33 **Abstract**

34 Density of seawater is a critical property that controls ocean dynamics. Previous works  
35 suggest the use of the  $\delta^{18}\text{O}$  calcite of foraminifera as a potential proxy for paleodensity.  
36 However, potential quantitative reconstructions were limited to the tropical and subtropical  
37 surface ocean and without an explicit estimate of the uncertainty in calibration model  
38 parameters. We developed the use of the  $\delta^{18}\text{O}_{\text{C}}$  of planktonic foraminifera as a surface  
39 paleodensity proxy using Bayesian regression models calibrated to annual surface density.  
40 Predictive performance of the models improves when we account for inter-species specific  
41 differences.

42 We investigate the additional uncertainties that could be introduced by potential evolution  
43 of the  $\delta^{18}\text{O}_{\text{C}}$ -density relationship with time (from the last glacial maximum (LGM) to the  
44 preindustrial (PI)) through the combination of past isotope enabled climate model  
45 simulations and a foraminiferal growth module. We demonstrate that additional  
46 uncertainties are weak globally, except for the Nordic Seas region.

47 We applied our Bayesian regression model to LGM and Late Holocene (LH)  $\delta^{18}\text{O}_{\text{C}}$   
48 foraminifera databases to reconstruct annual surface density during these periods. We  
49 observe stronger LGM density value changes at low latitudes compared to mid latitudes.  
50 These results will be used to evaluate numerical climate models in their ability to simulate  
51 ocean surface density during the extreme climatic period of the LGM.

52 The new calibration has great potential to reconstruct the past temporal evolution of ocean  
53 surface density over the Quaternary. Under climates outside the Quaternary period and in  
54 ocean basins characterized by anti-estuary circulation, like the current Mediterranean Sea  
55 and Red Sea, our calibration could provide density estimates with larger uncertainty, a point  
56 that requires further investigations.

69      1. Introduction

70      Temperature and salinity control the density of seawater and therefore the ocean dynamics  
71      too. Reconstruction of past ocean surface temperature with reasonable uncertainties is  
72      possible (MARGO, 2009; Tierney et al., 2020b) but reconstructions of past surface salinity  
73      remain very challenging in paleoceanography. When the current uncertainties on past  
74      temperature and salinity reconstructions are cumulated, it becomes unreasonable to  
75      combine these two parameters in order to quantify past ocean density and dynamics  
76      (Schmidt, 1999).

77      Rather than using the combination of temperature and salinity, previous works suggest the  
78      use of the  $\delta^{18}\text{O}$  of foraminiferal calcite as a potential proxy for paleodensity (Lynch-Stieglitz  
79      et al., 1999; Billups and Schrag, 2000, LeGrande et al., 2004; Lynch-Stieglitz et al., 2007). The  
80      oxygen isotopic composition of foraminifera calcite is controlled by 1) the temperature  
81      dependence of the equilibrium fractionation during calcite precipitation and 2) the isotopic  
82      composition of seawater in which the shell grows (Urey, 1947; Shackleton, 1974). Except in  
83      areas of sea ice formation or melt, the isotopic composition of seawater ( $\delta^{18}\text{O}_{\text{sw}}$ ) is regionally  
84      related to salinity, since they are affected by processes such as evaporation, precipitation,  
85      and the water masses advection and mixing (Craig and Gordon, 1965). Therefore, both  
86      temperature and  $\delta^{18}\text{O}_{\text{sw}}$  changes that affect the foraminifera  $\delta^{18}\text{O}$  calcite ( $\delta^{18}\text{O}_{\text{c}}$ ) signal are  
87      also the processes that ultimately define the seawater density in which the foraminifera  
88      calcifies (Lynch-Stieglitz, 1999; Billups and Schrag, 2000).

89      In addition to temperature and  $\delta^{18}\text{O}_{\text{sw}}$ , the shell  $\delta^{18}\text{O}_{\text{c}}$  signal can also be potentially  
90      influenced by biological processes, such as: 1) photosynthesis in algal symbionts (Duplessy et  
91      al., 1970; Ravelo and Fairbanks, 1992; Spero and Lea, 1993; Spero et al., 1997) and biases  
92      due to the formation of gametogenic or ontogenetic calcite (Williams et al., 1979; Spero and  
93      Lea, 1996; Hamilton et al., 2008), 2) changes in pH and carbonate ion concentration [ $\text{CO}^{2-}_3$ ]  
94      (Spero et al., 1997; Bijma et al., 1999; Zeebe, 1999), 3) dissolution and recrystallization for  
95      shells deposited in bottom waters undersaturated in [ $\text{CO}^{2-}_3$ ] (Schrag et al., 1995), and 4)  
96      bioturbation (Waelbroeck et al., 2005). **The four processes mentioned above have not been**  
97      **clearly demonstrated. In addition, the carbonate ion effect has been shown to have no**  
98      **detectable influence (Köhler and Mulitza, 2024)** and core top data have been selected to  
99      limit the bioturbation effect (Waelbroeck et al., 2005). Therefore, we do not account for

100     these processes. Transport of foraminifera shells by currents is another process that could  
101     lead to discrepancies between recorded  $\delta^{18}\text{O}_{\text{c}}$  and calculated  $\delta^{18}\text{O}_{\text{c}}$  or hydrographic data.

102     However, this effect is likely minimal because the ambient water mass is transported  
103     together with the shells. Later in this study (Sect. 3.1.2), we confirm that planktonic  
104     foraminifera  $\delta^{18}\text{O}_{\text{c}}$  is mainly related to the surface ocean density, growth season and habitat  
105     depth, with weak additional influence from biological processes.

106     Previously, Billups and Schrag (2000) used  $\delta^{18}\text{O}_{\text{c}}$  from the mixed layer planktonic  
107     foraminifera (*Globigerinoides ruber* and *Trilobatus sacculifer*) as a proxy of surface water  
108     density. They limited their study to the tropical and subtropical surface ocean.

109 In this study we investigate the use of planktonic foraminifera  $\delta^{18}\text{O}_{\text{C}}$  as a surface  
110 paleodensity proxy for the whole ocean, from low to high latitudes, using various  
111 foraminifera species: *Globigerinoides ruber* (*G. ruber*), *Trilobatus sacculifer* (*T. sacculifer*),  
112 *Globigerina bulloides* (*G. bulloides*), *Neogloboquadrina incompta* (*N. incompta*), and  
113 *Neogloboquadrina pachyderma* (*N. pachyderma*). Compared to Billups and Schrag (2000), we  
114 use extended late Holocene (LH) and last glacial maximum (LGM)  $\delta^{18}\text{O}_{\text{C}}$  databases  
115 (Malevitch et al., 2019; Caley et al., 2014, Waelbroeck et al., 2014; Tierney et al., 2020b). We  
116 develop mean annual surface density calibration models using a Bayesian approach. We also  
117 use numerical climate simulations obtained with isotope enabled climate models  
118 (iLOVECLIM and ECHAM5/MPI-OM) and a foraminiferal growth module (FAME) (Roche et al.,  
119 2018) to investigate the specific seasonal dynamic and depth habitat preference of  
120 foraminifera (Roche et al., 2018; Schiebel and Hemleben 2018). We discuss the applicability  
121 and validity of the foraminifera  $\delta^{18}\text{O}_{\text{C}}$  to the past quantification of surface ocean density. We  
122 then reconstruct past surface density changes during the LGM.

123

## 124 2. Methods

### 125 2.1 Planktonic foraminifera $\delta^{18}\text{O}$ databases

126 We compiled global foraminifera oxygen isotopic datasets from published LH and LGM  
127 measurements to allow reconstruction of past density. We used core-top and LH records of  
128 planktonic foraminifera  $\delta^{18}\text{O}_{\text{C}}$  from Malevitch et al. 2019 dataset that include records from  
129 the Multiproxy Approach for the Reconstruction of the Glacial Ocean (MARGO) (Waelbroeck  
130 et al., 2005) with additional sources. This dataset consists of 2,636 observations with 1,002  
131 for *G. ruber*, 635 for *G. bulloides*, 442 for *T. sacculifer*, 132 for *N. incompta* and 425 for *N.*  
132 *pachyderma* (Malevitch et al., 2019). Similarly to Malevitch et al. 2019, we gridded the core-  
133 top data to reduce the impact of spatial clustering by averaging samples for each species to  
134 the nearest  $1^{\circ}\text{X } 1^{\circ}$  grid point. So doing, we obtained a total of 1,415 grid points.

135 For the LGM time period, records derived in part from the MARGO collection (Waelbroeck et  
136 al., 2014), with additional data from Caley et al., 2014, Tierney et al., 2020b, and from more  
137 recent studies (34 measurements). The final dataset consists of 474 observations.  
138 Chronostratigraphic quality for the LGM and LH is consistent between all the published  
139 databases, the additional observations and use the same MARGO definition (MARGO, 2009).

### 140 2.2 Ocean dataset

141 In order to establish and test our calibrations between foraminifera  $\delta^{18}\text{O}_{\text{C}}$  and observed  
142 surface density, we used different ocean datasets. We used the Multi Observation Global  
143 Ocean Sea Surface density product for our core-top and Late Holocene calibration models  
144 (Droghei et al., 2016; 2018). This means that we calibrated Late Holocene core-top samples  
145 against observed density fields influenced by anthropogenic climate change, an issue that  
146 affects all core-top calibrations. To test the residual of our models against sea surface  
147 temperature and salinity (SST and SSS respectively) we used WOA18 products (Locarnini et  
148 al., 2018; Zweng et al., 2018).

