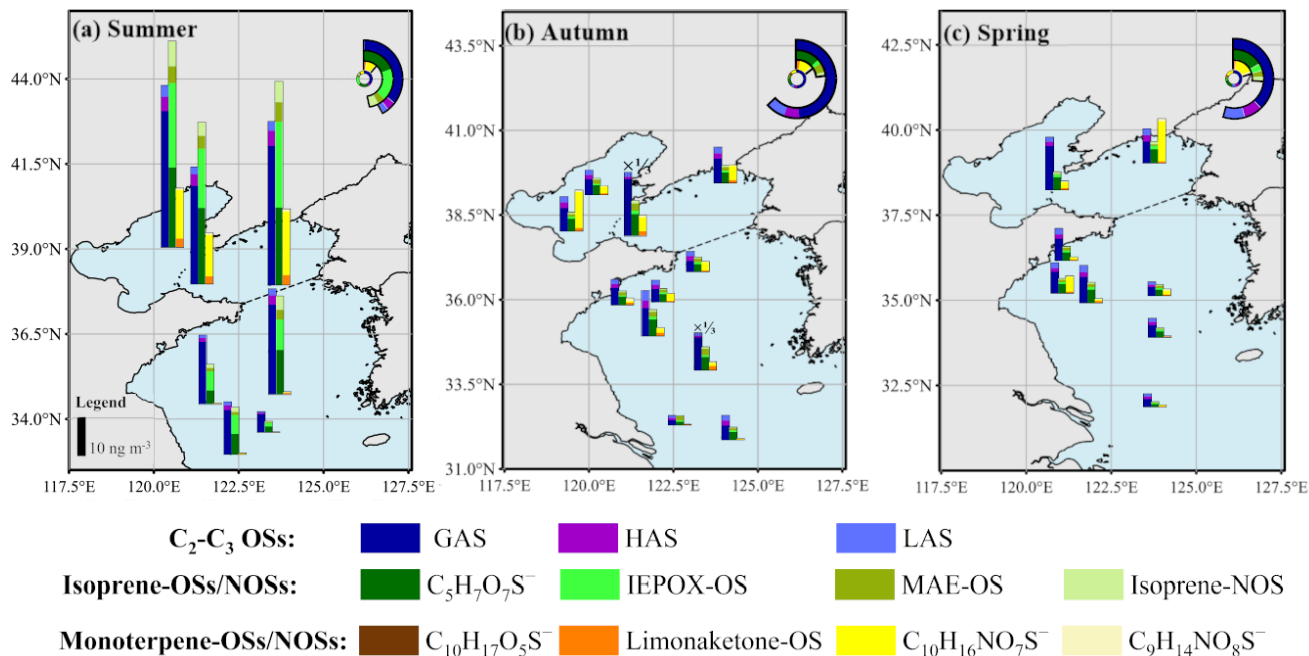
170 in fine particles, and thus our further discussion is focused on the results of the $PM_{2.5}$ samples.


Figure 1. Spatial distributions of OSs in $PM_{2.5}$ over the YBS during (a) summer, (b) autumn in 2021, and (c) spring in 2022. The inserted charts in panels (a, b, c) are the contribution of different OSs compounds. The dotted lines in the panels are the dividing line of the North Yellow Sea (nYS) and the South Yellow Sea (sYS).

The C_2-C_3 OSs, including glycolic acid sulfate (GAS), hydroxyacetone sulfate (HAS), and lactic acid sulfate (LAS), were the most abundant compound group across the observed seasons (Fig. 1, 2). The C_2-C_3 OSs concentrations were respectively 7.2±3.1, 24.2±12.4, and 12.8±14.4 ng/m³ in spring, summer, and autumn, comparable to the concentration levels at inland sites and lower than those in coastal areas (Fig. 2). In autumn and spring, the fraction of C_2-C_3 OSs, especially GAS, was much higher than other compound groups. The highest GAS concentration (47.8 ng/m³) over YBS was observed on 30 October during the autumn cruise. We noted that, in marine atmospheres, the contribution of C_2-C_3 OSs among the quantified OSs was much higher than those observed in various continental environments (Fig. 2). These low-molecular-weight OSs could be formed via the oxidation of VOCs precursors from both biogenic and anthropogenic origins (Wang et al., 2023a), and have been frequently observed as one of the most abundant OSs groups in previous studies (Wang et al., 2018, 2020; Cai et al., 2020).