149

## 150 2.3 Bayesian calibration models and evaluation

151

152 Following the general approach of Malevich et al. (2019), we use Bayesian regressions to  
 153 model the relationship between the calcite oxygen isotopic composition of planktonic  
 154 foraminifera,  $\delta^{18}\text{O}_c$  (‰ VPDB), and annual mean surface density,  $\rho$  (kg/m<sup>3</sup> relative to the  
 155 water density of 1000 kg/m<sup>3</sup>). By explicitly estimating uncertainty in the calibration model  
 156 parameters, each model produces a full posterior predictive distribution for the predictant  $\rho$ .  
 157 We implement three Bayesian models—two pooling models with first- and second-degree  
 158 polynomials, and a hierarchical first-degree polynomial model—using Markov chain Monte  
 159 Carlo (MCMC) methods (see Kruschke, 2014; McElreath, 2018 for review).

## 160 2.3.1 Three Bayesian calibration models

## 161 1. First-Degree Polynomial (Pooled), poly1\_pool:

162 A simple linear regression is fit to all foraminifera species combined:

$$166 \rho \sim N(\mu, \sigma^2), \quad \mu = \beta_0 + \beta_1 \delta^{18}\text{O}_c.$$

163 Weakly informative data-adaptive normal hyperpriors are used for  $\beta_0$  and  $\beta_1$ , and an  
 164 exponential prior for the noise term sigma. This pooled model assumes a common  
 165 relationship across all foraminifera species (see Appendix).

## 167 2. Second-Degree Polynomial (Pooled), poly2\_pool:

168 Motivated by empirical evidence (e.g., Billups and Schrag (2000)), the second model  
 169 incorporates a quadratic term:

$$172 \rho \sim N(\mu, \sigma^2), \quad \mu = \beta_0 + \beta_1 \delta^{18}\text{O}_c + \beta_2 (\delta^{18}\text{O}_c)^2.$$

170 Again, we apply weakly informative normal priors for the  $\beta_i$  parameters, ensuring  
 171 flexibility while constraining the plausible range based on the observed data.

## 173 3. First-Degree Polynomial (Hierarchical), poly1\_hier:

174 The third model recognizes that species-specific differences in calcification, depth,  
 175 seasonality and vital effects can affect  $\delta^{18}\text{O}_c$  (Malevich et al., 2019). Hence, we use a  
 176 hierarchical structure:

$$177 \rho \sim N(\mu_s, \sigma_s^2), \quad \mu_s = \beta_{s,0} + \beta_{s,1} \delta^{18}\text{O}_c.$$

178 where each species  $s$  has its own intercept ( $\beta_{s,0}$ ) and slope ( $\beta_{s,1}$ ). These species-level  
 179 parameters are drawn from common hyperdistributions  $\nu_i$  and  $\kappa_i$  (Appendix A),  
 ensuring partial pooling of information across species.

## 181 2.3.2 Model fitting and evaluation

182

183 All models were fitted with six independent MCMC chains of 4000 iterations each, discarding  
 184 the first 2000 as burn-in. We used rank-normalized  $\hat{R}$  (Vehtari et al. 2021) to assess  
 185 convergence, finding all values below 1.05. Prior and posterior predictive checks confirmed  
 186 the adequacy of the models. To compare predictive performance, we computed the  
 187 expected log pointwise predictive density (ELPD) via Pareto-smoothed importance sampling  
 188 leave-one-out cross-validation (LOO) (Vehtari et al., 2017), which provides a principled basis  
 189 for selecting the model that best characterizes the relationship between  $\delta^{18}\text{O}_c$  and  $\rho$ . The

190 ELPD measures the expected predictive accuracy of a Bayesian model. It is defined as the  
191 sum over all data points of the expected log posterior predictive density (Gelman et al.,  
192 2014). In our case, a higher ELPD means the model makes sharper and more accurate  
193 density predictions.

194

195 2.4 Isotope enabled numerical climate models

196 2.4.1 The iLOVECLIM model

197 The iLOVECLIM (version 1.1.3) **earth system model of intermediate-complexity** is a derivative  
198 of the LOVECLIM-1.2 climate model extensively described in Goosse et al. (2010). From the  
199 original model, we retain the atmospheric (ECBilt, resolution of 5.6° in latitude and  
200 longitude), oceanic (CLIO, 3x3° horizontal resolution, 20 vertical layers and a free surface),  
201 vegetation (VECODE) and land surface (LBM) components and develop a complete,  
202 conservative, water isotope cycle through all cited components. A detailed description of the  
203 method used to compute the oxygen isotopes in iLOVECLIM can be found in Roche (2013)  
204 and the validation of model results can be found in Roche and Caley (2013), Caley and Roche  
205 (2013) and Extier et al., 2024.

206 We use the boundary conditions defined in/by the PMIP2 protocol to simulate the annual  
207 LGM climate (Caley et al., 2014). Details about the model simulations (LGM and pre-  
208 industrial (PI)) and validation of results for oxygen stable isotopes and temperature can be  
209 found in Caley et al. 2014.

210 2.4.2 The ECHAM5/MPI-OM model

211 We also use the ECHAM5/MPI-OM **coupled General Circulation Model (GCM)**, also  
212 previously named community Earth system model COSMOS. It is a fully coupled ocean–  
213 atmosphere–sea ice– land surface model (Jungclaus et al., 2006) with stable water isotope  
214 diagnostics in all relevant model components. Mass, energy, and momentum fluxes, as well  
215 as the related isotope masses of H<sub>2</sub>18O and HDO, are exchanged between the atmosphere  
216 and ocean once per day. Further details about the model can be found in Werner et al.,  
217 2016.

218 We used monthly outputs of the two simulations performed for the PI and for the LGM  
219 climate as described and evaluated for oxygen stable isotopes in Werner et al., 2016.

220

221 2.5 The FAME module

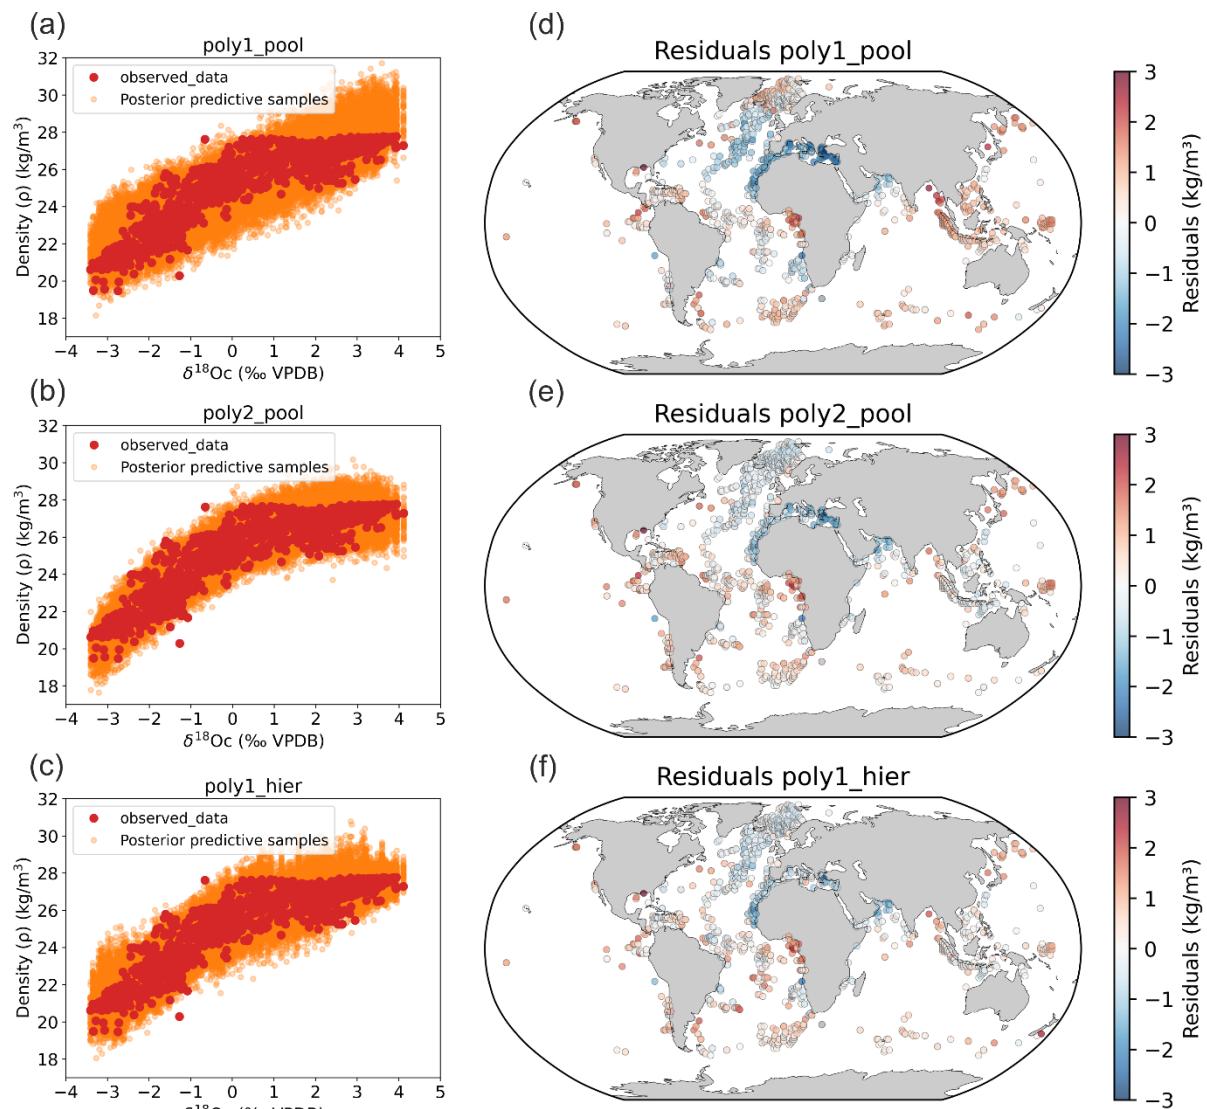

222 Foraminifera as Modelled Entities (FAME; Roche et al., 2018) is a foraminiferal growth  
223 module that tackles the dynamic seasonal and depth habitat of planktonic foraminifera. The  
224 module predicts the presence or absence of commonly used planktonic foraminifera and  
225 their  $\delta^{18}\text{O}$  values. It uses a very limited number of parameters, almost all derived from  
226 culture experiments (Lombard et al., 2009).

227

## 228 3. Results and discussion

229 3.1 Ocean surface density from planktonic foraminifera calcite  $\delta^{18}\text{O}$ 230 The three Bayesian calibration models reasonably replicate core top data spread when we  
231 predict surface density (Fig. 1).

232

233

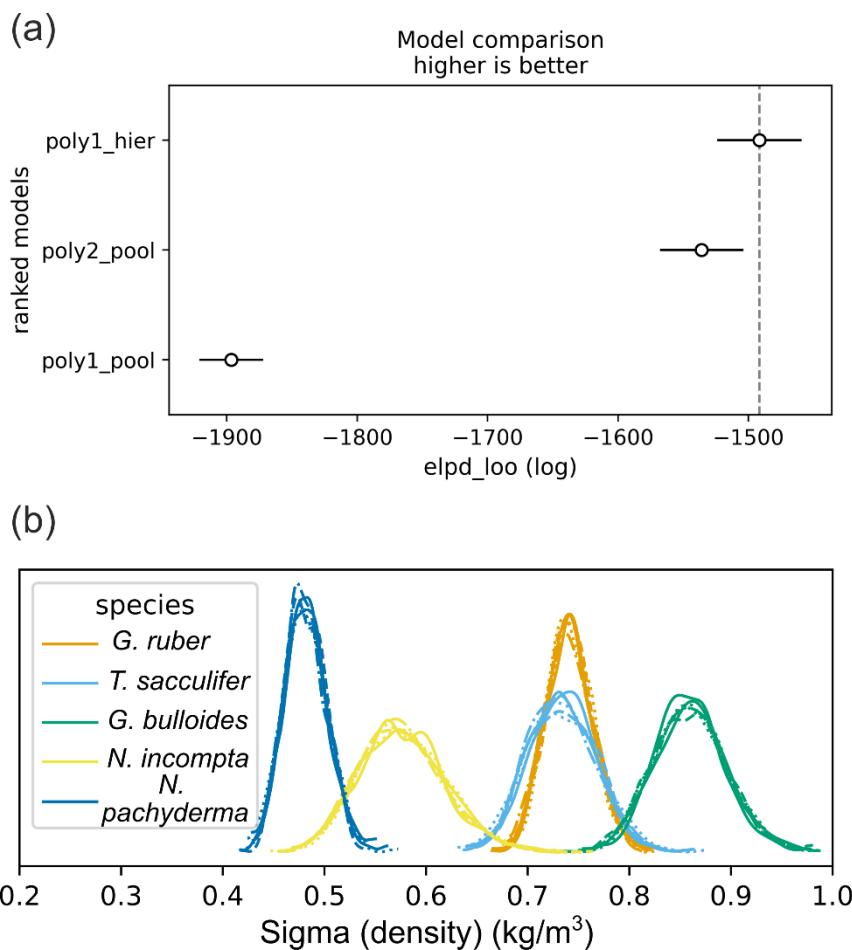

234 Figure 1: Bayesian calibration models for late Holocene core-top samples against observed  
235 density. (a), (b) and (c) The three Bayesian regression models between foraminifera  $\delta^{18}\text{O}$   
236 and annual surface density and (d), (e) and (f) associated density residuals (predicted -  
237 observed).

238 Compared to the Billups and Schrag (2000) study which was restricted to the 21-26 density  
239 range in tropical and subtropical regions, our models provide estimates of the density  
240 changes over the whole density range from 19 to 28 (Fig. 1). In our new calibrations, we also  
241 explicitly estimate the uncertainty in calibration model parameters (Fig. 1) using a Bayesian  
242 approach to calculate robust confidence intervals.

243 We observe a saturation of density values close to 28 in the calibrations that correspond to  
 244 high latitudes regions (Nordic Seas and Austral Ocean). When density is already high,  
 245 temperature changes have a smaller effect. Cold water is already dense, so cooling it further  
 246 doesn't increase density as much. Consequently, we observe a sensitivity decrease. The rate  
 247 of change of density with respect to temperature flattens out, meaning that the system  
 248 becomes less responsive to temperature changes. Small changes in temperature and salinity  
 249 no longer cause significant shifts in density. This behavior reflects to the non-linearity of the  
 250 seawater equation of state. Although the regression becomes less predictive in this range,  
 251 the estimated density values remain correct and are not expected to change strongly as  
 252 ocean surface density approaches its upper limits.

253 3.1.1 Model comparison and residuals

254 Looking at the density residual (predicted - observed) for the three models, the first model  
 255 (linear pools) has the highest values of residual and the third model (hierarchical design)  
 256 performs best (Fig. 1). The second model performs clearly better than the first one but less  
 257 than the hierarchical design. This is supported by model evaluation using log pointwise  
 258 predictive density (ELPD) (Vehtari et al., 2017) (Fig. 2). Predictive performance of the model  
 259 improves when we account for species-specific differences and species-specific prediction  
 260 uncertainty (sigma) in surface density predictions vary between foraminifera species (Fig. 2).

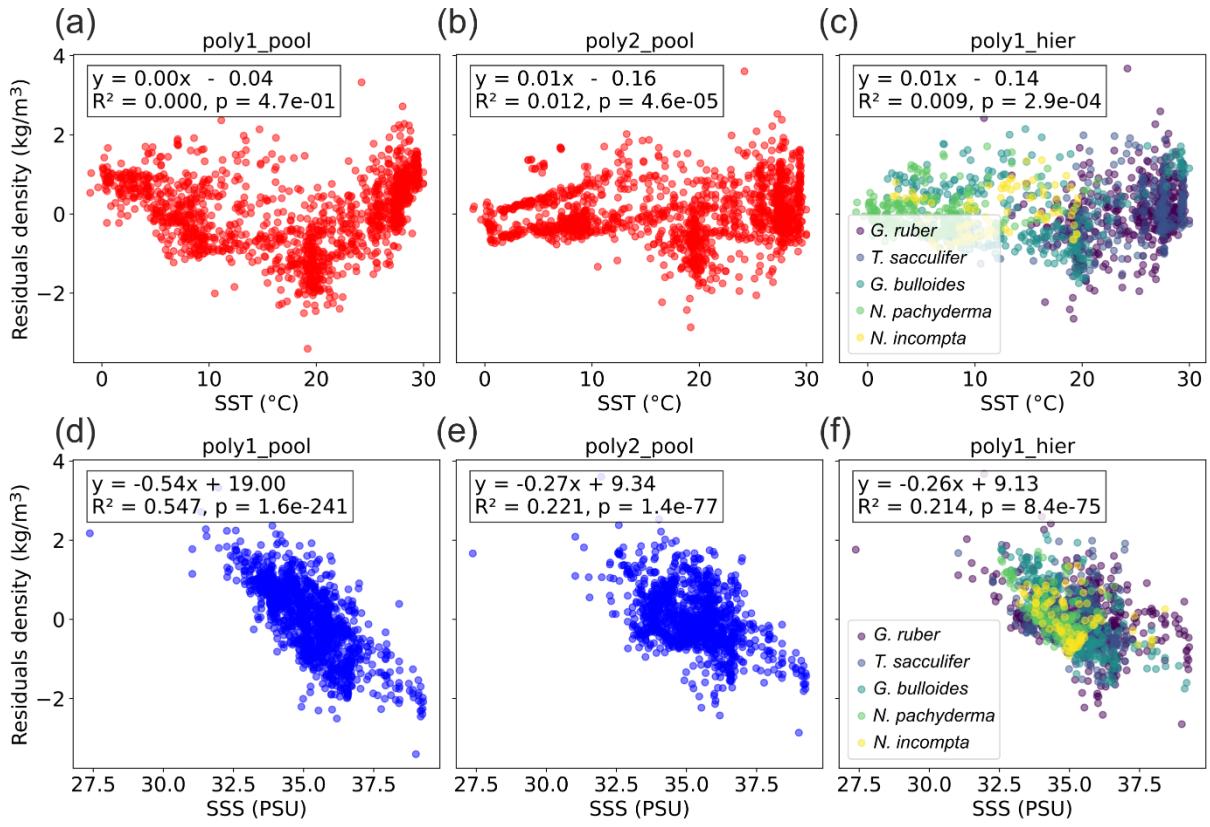

277 Figure 2: Model comparison and prediction uncertainty across species. (a) Expected log  
278 pointwise predictive density (ELPD) for the three models; higher values indicate better  
279 predictive performance. (b) Posterior distributions of the prediction-error parameter (sigma  
280 density) from the hierarchical model for each foraminifera species (six MCMC chains shown).  
281 Among these, *N. pachyderma* exhibits the lowest uncertainty, while *G. bulloides* shows the  
282 highest.

283

284 We still observe residuals with the hierarchical model (Fig. 1), so we checked their relation to  
285 SST and SSS (Fig. 3). The residuals of the pooled linear annual calibration model exhibit a  
286 relationship with SST and a linear relationship with SSS with a relatively high correlation ( $R^2 =$   
287 0.55, p-value <0.05). In contrast, the residuals of the hierarchical annual calibration model  
288 show no correlation to SST ( $R^2 = 0$ , p-value <0.05) and only a very weak correlation with SSS  
289 ( $R^2 = 0.21$ , p-value <0.05). This suggests that factors other than SST and SSS influence the  
290 remaining residual structures, and some may be indirectly associated with SSS gradients.  
291 Indeed, ecological factors (e.g. seasonality and habitat depth) and secondary environmental  
292 parameters (e.g. nutrients and light penetration) may also contribute. This is supported by  
293 the fact that the residual of individual species (Fig. 3) show various significant relations (p-  
294 value <0.05) with SSS, with  $R^2$  values of 0.17 for *G. ruber*, 0.12 for *T. sacculifer*, 0.54 for *G.*  
295 *bulloides*, 0.15 for *N. incompta*, and 0.32 for *N. pachyderma*. For example, negative residuals  
296 are observed in the Benguela, Canary, Peru and North Arabian regions (Fig. 1). All these  
297 coastal areas correspond to upwelling systems and previous work already suggested that  
298 foraminifera species could have a preference for nutrient-rich waters with high turbidity.  
299 This is particularly true for the seasonal specie *G. bulloides* (Peeters et al., 2002; Gibson et  
300 al., 2016). The  $\delta^{18}\text{O}$  may therefore be biased toward colder temperatures even when  
301 accounting for seasonality and species-specific sensitivity (Malevich et al., 2019). This could  
302 explain why all three models yield lower densities than the observed annual mean densities  
303 in the upwelling zones. The negative density residuals in these upwelling regions may reflect  
304 this habitat preference (Fig. 1).