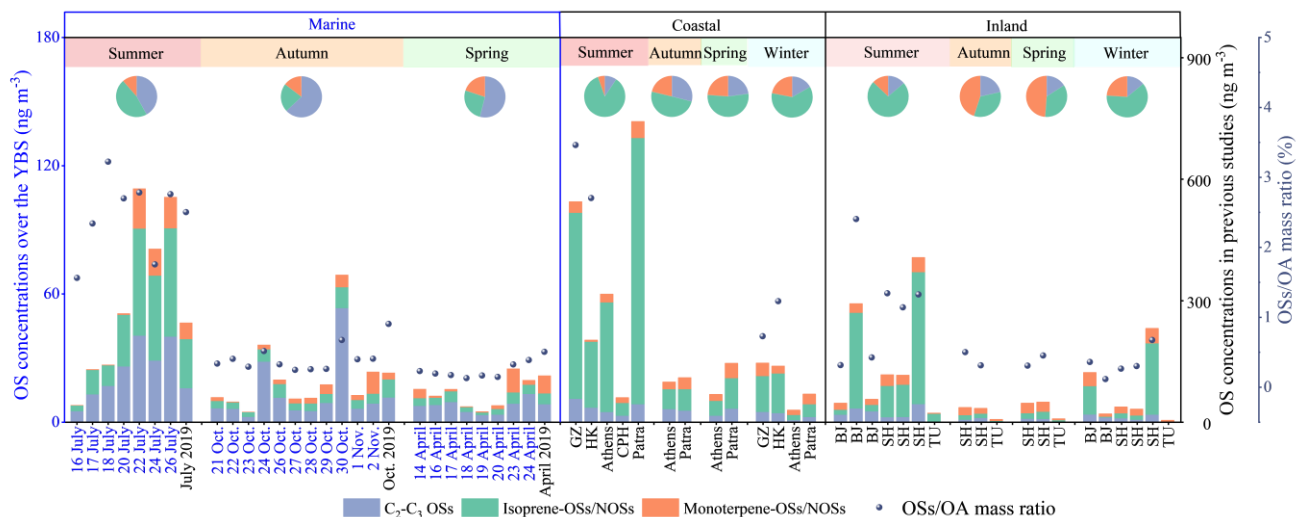
187


Figure 2. Atmospheric OSs concentrations and mass ratios of (OSs+NOSs)/OA over the YBS in this study and in inland and coastal atmospheres reported in previous studies (Kanellopoulos et al., 2022; Meade et al., 2016; Nguyen et al., 2014; Wang et al., 2020, 2021, 2022b). The data labels in this work are denoted in blue, and those from previous studies are in black. The pie charts represent the average contribution of OSs compound groups in each season. It is noted that the OSs abundance over the YBS and at coastal or inland sites are represented by different y-axes concentration ranges.

193

The total concentration of quantified isoprene-OSs and NOSs ranged from 1.3 to 56.9 ng/m³, which were the most abundant group in summer over the YBS (Fig. 1). The predominance of isoprene OSs has been well documented at both coastal and inland sites (Fig. 2), which is attributed to the substantial biogenic isoprene emissions, especially during warmer seasons. Wu et al. (2021) reported abundant emission of isoprene from coastal and shelf seas (Wu et al., 2021), and isoprene OSs would then form via the interaction between sulfate aerosols and isoprene oxidation products (Surratt et al., 2010; Cooke et al., 2022). In the marine atmosphere over YBS, isoprene-derived OSs displayed a dominance by IEPOX-OS and $C_5H_7O_7S^-$ during summer, and by $C_5H_7O_7S^-$ during spring and autumn (Fig. 1). The $C_5H_7O_7S^-$ compound has been suggested as a further oxidized or aged form of IEPOX-OS (Armstrong et al., 2022; Chen et al., 2020). The abundant presence of $C_5H_7O_7S^-$ in marine aerosols across seasons indicated the rapid oxidation and aging processes of isoprene SOA in marine atmospheres. The high contribution of $C_5H_7O_7S^-$ molecule among isoprene-derived OSs has been reported in marine aerosols, as well as in coastal and inland atmospheres (Hettiyadura et al., 2015; Kanellopoulos et al., 2022; Surratt et al., 2008; Wang et al., 2018, 2022b, 2023b). The IEPOX-OS was one of the dominant OSs compounds during the summer cruise (Fig. 1), which is a typical low-NO oxidation product of isoprene formed via the acid-catalyzed ring opening of isoprene epoxydiols and subsequent nucleophilic addition of inorganic sulfate (Surratt et al., 2010; Lin et al., 2012). The dominance of IEPOX-OS among the biogenic OSs observed here is consistent with previous field observations under low-NO and high-RH conditions (Cooke et al., 2022; Lam et al., 2019; Liao et al., 2015). For the summertime samples, the contribution of IEPOX-OS among isoprene-OSs here is higher than that in a previous study conducted in 2019 over the YBS (Wang et al., 2023b). This could be due to the reduction of NO_x

211 emissions in the North China Plain (Li et al., 2024), resulting in a lower NO condition in 2022 than in 2019. It is also noted

212 that a BEH Amide column and synthesized OSs standards were employed to separate and quantify the C_2-C_3 OSs and isoprene

213 OSs in this study. The HILIC provides better separation and retention for the low-molecular-weight C_2-C_3 OSs and isoprene

214 OSs, reflected by the retention time listed in Table S2. The OSs quantification here was more accurate than our previous study

215 in 2019, in which a reversed-phase column and surrogate standard were used to separate and quantified the low-molecular-

216 weight and highly polar OSs (Wang et al., 2023b). Separation of polar C_2-C_3 OSs and isoprene OSs using the reversed-phase

217 chromatography could result in measurement bias due to the coelution and matrix effects (Hettiyadura et al., 2015; Liang et

218 al., 2025). This could be an additional reason for the different OSs proportions between the two studies. The concentrations of

219 methacrylic acid epoxide (MAE)-OS and isoprene-NOS, usually originated via NO/NO_2 pathway or under high-NO

220 conditions(Worton et al., 2013), were much lower than those of IEPOX-OS and its aged product ($C_5H_7O_7S^-$) in the marine

221 atmospheres (Fig. 1, Table S2).

222 The mass concentration and contribution of monoterpene-derived (nitrooxy-)OSs were lower than those of C_2−C_3 OSs and

223 isoprene-derived OSs over the YBS (Fig. 1, 2). This compound group was dominated by monoterpene NOSs ($C_{10}H_{16}NO_7S^-$),

224 which were formed via the oxidation of monoterpenes in the presence of anthropogenic NO_x (Surratt et al., 2008; Wang et al.,

225 2018). The formation of monoterpene OSs/NOSs in marine atmospheres was driven by the transported continental pollutants.

226 The concentration levels of monoterpene OSs/NOSs over the YBS were generally lower than those observed in continental

227 atmospheres (Fig. 2) (He et al., 2014; Meade et al., 2016; Nguyen et al., 2014; Wang et al., 2020, 2021, 2022b).

228

3.2 Importance of OSs in marine atmospheres

230 The OSs concentrations and mass contribution among marine OA were the highest in summer, followed by those in autumn

231 and spring (Fig. 1, 2). The average OSs concentration was 57.8±38.9, 20.4±19.7, and 13.3±8.3 ng/m³ in summer, autumn, and

232 spring, respectively. During the summer cruise, OSs occupied 1.6%−3.2% (2.5% on average) of the marine OA mass

233 concentrations, which were comparable to those observed in coastal regions and higher than those at the inland sites (Fig. 2).