305

306

307 Figure 3: Relation between density residuals (predicted - observed) and (a), (b) and (c) for  
 308 SST and (d), (e) and (f) for SSS (WOA18 products, Locarnini et al., 2018; Zweng et al., 2018)  
 309 for the three Bayesian regression models.  $R^2$  and p-values are indicated.

310 Strong negative residuals are also observed in the eastern part of the Mediterranean Sea.  
 311 Malevich et al. 2019 reported reduced performance of their hierarchical seasonal calibration  
 312 model for  $\delta^{18}\text{O}_{\text{C}}$  and SST in this region and attributed it to the unusual behavior of *G.*  
 313 *ruber*, potentially linked to depth-habitat migration. But estimation of seasonality for this  
 314 region could also be problematic and play a role as highlighted in the study of Ayache et al.  
 315 2024. Alternatively, biases in Mediterranean net freshwater fluxes and thermohaline  
 316 circulation could affect late Holocene  $\delta^{18}\text{O}_{\text{C}}$  values (Ayache et al., 2014). Future modelling  
 317 developments, such as the use of high-resolution regional model in combination with the  
 318 FAME module, could help to better understand the relation between  $\delta^{18}\text{O}_{\text{C}}$ , density,  
 319 temperature and  $\delta^{18}\text{O}_{\text{sw}}$  during past climate changes in the Mediterranean Sea.

320 We also observe high positive residual values in the Equatorial and South Atlantic Ocean, in  
 321 particular on the equatorial African margin and to a lesser degree in the Equatorial East  
 322 Pacific Ocean. As discussed later (Sect. 3.1.2), these positive density residuals could be  
 323 related to ecological factors such as seasonality.

324 It is possible to take into account seasonality based on an estimation of foraminiferal  
 325 seasonal abundance (Malevich et al. 2019), or using the FAME module. This module predicts  
 326 the mean  $\delta^{18}\text{O}_{\text{C}}$  of a foraminifera sample constituted of a number of individuals by weighting  
 327 in space (depth in the water column) and time (months) the oceanic conditions by the  
 328 growth rate of each individual.

329 We decided to not directly develop seasonal calibration models for several reasons. First, we  
330 want to predict annual surface density to be able to compare and evaluate numerical  
331 climate models against annual surface density. Second, including seasonal signals in  
332 foraminifera in our Bayesian models using sediment trap data (Malevich et al. 2019) or  
333 seasonality and habitat depth using FAME (that uses the temperature dependence of growth  
334 derived from culture experiments (Lombard et al., 2009)) would be a simplification that does  
335 not consider factors such as light and nutrient availability. Third, even if it could potentially  
336 improve the models for the present day calibration, although a hierarchical seasonal model  
337 does not necessary show an increase in validation performance compared to the hierarchical  
338 annual model (Malevich et al., 2019), this approach assumes that seasonality or habitat  
339 depth would not change during past periods. Results using FAME demonstrate that  
340 seasonality or habitat depth change during past periods (Roche et al., 2018). Therefore,  
341 changes in seasonality and habitat depth could introduce additional uncertainties when  
342 using a seasonal calibration model to predict past seasonal surface density. One possibility  
343 would be to use simulation results for past periods to force the FAME module and create  
344 past Bayesian calibration models between  $\delta^{18}\text{Oc}$  and surface density that would take into  
345 account ecological changes. However this would not be independent of climate models and  
346 would lead to circular reasoning if the purpose is to use reconstructed density for  
347 comparison and evaluation of past climate simulations.

348 We therefore adopt a different strategy. We use past isotope enable climate model  
349 simulations for the pre-industrial (PI) and LGM periods to force the FAME module in order to  
350 test within the “model world” if a PI Bayesian calibration (hierarchical design) between the  
351  $\delta^{18}\text{Oc}$  and annual surface ocean density is stable with time and if the changes in foraminifera  
352 growth season and habitat depth lead to additional uncertainties when applying a PI relation  
353 to past annual predictions (LGM).

354

### 355 3.1.2 Testing the stability of the $\delta^{18}\text{Oc}$ -density relation during past periods

356 Because the proposed approach to reconstruct ocean surface density uses the temperature  
357 and  $\delta^{18}\text{Osw}$  influence on the  $\delta^{18}\text{Oc}$  signal, we investigated the potential evolution of the  
358  $\delta^{18}\text{Oc}$ -density relationship with time before applying this approach to past density  
359 reconstructions. In particular, we investigated two questions: does the present day  $\delta^{18}\text{Osw}$ -  
360 salinity relationship and its known past temporal evolution (Rohling, 2000, LeGrande and  
361 Schmidt, 2011, Caley and Roche, 2015) significantly affect the density- $\delta^{18}\text{Oc}$  relation  
362 evolution? Do ecological changes (foraminifera growth season and habitat depth)  
363 significantly affect the density- $\delta^{18}\text{Oc}$  relation evolution?

364 We use numerical climate simulations (LGM and PI) of two isotope enabled numerical  
365 climate models, iLOVECLIM and ECHAM5/MPI-OM, to address these questions. We calculate  
366 the  $\delta^{18}\text{Oc}$  signal based on the simulated  $\delta^{18}\text{Osw}$  and ocean temperature for both PI and LGM  
367 using the quadratic approximation of Kim and O’Neil (1997) given in Bemis et al. (1998). We  
368 use the FAME module to predict the  $\delta^{18}\text{Oc}$  values and account for foraminifera specific living  
369 habitats in the water column and along the year as described in Roche et al. (2018). A

370 comparison of the simulated and observed core-top data  $\delta^{18}\text{Oc}$  (Fig. 4) shows high  
 371 correlation ( $R^2$  of 0.93 and 0.89 for ECHAM5/MPI-OM and iLOVECLIM respectively). The  
 372 slightly higher correlation with ECHAM5/MPI-OM and associated lower root mean square  
 373 error (RMSE) (Fig. 4) could be related to differences in climate models but also to the fact  
 374 that in the chosen configuration iLOVECLIM generated only annual  $\delta^{18}\text{O}_{\text{sw}}$  and ocean  
 375 temperature hydrographic data contrary to ECHAM5/MPI-OM that produces monthly  
 376 results. Therefore, the seasonality effect is only simulated by combining FAME and  
 377 ECHAM5/MPI-OM whereas the habitat depth effect is simulated in both experiments.

378 We tested this hypothesis by using yearly ECHAM5/MPI-OM values to compute the  $\delta^{18}\text{Oc}$   
 379 and compared the results with those obtained with seasonal values (shown in Figure 4a) and  
 380 better assess the effect of seasonality. Results indicate a slight decrease of the  $R^2$  of 0.02 and  
 381 a slight increase in RMSE of 0.06 when seasonality is not taken into account. These  
 382 differences are significant according to paired t-tests. Therefore, seasonality partly explains  
 383 the small difference between the results using ECHAM5/MPI-OM and iLOVECLIM. Lower  
 384 resolution of iLOVECLIM or other missing/biased processes in this model could also  
 385 contribute to this small difference.

386 Although climate models are not perfect, the observed high correlations demonstrate that 1)  
 387 these numerical climate models can be used to address our questions regarding the stability  
 388 of the  $\delta^{18}\text{Oc}$ -density relation during the past and 2) our hypothesis that planktonic  
 389 foraminifera  $\delta^{18}\text{Oc}$  is mainly related to the surface ocean density, growth season and habitat  
 390 depth, with weak additional influence by biological processes (Sect. 1.) is valid.