234 The elevated concentration levels and contributions of biogenic OSs, especially isoprene OSs and C_2−C_3 OSs, in summer were

235 attributed to the increased biogenic VOCs emissions from marine phytoplankton or photochemical reactions in surface

236 microlayer (Conte et al., 2020). The filter-sampling-averaged *Chl-a* concentrations were 0.6−5.3 mg/m³ (n=7, 2.1±1.7 mg/m³

237 on average) during summer, 1.0−2.4 mg/m³ (n=8, 1.7±0.5 mg/m³ on average) during spring and 0.5−2.2 mg/m³ (n=11, 1.4±0.6

238 mg/m³ on average) during autumn. High seawater *Chl-a* conditions (5.3 and 3.6 mg/m³) were observed during the summer

239 cruise. In addition, the air temperature in summer was significantly (p< 0.001) higher than that in other seasons (Fig. S3), and

240 the summertime high temperature favored the sea-to-air transfer process of isoprene. The vital importance of biogenic OSs to

241   OA formation in summer has been highlighted in previous observations at both marine and continental sites (Hettiyadura et

242   al., 2017; Kanellopoulos et al., 2022; Meade et al., 2016; Nguyen et al., 2014; Wang et al., 2020, 2021, 2022b). We cannot

243   exclude the potential influence of terrestrial biogenic VOCs emissions based on the observational evidence. The air masses

244   were dominantly from the open ocean in summer (Fig. S1), indicating limited impacts from the continental outflows. During

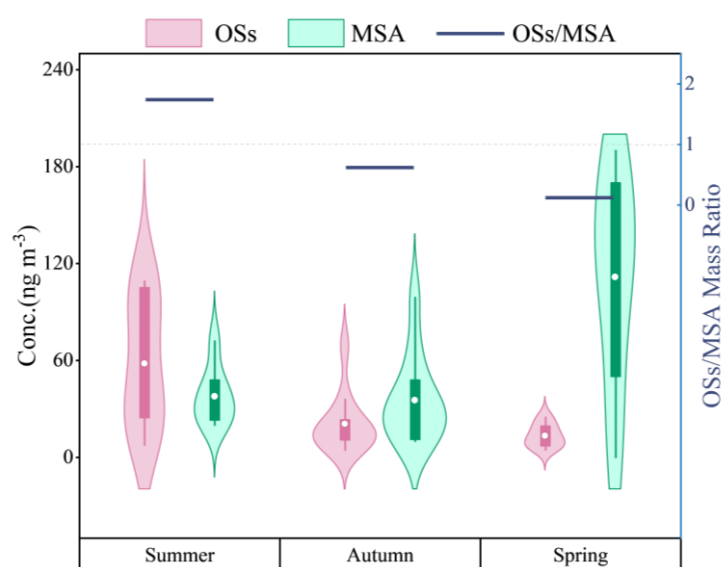
245   spring or autumn, the lower *Chl-a* and air temperature resulted in the decrease of biogenic OSs formation (Fig. 2). Though the

246   seawater *Chl-a* was at similar concentration levels in spring and autumn (Fig. S3), the OSs abundance was lower in spring.

247   The ambient temperature was lower in spring, and the oceanic phytoplankton had not revived from the low temperature

248   conditions throughout winter. Thus, the biological activity and biogenic VOCs production were likely at low levels during the

249   spring cruise.

250


251
252   **Figure 3.** The OSs, MSA concentrations and OSs/MSA mass ratios in atmospheric aerosols over the YBS.

253

254   During summer, the active interactions between biogenic VOCs, especially isoprene, and acidic sulfate converted notable

255   fractions of inorganic sulfate aerosols to OSs in marine atmospheres. The abundance of OSs was comparable to that of MSA

256   in summer, and their mass ratios were higher than those in autumn and spring (Fig. 3). During the summer cruise, the ratio of

257   OSs-S/SO_4^{2-}-S and MSA-S/SO_4^{2-}-S were respectively 0.2%-1.9% (1.1% on average) and 0.9%-2.5% (1.6% on average) in

258   terms of the molar mass of sulfur. Previous studies have suggested that atmospheric MSA formed via the oxidation of DMS

259   contributes to the CCN formation in the marine boundary layer, which is a vital species relevant to the CLAW hypothesis of

260   oceanic phytoplankton-controlled climate regulation (Ayers et al., 1997; Charlson et al., 1987; Quinn and Bates, 2011).