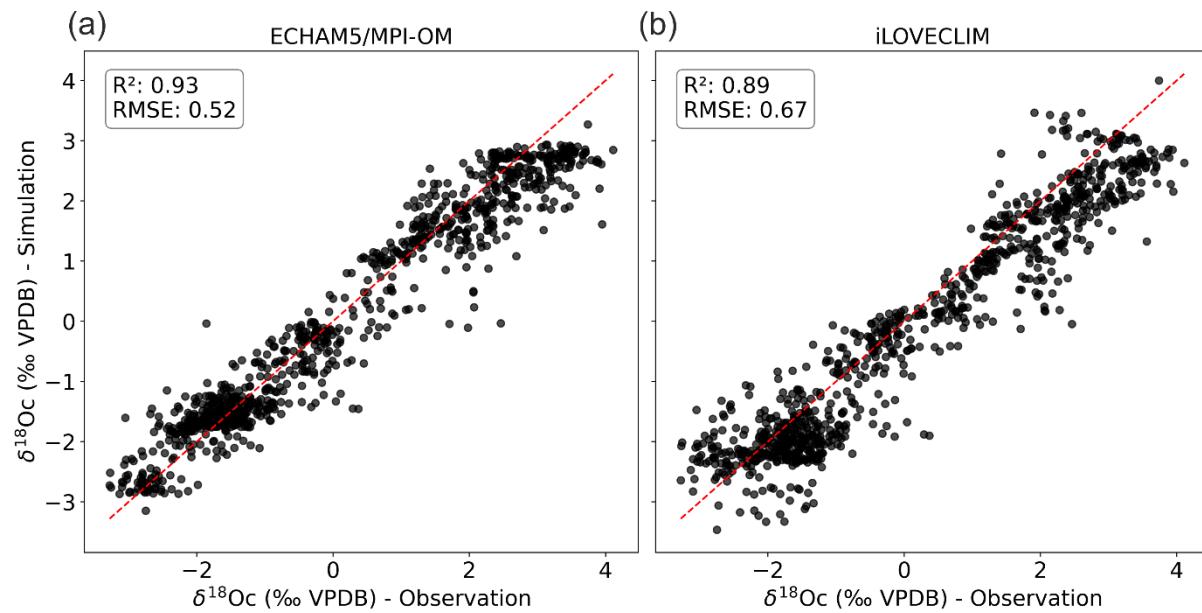

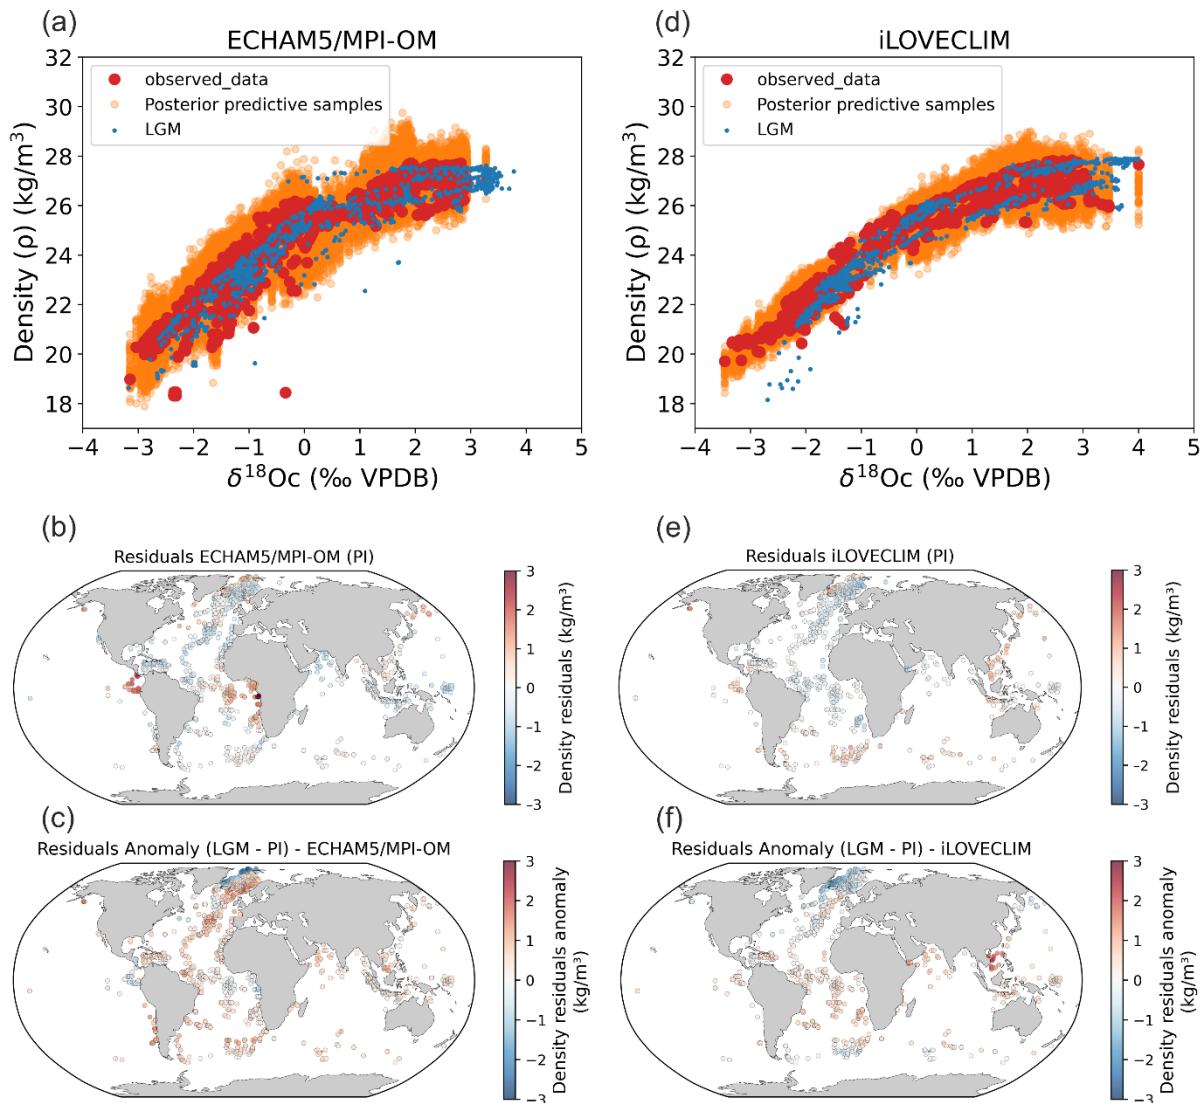

Figure 4: comparison between simulated PI foraminifera  $\delta^{18}\text{Oc}$  (FAME module forced with  
 (a) ECHAM5/MPI-OM and (b) iLOVECLIM climate model hydrographic data) and observed LH  
 core-top  $\delta^{18}\text{Oc}$  data. The 1:1 line is indicated.

We developed two PI Bayesian calibrations (hierarchical design) between the  $\delta^{18}\text{Oc}$  and  
 annual surface ocean density based on FAME forced by ECHAM5/MPI-OM and iLOVECLIM  
 hydrographic data (Fig. 5a). These Bayesian calibration models are comparable to the

407 poly1\_hier Bayesian calibration model of Fig. 1. We then used the LGM simulations to force  
408 FAME and produce  $\delta^{18}\text{Oc}$  LGM values comparable to those that could be measured in a  
409 marine sediment core (but in the model world). We can use these  $\delta^{18}\text{Oc}$  LGM values and the  
410 PI Bayesian calibrations to predict the ocean surface density at the LGM. We can then  
411 compare the density reconstructed from the  $\delta^{18}\text{Oc}$  values to the density simulated directly at  
412 the LGM by ECHAM5/MPI-OM and iLOVECLIM. This furnish a test in the model world  
413 regarding the stability of the  $\delta^{18}\text{Oc}$ -density relation during the past.

414 Interestingly, the observed (Fig. 1) and simulated (Fig. 5b [and e](#)) density residuals (predicted  
415 - observed) are overall in good agreement for both PI ECHAM5/MPI-OM and iLOVECLIM  
416 experiments in terms of qualitative changes (positive or negative residuals) (Fig. 5b [and e](#)  
417 and Fig. 1). Nonetheless, differences for some regions in terms of magnitude of the residual  
418 values exist between ECHAM5/MPI-OM and iLOVECLIM experiments. We observe high  
419 positive residuals in the Equatorial and South Atlantic Ocean in the ECHAM5/MPI-OM  
420 experiment, in particular on the equatorial African margin and in the Equatorial East Pacific  
421 Ocean. As discussed before (Sect. 3.1.1), these positive density residuals are also visible in  
422 the observations (Fig. 1f). We attribute these high positive residuals in ECHAM5/MPI-OM  
423 (Fig. 5b) that better fit the observations (Fig. 1f) to a seasonality effect because seasonality is  
424 only taken into account in ECHAM5/MPI-OM experiment. Negative residuals previously  
425 discussed in upwelling regions are visible in simulated residuals but with lower magnitude in  
426 comparison to observations (Fig. 1f and 5b [and e](#)). This could be related to the fact that  
427 upwellings are not well simulated in the two experiments or to the role of secondary  
428 environmental parameters such as nutrients and light penetration.

429 We apply the PI annual Bayesian calibration to the simulated LGM  $\delta^{18}\text{Oc}$  after a correction of  
430 1.0‰ of LGM  $\delta^{18}\text{Osw}$  values (value added at LGM for the ECHAM5/MPI-OM and iLOVECLIM  
431 experiments, Caley et al., 2014, Werner et al., 2016) to account to a change of the global  
432 oceanic  $\delta^{18}\text{Osw}$  signal due to the increased LGM ice sheets. This yields a prediction of the  
433 LGM surface ocean density that we can compare to the directly simulated LGM surface  
434 density in both experiments. We calculate the density residual at the LGM (density  
435 reconstructed from the  $\delta^{18}\text{Oc}$  values - density simulated directly at the LGM). Finally, we  
436 calculate the density residuals anomaly between LGM and PI as: density residuals at LGM -  
437 density residuals at PI (Fig. 5c [and f](#)). This allows us to investigate the additional uncertainties  
438 linked to the evolution of the density- $\delta^{18}\text{Oc}$  relation (Fig. 5c [and f](#)).

439

440 Figure 5: Stability of foraminifera  $\delta^{18}\text{Oc}$ -density relations between PI and the LGM calculated  
441 with FAME and forced by global ECHAM5/MPI-OM (left panels, Werner et al., 2016) and  
442 iLOVECLIM (right panels, Caley et al., 2014) hydrographic data. (a) and (d) PI Bayesian  
443 regression models between foraminifera  $\delta^{18}\text{Oc}$  and annual surface density. Data in the PI  
444 experiments have been selected at the same locations as observations (Fig. 1). Posterior  
445 predictive samples and the LGM  $\delta^{18}\text{Oc}$ -density relation (LGM) are visible. (b) and (e) Density  
446 residuals (predicted - observed) for the PI experiments. (c) and (f) Density residuals anomaly  
447 between LGM and PI. Results for the Mediterranean Sea have been excluded because of its  
448 difficulty to be simulated and inconsistency between the two model simulations because of  
449 their different grid resolutions. Annual mean temperature and  $\delta^{18}\text{O}_{\text{sw}}$  were used for the  
450 iLOVECLIM experiment whereas monthly temperature and  $\delta^{18}\text{O}_{\text{sw}}$  were used for the  
451 ECHAM5/MPI-OM experiment.

452 The surface density residuals anomalies (LGM - PI) are overall rather close to 0 except in the  
453 Nordic Seas region (north of 40°N in the Atlantic). For the following analyses we do not  
454 consider the North Indian Ocean for iLOVECLIM. Indeed, this region is affected by a well-  
455 known bias of this climate model due to a shift of the African precipitation regions from the

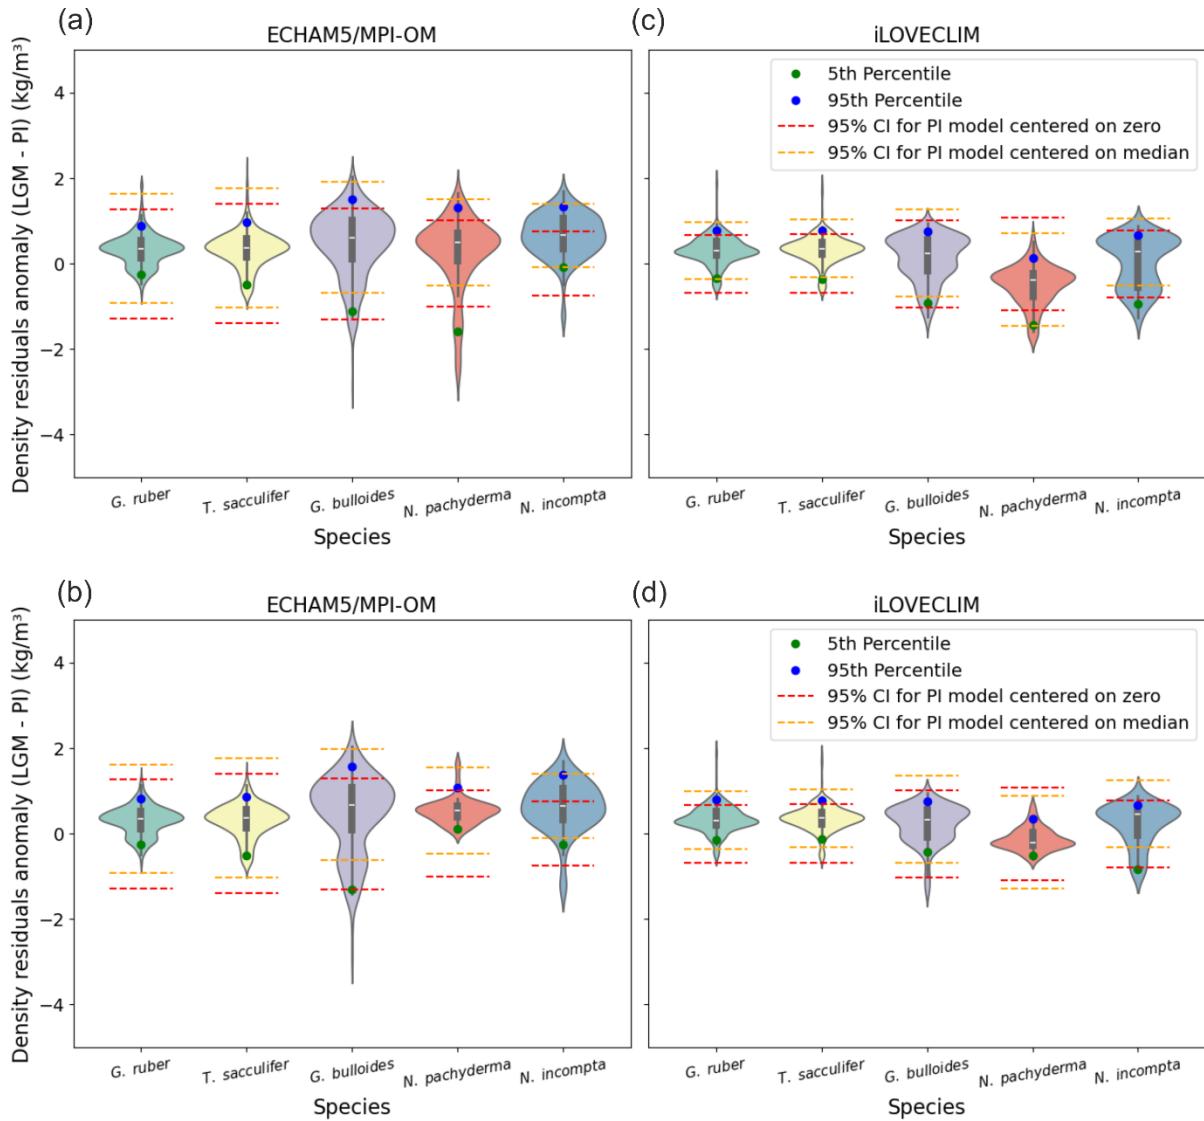

456 west to the east of the continent, leading to much less saline waters than presently observed  
457 (and unrealistically depleted  $\delta^{18}\text{O}_{\text{sw}}$ ) in the North Indian Ocean (Roche and Caley, 2013).  
458 Higher residuals anomaly in Nordic Seas region could be associated with difficulty in  
459 simulating the  $\delta^{18}\text{O}_{\text{sw}}$ -salinity relation evolution related to ice-sheets and sea ice changes  
460 and/or to foraminifera ecological changes between LGM and PI. **We also observe in this**  
461 **region larger surface density residuals anomalies (LGM – PI) with ECHAM5/MPI-OM than**  
462 **with iLOVECLIM (Figure 5c and f).** This can be explained by different simulated sea ice  
463 coverage in ECHAM5/MPI-OM compared to iLOVECLIM. Indeed, the Nordic Seas is the  
464 region with the largest difference between the two model simulations of modeled annual SST  
465 below 0°C (<https://doi.org/10.5194/egusphere-2025-2459-AC2>). Temperature is used to  
466 calculate the  $\delta^{18}\text{O}_{\text{c}}$  signal, ocean density and to force the FAME module. Any temperature  
467 difference in the Nordic Seas thus affects density reconstructions and hence the density  
468 residuals (Figure 5c and f).

469

470 To further investigate in a more quantitative way if the use of the PI bayesian calibration to  
471 predict LGM surface density introduces additional uncertainties, we compare probability  
472 distributions of surface density residuals anomaly (LGM - PI) using violin and box plots to the  
473 95% confidence interval (CI) of the PI bayesian calibration (Fig. 6). We consider each  
474 foraminifera species separately. Global results indicate for the *G. ruber* and *T. sacculifer*  
475 species that 1) the 5th to 95th percentile and interquartile range of the surface density  
476 residuals anomaly is well inside the 95% CI of the PI bayesian calibration for both  
477 ECHAM5/MPI-OM and iLOVECLIM experiment and 2) high probability and median values are  
478 close to 0 (Fig. 6a **and c**). This is not the case for *G. bulloides*, *N. incompta*, and for *N.*  
479 *pachyderma*.

480 When the Nordic Seas region is removed, results indicate that for all the foraminifera  
481 species, the interquartile range of the surface density residuals anomaly is well inside the  
482 95% CI of the PI bayesian calibration for both experiments (ECHAM5/MPI-OM and  
483 iLOVECLIM). High probability and median values are closest to 0 (Fig. 6b **and d**). The 95% CI  
484 of the PI bayesian calibration is closest to the 5th to 95th percentile range of the surface  
485 density residuals anomaly.

486

487

488 Figure 6: probability distributions of surface density residuals anomaly (LGM - PI) for  
 489 ECHAM5/MPI-OM and iLOVECLIM, for global data (a and c), and without the Nordic Seas and  
 490 northern North Atlantic (north of 40°N) (b and d). North Indian Ocean data for iLOVECLIM  
 491 have been removed in both cases.

492 We conclude based on our tests that the use of a Bayesian calibration model (hierarchical  
 493 design) to predict annual surface density during past periods (with the example here of the  
 494 LGM climate) is valid globally within the explicitly estimated uncertainty in calibration model  
 495 parameters, except for the Nordic Seas region.

496 **3.2 Reconstruction of past ocean surface absolute density**

497 To reconstruct past ocean surface absolute density based on foraminifera  $\delta^{18}\text{O}_{\text{C}}$  values that  
 498 have been corrected from the  $\delta^{18}\text{O}_{\text{sw}}$  ice effect, an additional correction is necessary.  
 499 Indeed, it is necessary to account for mean ocean density changes related to ocean volume  
 500 changes that affect mean ocean salinity. Without this additional correction, the ocean  
 501 density reconstructed corresponds to density changes linked to hydrographic changes in SST  
 502 and SSS.

503 To determine the mean ocean density change related to the change in ocean volume at LGM  
504 we used model simulation results (ECHAM/MPI-OM and iLOVECLIM) and added or removed  
505 1 psu salinity (Duplessy et al., 1991) in global salinity outputs. Note that adding 1 psu of  
506 salinity at LGM in climate model simulations has only small effects on ocean dynamics.  
507 Indeed, the effect is due to the small non-linearity in the sea-ice freezing, hence generating  
508 small differences in regions of sea ice and deep water formation. We have tested it in new  
509 simulations performed with the iLOVECLIM model and found the dynamical effect of a 1 psu  
510 salinity change in the regions we are analyzing to be very small (not shown).

511 Both model simulations agree and yield a mean ocean salinity effect on density of 0.776 ( $\sigma = 0.02$ ) for ECHAM/MPI-OM and 0.772 ( $\sigma = 0.02$ ) for iLOVECLIM. We also performed a  
512 calculation to estimate this effect based on observations (reference state based on present  
513 day observations and LGM state based on Tierney et al., 2020 for SST and Duplessy et al.,  
514 1991 for SSS) and found very consistent results (<https://doi.org/10.5194/egusphere-2025-2459-AC1>).

517 Therefore, the additional correction that is necessary to reconstruct past ocean surface  
518 absolute density at the LGM is estimated to be equal to + 0.77.