261   Atmospheric OSs could modify the aerosol morphology, suppress the surface tension, and might play roles in altering the

262   cloud formation (Estillore et al., 2016; Riva et al., 2019). The relevance of MSA and OSs in climate regulation and the CLAW

263   hypothesis should be assessed considering their abundance in the atmosphere as well as their distinct physicochemical

264   properties.

265   We noted that the OSs and MSA displayed strong correlations (r = 0.86, p < 0.01) in autumn (Fig. S4). This suggested that the

266   atmospheric OSs and MSA formation were limited by the same environmental factors in autumn, which could be the lower

267   marine biological activities indicated by the seawater *Chl-a* and temperatures (Fig. S3). The increase of marine phytoplankton

268   emissions (e.g., DMS) may drive the formation and elevation of OSs during autumn over the YBS. Atmospheric OSs and MSA

269   did not show an obvious correlation in summer. The seawater *Chl-a* and SST were higher during the summer cruise than during

270   the other cruises (Fig. S3), indicating abundant marine biogenic emissions and sea-to-air exchange processes in summer. We

271   proposed that the marine biogenic emitted precursors (e.g., DMS, isoprene) were abundant and in excess for the MSA and OSs

272   formation in summer. The formation of MSA or OSs might be limited by different atmospheric oxidation or subsequent reaction

273   processes of these precursors, and the environmental conditions driving their formation in summer need further investigation.

274   The cruise observations indicated that organosulfates, besides MSA, should be taken into consideration when studying the

275   sulfur cycle in marine atmospheres. The roles of atmospheric OSs in altering cloud formation need further investigation

276   through shipboard observations, especially over oceanic regions with high phytoplankton biomass and high temperature.

277   **3.3 Seasonal variation of atmospheric OSs composition**

278   For the seasonal variations of OSs composition, the chemical spaces of the autumn and spring samples are highly overlapped,

279   which are different from that of the summer samples (Fig. 4a). The fraction of isoprene-derived (nitrooxy-)OSs was higher

280   during the summer cruise than those observed during the other two seasons. The autumn and spring samples generally showed

281   a higher contribution by monoterpene-derived OSs compounds. The seasonal variation was attributed to the relatively lower

282   isoprene emissions, indicated by the lower seawater *Chl-a* (Fig. S3), and the more severe influence of anthropogenic pollutants

283   transported from the continent in spring and autumn (Fig. S1). In addition to the air mass back trajectories, the more severe

284   impacts of continental outflows in spring and autumn were also indicated by elevated elemental carbon (EC) concentrations

285   (0.5 $\mu gC/m^3$ and 0.4 $\mu gC/m^3$ compared to 0.2 $\mu gC/m^3$ in summer). In marine atmospheres over the YBS, the relative

286   contribution of monoterpene-derived (nitrooxy-)OSs was lower than that in continental atmospheres under more severe

287   impacts of anthropogenic pollutants (Fig. 4a).

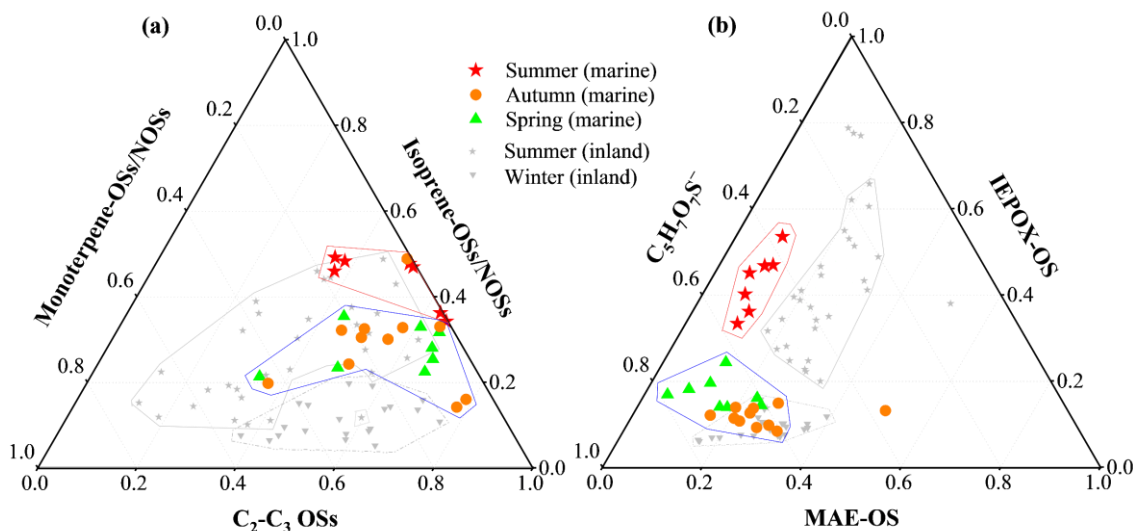
288


Figure 4. (a) Relative abundance of isoprene OSs, monoterpene OSs, and C_2-C_3 OSs, and (b) composition of isoprene OSs over the YBS in summer (red), autumn (orange) and spring (green). The results previously reported at the inland urban site (Wang et al., 2020) are colored gray.

In marine atmospheres over the YBS, different influences of marine emissions versus continental outflows across seasons resulted in the variation of C_2-C_3 OSs/isoprene-OSs mass ratios (Fig. S5). Strong correlations (r=0.79−0.97, p≤0.05) between isoprene-OSs and C_2-C_3 OSs suggested their consistent biogenic sources dominated by isoprene oxidation, which has been reported in previous studies(Schindelka et al., 2013; Surratt et al., 2008; Wang et al., 2020). In summer, the abundance of C_2-C_3 OSs was comparable to that of isoprene OSs. However, during autumn and spring, we observed higher mass ratios of C_2-C_3 OSs versus isoprene-OSs due to the additional sources of C_2-C_3 OSs contributed by anthropogenic sources (Fu, 2008; Huang et al., 2018; Liao et al., 2015).

The chemical space distributions of isoprene OSs also displayed obvious seasonal variations. The fraction of IEPOX-OS among the isoprene-derived OSs was substantially higher, and that of MAE-OS was relatively lower in summer compared with those in spring and autumn (Fig. 4b). The low-NO conditions in summer favored the IEPOX formation from isoprene oxidation via HO_2 pathway, and the formation of MAE via NO/NO_2 pathway increased under the influence of continental pollutants in autumn and spring (Wang et al., 2020; Worton et al., 2013). The average mass ratio of IEPOX-OS/MAE-OS was 4.7 during the summer cruise, much higher than those observed during spring (1.53) or autumn (0.49). The seasonal variations of IEPOX-OS/MAE-OS mass ratios indicated that the isoprene oxidation pathways were dominated by the HO_2 pathway in summer, and the importance of NO/NO_2 pathway elevated during the other seasons over the YBS. During summer, the relative contribution of MAE-OS among isoprene-OSs in marine aerosols over the YBS was lower than those observed in continental atmospheres, indicated by the gray markers in Fig. 4b. This was due to the lower anthropogenic pollutants and NO conditions in marine atmospheres than in continental atmospheres. The proportions of $C_5H_7O_7S^-$, a further oxidation or aged forms of IEPOX-OS(Armstrong et al., 2022; Chen et al., 2020), were also higher in autumn and spring than in summer. The dominant

312   presence of $C_5H_7O_7S^-$ compared to IEPOX-OS indicated a highly oxidized state of marine SOA in spring and autumn.

313   **3.4 Spatial distribution of OSs regulated by continental outflows**

314   As shown in Fig. 5, atmospheric OSs concentrations over the Bohai Sea and the North Yellow Sea (nYBS, 51.3 ± 37.4 ng/m^3)

315   were notably higher than those over the South Yellow Sea (sYS, 16.1 ± 11.9 ng/m^3). Surrounded by the continent, the nYBS

316   region was under more severe impacts of transported anthropogenic pollutants compared with the relatively open sYS. This is

317   also indicated by the variation of EC concentrations in atmospheric aerosols over nYBS and sYS areas (Fig. S6). Marine

318   emissions dominated the biogenic OSs formation over the YBS in summer. However, we cannot exclude the potential influence

319   of transported continental air masses, especially over the nYBS. This could be a reason for the higher OSs concentrations over

320   the nYBS than those over the sYS.