### 519 3.3 LGM annual surface density reconstruction

520 We applied the poly1\_hier calibration model to the LGM and LH  $\delta^{18}\text{O}$  foraminifera  
521 database, excluding the Nordic Seas region, after subtraction of 1.0 ‰ from LGM  $\delta^{18}\text{O}$   
522 values (Labeyrie et al. 1987; Schrag et al., 1996; Schrag et al., 2002; Adkins et al., 2002;  
523 Duplessy et al., 2002) in order to reconstruct LGM and LH annual surface density. **Absolute**  
524 **LGM annual surface density was calculated by adding 0.77 to density changes linked to**  
525 **hydrographic changes in SST and SSS.** The benefit of our Bayesian model is the possibility to  
526 propagate uncertainty from calibration into predictions of past climate conditions (Fig. 7).

 567 **associated 68 % C.I (grey lines).**

568

569 Ocean surface density increases globally during the LGM in agreement with colder SST  
 570 (MARGO, 2009; Tierney et al., 2020b) and increases global salinity (Duplessy et al., 1991;  
 571 Adkins et al., 2002) (Fig. 7a). We also observe stronger LGM density value changes at low

572 latitudes compared to mid latitudes (Fig. 7b, c and d). This is probably the result of the LGM  
573 cooling (MARGO, 2009; Tierney et al., 2020b) in combination with a reduction of the  
574 intensity of low latitudes hydrological cycle (Kageyama et al., 2021), whereas higher latitudes  
575 are already close to ocean density maximum. Further regional analyses of ocean surface  
576 density and comparison with numerical climate models are presented in Barathieu et al. in  
577 prep.

578

#### 579 4. Conclusions

580 We developed three Bayesian regressions to model the relationship between the calcite  
581 oxygen isotopic composition of planktonic foraminifera,  $\delta^{18}\text{O}_{\text{C}}$ , and annual mean surface  
582 density,  $\rho$ . This allowed us to explicitly estimate the uncertainty in calibration model  
583 parameters. We find that predictive performance of the model improves when we account  
584 for inter-species specific differences. Before applying this model to past density  
585 reconstructions, we used results of isotope enabled climate model simulations for PI and  
586 LGM time periods to force the FAME module. We then investigated the additional  
587 uncertainties that could be introduced by potential evolution of the  $\delta^{18}\text{O}_{\text{C}}$ -density  
588 relationship with time. It could be caused by changes in the  $\delta^{18}\text{O}_{\text{sw}}$ -salinity relationship or  
589 by foraminifera ecology. We demonstrate that additional uncertainties are weak and that  
590 our approach is valid (except for the Nordic Seas region), within propagated uncertainty  
591 from calibration into predictions of past climate conditions.

592 By applying our Bayesian regression hierarchical model to LGM and LH  $\delta^{18}\text{O}_{\text{C}}$  foraminifera  
593 databases, we reconstructed LGM and LH annual surface density and found stronger LGM  
594 density value changes at low latitudes compared to mid latitudes. The logical next step will  
595 be to compare globally and in more detail (regional scale) our quantitative annual surface  
596 density reconstruction with densities obtained by numerical climate model simulations  
597 during the LGM. This will be used to evaluate these climate models in their ability to  
598 simulate this parameter during this extreme climatic period (Barathieu et al., in prep). The  
599 quantification of density together with the estimation of uncertainties could also be used for  
600 data assimilation approaches, allowing local paleoclimate proxy information to be used to  
601 infer global climate metrics (Tierney et al., 2020a).

602 We demonstrate that our approach is valid to quantitatively reconstruct annual surface  
603 density during one of the coldest climates of the Quaternary period. We also demonstrate  
604 this for the mid Holocene and last interglacial periods (Appendix B). Hence, our calibration  
605 has great potential to be applied to other past periods and to reconstruct past temporal  
606 evolution of ocean surface density downcore during the Quaternary. Under very extreme  
607 climates outside the Quaternary (Appendix B) and in ocean basins characterized by anti-  
608 estuary circulation, like the current Mediterranean Sea and Red Sea, our calibration could  
609 provide density estimates with larger uncertainty, a point that requires further  
610 investigations.

611 Finally, our calibration method to quantitatively reconstruct past ocean surface density is  
612 stable with time. A combination with existing calibration methods to reconstruct past SST

613 could lead to a “time stable” method to quantitatively reconstruct past SSS over the  
614 Quaternary, contrary to the use of the  $\delta^{18}\text{O}_{\text{sw}}$ -SSS approach. Before realized SSS  
615 reconstructions, further investigations and calculation of uncertainties are necessary for this  
616 potential new method. This is clearly a way forward as SSS is a crucial parameter that can  
617 provide insights into hydrological cycle dynamics and its evolution.

# 642 Appendices

## 643 Appendix A. Detailed Prior Specifications

644 Below we provide the exact prior definitions and hyperparameter settings for each of the three  
645 Bayesian models. In the following,  $\rho$  denotes annual mean surface density, and  $\delta_c$  represents  $\delta^{18}\text{O}$ .  
646 Let  $E[\rho]$  and  $\text{var}(\rho)$  be the sample mean and variance of  $\rho$ , respectively, and let  $\text{var}(\delta_c)$  be the sample  
647 variance of  $\delta_c$ .

### 648 1. First-Degree Polynomial (Pooled)

$$651 \rho \sim N(\mu, \sigma^2) \\ 652 \mu = \beta_0 + \beta_1 \delta_c.$$

653 We chose weakly informative and data-adaptive priors, meaning they center around observed  
654 mean/variance but are broad enough to allow for uncertainty.

$$656 \beta_0 \sim N(E[\rho], 2.5 \sqrt{\text{var}(\rho)}), \quad \beta_1 \sim N(0, 2.5 \sqrt{\frac{\text{var}(\rho)}{\text{var}(\delta_c)}}), \quad \sigma \sim \text{Exp}(\sqrt{\text{var}(\rho)^{-1}}).$$

### 659 2. Second-Degree Polynomial (Pooled)

$$661 \rho \sim N(\mu, \sigma^2) \\ 662 \mu = \beta_0 + \beta_1 \delta_c + \beta_2 \delta_c^2.$$

663 We set the priors to

$$664 \beta_i \sim N(0, 6.08^2) \quad \text{for } i \in \{0, 1, 2\}, \quad \sigma \sim \text{Exp}(\sqrt{\text{var}(\rho)^{-1}}).$$

666 Here, the normal priors were chosen to ensure that 90 % of the prior mass for each  $\beta_i$   
667 lies within [-10, 10].

### 669 3. First-Degree Polynomial (Hierarchical)

$$677 \rho \sim N(\mu_s, \sigma_s^2) \\ 678 \mu_s = \beta_{s,0} + \beta_{s,1} \delta_c$$

671 where each species  $s$  has its own slope and intercept. These species-level  
672 parameters share hyperpriors:

#### 674 Species-Level Parameters

$$680 \beta_{s,i} \sim N(\nu_i, \kappa_i^2), \quad i \in \{0, 1\}, \quad \sigma_s \sim \text{Exp}(\lambda_s).$$

#### 681 Hyperpriors

682  
684  $\nu_0 \sim N(E[\rho], 10), \quad \nu_1 \sim N(0, 10)$

685  $\kappa_0 \sim Exp(2.5 \sqrt{var(\rho)}), \quad \kappa_1 \sim Exp(2.5 \sqrt{\frac{var(\rho)}{var(\delta_c)}}),$   
686  $\lambda_s^{-2} \sim LogNormal(0, 1).$