321
322

323   **Figure 5.** Concentration ratios of atmospheric OSs over the nYBS versus those over the sYS. The pie charts show the relative

324   contribution of OSs compound groups over the nYBS and the sYS during each season.

325

326   The concentration levels and compositions of OSs in atmospheric aerosols over the nYBS and the sYS are compared in Fig.

327   5. Among the quantified OSs derived from different VOCs precursors, monoterpene-NOSs displayed the most obvious

328   enhancement ratios over the nYBS compared to those over the sYS (Fig. 5). During the summer cruise, monoterpene-NOSs

329   over the nYBS elevated to nearly two orders of magnitude higher than those over the sYS. The mass contributions of

330   monoterpene-NOSs among the total OSs over nYBS were higher than those over the sYS, as shown in the pie charts of Fig. 5.

331   Monoterpene-NOSs are usually formed via the interactions between anthropogenic NO_x, sulfate, and monoterpenes (Bryant et

332   al., 2021, 2023; Wang et al., 2018). A recent study also suggested monoterpenes could be generated by biomass burning,

besides the biogenic emissions (Wang et al., 2022a). The spatial difference of monoterpene-NOSs further indicated the more severe influence of anthropogenic pollutants over the nYBS.

The OSs abundance displayed the most obvious enhancement over the nYBS in the summer samples, in which the concentrations of C_2-C_3 OSs and isoprene-OSs/NOSs over the nYBS elevated to 2.4 and 3.9 times of those over the sYS. The biogenic emissions from marine phytoplankton were more abundant in summer than in the other seasons. Transported anthropogenic pollutants over the nYBS would promote the formation of biogenic OSs via anthropogenic-biogenic interactions in marine atmospheres. Previous observation has suggested that the formation of biogenic SOA, including isoprene OSs, could be obviously mediated by anthropogenic sulfate and NO_x in regions with substantial anthropogenic-biogenic interactions (Xu et al., 2015). We noted that isoprene-OSs were not observed in remote marine aerosols over the Southern Ocean or the southern Indian Ocean, where the influence of transported anthropogenic pollutants was likely limited (Claeys et al., 2010; Cui et al., 2019). Our results suggested the universal existence of biogenic OSs in marine aerosols over regions with anthropogenic-marine interactions. Further observation evidences are needed to understand the presence of OSs in different marine environments.

3.5 Origins and influence factors of atmospheric OSs

Principal Component Analysis (PCA) was performed using 26 aerosol samples to further understand the sources of atmospheric OSs over the YBS (Fig. 6, Table S3). A total of 18 particulate components, including OSs, water-soluble ions, EC, and MSA, were chosen to carry out the statistics. Three factors could explain 83% of the measurements. Majority of the OSs and NOSs compounds showed high loadings in Factor 1, which explained 52% of the measurements. Characterized by high loadings of nss-sulfate, Cl^-, and low loadings of anthropogenic species (e.g., EC, nss-K^+), Factor 1 represented the sulfate-catalyzed reactions with VOCs dominated by marine emissions. Factor 2 shows high loadings of EC, nss-K^+, and NO_3^-, suggesting the transported anthropogenic origins dominated by combustion emissions, which explained 21% of the measurements (Table S3). Factor 3, dominated by MSA, EC, and sea salts, was a mixed source of marine-anthropogenic interaction, which explained 10% of the variance (Table S3). In this work, each aerosol sample was collected for 10–24 h, and the time-averaged aerosol component concentrations were used for the PCA analysis. The PCA factors reflected the overall variations of the atmospheric OSs sources across seasons over the YBS. The diurnal patterns of atmospheric OSs or their variation during some short-term episodes cannot be captured based on the filter-based analysis in this study. For example, the diurnal variations of marine boundary layer heights or atmospheric oxidation conditions may influence the OSs concentrations or formation pathways. Marine aerosol sampling and analysis with high time resolution are needed to gain insight into the day-night variations of OSs in marine aerosols in the future studies.

362
Figure 6. PCA statistics of the measured OSs and NOSs during the cruise observations. PC1, PC2, and PC3 represent the source of sulfate-catalyzed reactions with biogenic VOCs, transported anthropogenic origin, and a mixed source of marine-anthropogenic interaction, respectively.

366

367 The majority of quantified OSs compounds, especially the isoprene-derived ones (IEPOX-OS, MAE-OS, $C_5H_7O_7S^-$, isoprene-

368 NOS, GAS, and HAS), were dominated by the source of sulfate-catalyzed reactions with biogenic VOCs (Factor 1), as

369 displayed in Fig. 6 and Table S3. The homogeneous origin of C_2–C_3 OSs and isoprene-OSs/NOSs from the oxidation of

370 isoprene has been approved in this work and previous observations(Surratt et al., 2008; Riva et al., 2016). This source factor

371 was more related to the marine emissions, rather than anthropogenic pollutants, indicated by the low loadings of anthropogenic

372 EC or nss-K^+. Isoprene could be largely emitted by phytoplankton and from photochemical processes in surface seawater, and

373 then released into marine atmospheres (Brüggemann et al., 2018; Cui et al., 2023). The reactive uptake of isoprene by sulfate

374 aerosols could be a vital reaction pathway for OSs formation in marine aerosols (Wang et al., 2023b). OSs concentrations

375 elevated with increasing air temperature in summer and increasing wind speed in spring (Fig. 7). Higher temperature or wind

376 speed would promote the sea-to-air exchange of isoprene and favored the OSs formation in marine atmospheres.

377

378
Figure 7. Variations of OSs concentrations as a function of chlorophyll-a (*Chl-a*) in (a) summer, (b) autumn, and (c) spring. The markers are colored by air temperature, EC, and wind speed, respectively.

The loadings of monoterpene-OSs/NOSs in anthropogenic-related sources (Factor 2 and Factor 3) cannot be neglected, which was different from the main source of isoprene OSs from marine-dominated sulfate-biogenic VOCs interaction (Factor 1). Lactic acid sulfate over the YBS showed comparable loadings in the transported anthropogenic origin (Factor 2, 0.70) and the marine-dominated sulfate-biogenic VOCs interaction source (Factor 1, 0.59). The loadings of LAS in the mixed source of marine-anthropogenic interaction (Factor 3) were higher than other identified OSs species (Fig. 6). A relatively high loading of GAS (0.48) was also observed in Factor 2 (Table S3). The PCA result provided observational evidence on the additional sources of monoterpene-OSs/NOSs and C_2-C_3 OSs from transported anthropogenic pollutants over marginal seas. During the autumn cruise, higher OSs concentration levels were observed when higher EC concentrations occurred, which also indicated the additional contribution of OSs by anthropogenic sources (Fig. 7b).

This work quantified and characterized the atmospheric OSs derived from isoprene and monoterpenes over the Asia marginal seas. The chemical nature and distribution of OSs were modified by the joint influence of oceanic biological emissions and transported continental pollutants. The results highlight the abundant formation of airborne OSs in summer, which is promoted by the elevated biogenic VOCs emissions from the surface ocean. During high biological activity periods, atmospheric OSs levels could surpass the MSA concentrations in marine aerosols, which is a vital species in the well-known climate regulation via oceanic phytoplankton sulphur emissions (CLAW hypothesis). In the future studies, isoprene-derived OSs are suggested to be included as the molecular tracers of marine SOA related to phytoplankton emissions, especially during summer or over oceanic regions with high phytoplankton activities and high SST. Shipboard observations over open ocean areas are needed to gain further understanding on the roles of OSs in modifying the sulfur cycle, biogenic VOCs oxidation and regulating climate in marine boundary layer.

Author contribution

Y.W. designed and supervised the research. M.H. supervised and provided the instrumentations. S.L., Y.Z., Y.Y., Y.G., C.Y. and Y.J. conducted the measurements. S.L. analyzed the data. Y.C.W synthesized the standards. S.L. and Y. W. wrote the manuscript with contributions from all co-authors.