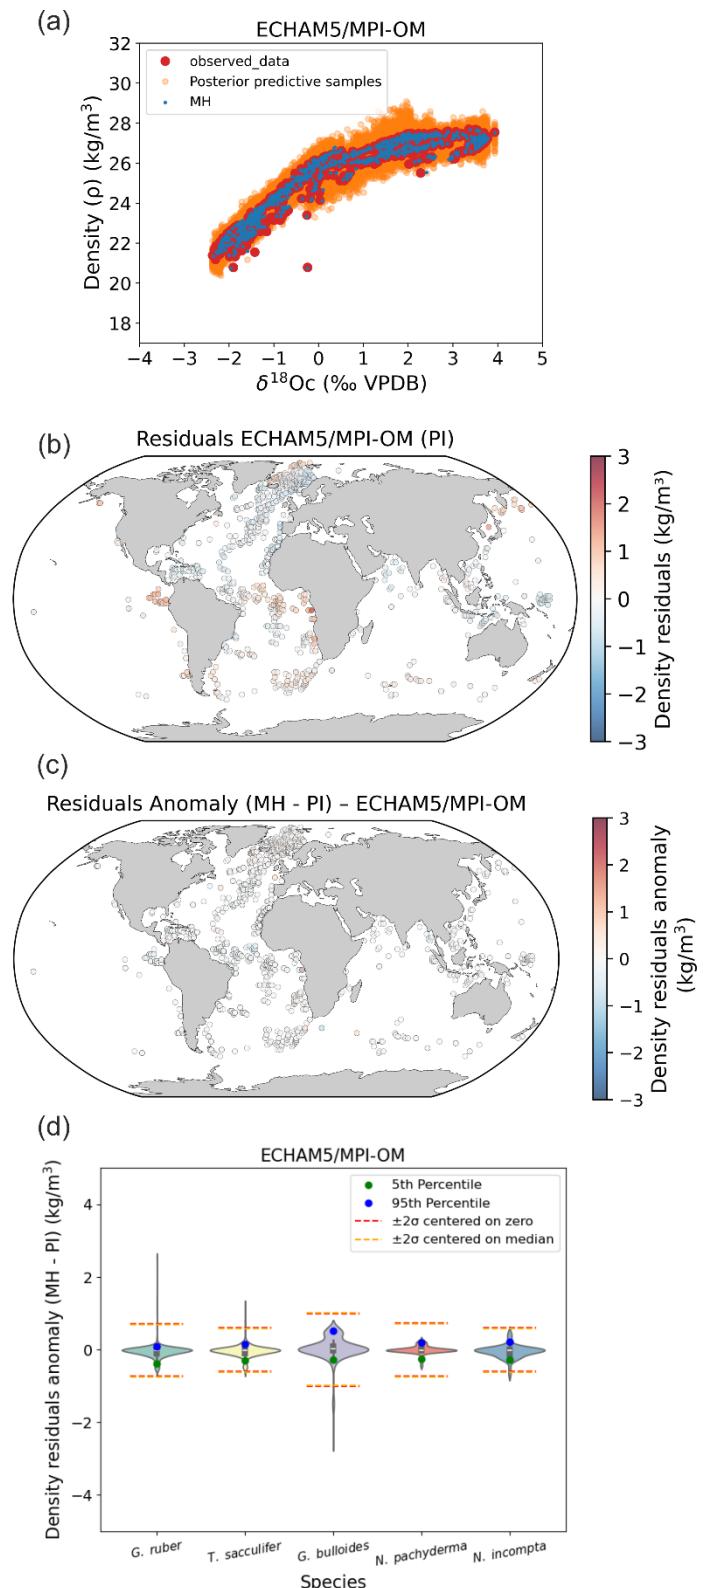

687  
688

689 **Appendix B. Application of our calibration to other past periods**

690 Our study is focused on the LGM but it is interesting to examine if our results remain valid  
691 for other climate periods. In this appendix, we present tests using isotope-enabled model  
692 runs representing different past climate conditions in order to demonstrate that additional  
693 uncertainties due to the evolution of the  $\delta^{18}\text{O}_c$ -density relationship with time are globally  
694 small and that the new calibration has great potential to reconstruct the past temporal  
695 evolution of ocean surface density over the Quaternary period.

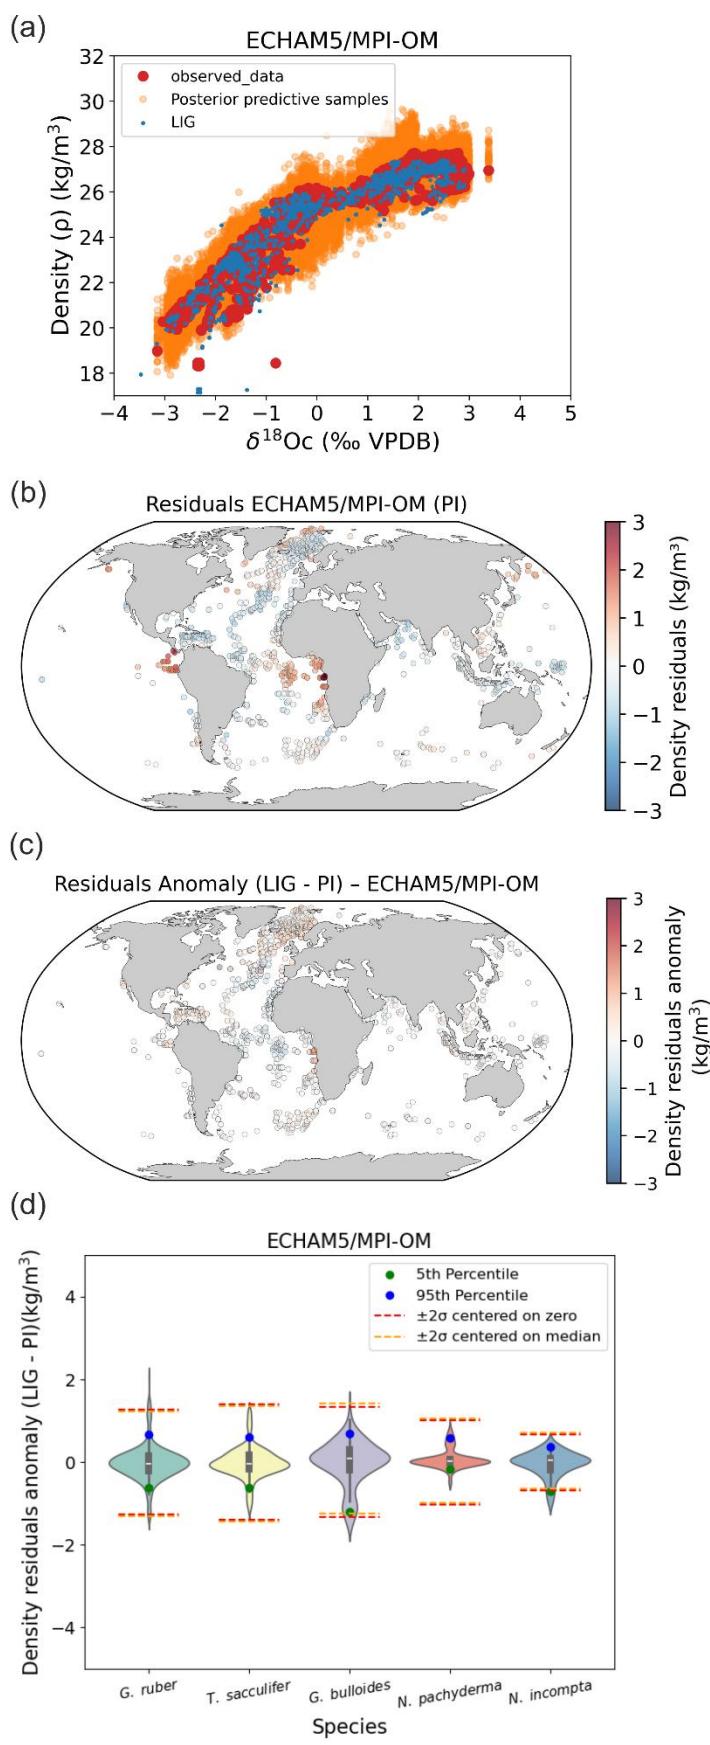

696 In addition to the LGM time period investigated in our study, we tested the Mid Holocene  
697 (MH) period and the last interglacial period (LIG) (Figs. B1 and B2). Results clearly indicate  
698 a strong stability of foraminifera  $\delta^{18}\text{O}_c$ -density relations between MH, LIG and the PI, that is  
699 a very weak influence of the changes in the  $\delta^{18}\text{O}$ /Salinity relation or foraminifer ecology (i.e.  
700 habitat depth and growing season) on final density predictions (Figs. B1 and B2).

773 Fig. B2: Stability of foraminifera  $\delta^{18}\text{O}_{\text{C}}$ -density relations between PI and the LIG calculated  
 774 with FAME and forced by global ECHAM5/MPI-OM (Gierz et al., 2017) hydrographic data.  
 775 (a) PI Bayesian regression models between foraminifera  $\delta^{18}\text{O}_{\text{C}}$  and annual surface density.  
 776 Posterior predictive samples and LIG  $\delta^{18}\text{O}_{\text{C}}$ -density relations (LIG) are visible. (b) Density  
 777 residuals (predicted - observed) for the PI experiments. (c) Density residuals anomaly  
 778 between LIG and PI. (d) Probability distributions of surface density residuals anomaly (LIG -  
 779 PI) without Nordic Seas and northern North Atlantic (north of 40°N).

780

781 Applying our calibration to past climates (and taking into account foraminifer ecological  
 782 changes) provides density predictions that remain within the uncertainties of the calibration,  
 783 as demonstrated for the LGM, MH and LIG time periods. These time periods correspond to  
 784 extreme climate configurations over the Quaternary period as shown on Fig. B3, so the new  
 785 calibration can be reliably applied to reconstruct the past temporal evolution of ocean surface  
 786 density over the entire Quaternary (last 2.6 Ma).

787

798 Fig. B3:  $\delta^{18}\text{O}$  benthic foraminifera curve (LR04, Lisiecki and Raymo, 2005) as a proxy of ice  
 799 volume and deep ocean temperature changes, used here to select extreme climatic periods  
 800 (colder and more arid glacial periods versus warmer and more humid interglacial periods).  
 801 Extreme climate periods tested with isotope-enabled model runs representing the mid-  
 802 Holocene, LIG and LGM are represented by blue dots. Blue lines indicate the range of  
 803 extreme climate conditions investigated with our climate simulations tests.

804 Nonetheless, under very extreme climates outside the Quaternary period (Fig. B3) and in  
 805 ocean basins characterized by anti-estuary circulation, like the current Mediterranean Sea and  
 806 Red Sea, our calibration could provide density estimates with larger uncertainty, a point that  
 807 requires further investigations.

808

809

810 **Code and data availability**

811 The Python code for Bayesian calibration models is freely available at the following  
812 repository: [https://github.com/nicrie/density\\_uncertainty](https://github.com/nicrie/density_uncertainty). Core top data used for this  
813 analysis are from Malevich et al. 2019 and are available at  
814 <https://agupubs.onlinelibrary.wiley.com/doi/10.1029/2019PA003576>. LGM and LH  $\delta^{18}\text{O}$   
815 dataset are available at doi:10.5194/cp-10-1939-2014-supplement for Caley et al., 2014, at  
816 <https://doi.org/10.1594/PANGAEA.894229> for Waelbroeck et al., 2014 and at  
817 <https://doi.org/10.1594/PANGAEA.920596> for Tierney et al., 2020b. The additional LGM and  
818 LH  $\delta^{18}\text{O}$  dataset is available at the following repository:  
819 [https://github.com/nicrie/density\\_uncertainty](https://github.com/nicrie/density_uncertainty).

820 **Author contributions**

821 TC and DR initially designed the study. TC developed the study. NR and TC developed the  
822 Bayesian calibration models. MW provided ECHAM5/MPI-OM model outputs. CW furnished  
823 the new  $\delta^{18}\text{O}$  dataset. TC analysed the results with contribution and discussion of all co-  
824 authors. TC produced the figures and wrote the article with input from all co-authors.

825 **Competing interests**

826 The contact author has declared that none of the authors has any competing interests.

827 **Acknowledgements**

828 T.C. is supported by CNRS Terre & Univers. This study has been conducted using E.U.  
829 Copernicus Marine Service Information; <https://doi.org/10.48670/moi-00051>.
