27

28 **Key Points:**

29 • Proximal northward-recurving typhoons are the most likely to induce ozone
30 pollution.

31 • The northward typhoon will cause ozone to increase by 0.3~14.5ppbv in
32 vertical height.

33 • The contribution rate of transboundary layer transport under the influence of
34 typhoon to the ozone in the boundary layer can reach 16%.

35

36

37

38

39

40 **Abstract**

41 Ozone (O_3) pollution has emerged as one of the core challenges in atmospheric
42 environmental governance in China, particularly in Guangdong Province. As a crucial
43 weather system during East Asian summers, typhoons exert profound influences on
44 O_3 formation, accumulation, and transboundary transport through variations in their
45 tracks and intensities. This study examined 237 historical typhoons approaching or
46 making landfall in China between 2013-2023 classifying them into three distinct
47 trajectory types using k-means clustering: westward-moving typhoons (Type 1),
48 Distant northward-recurving typhoons (Type2) and Proximal northward-recurving
49 typhoons (Type3). By integrating ground-based observations, reanalysis data, and
50 WRF-CMAQ model simulations, the mechanisms through which typhoon tracks affect
51 ozone pollution in Guangdong Province were investigated. The results demonstrate
52 that for Guangdong Province, proximal northward-recurving typhoons induce more
53 extreme meteorological conditions compared to westward-moving and distant
54 northward-moving typhoons. The analysis of consecutive northward-moving
55 typhoons' impact on ozone pollution in Guangdong Province reveals that surface
56 photochemical reactions served as the dominant factor, while vertical downward
57 transport of upper-level ozone acted as a secondary contributor. Nevertheless, the
58 long-range vertical transport induced by typhoons cannot be neglected. During this
59 event, vertical transport contributed up to 39.9 ppbv to near-surface (100 m) ozone
60 concentrations, with cross-boundary-layer transport accounting for up to 16% of
61 boundary layer ozone concentrations, demonstrating that typhoon-induced vertical
62 transport significantly enhances boundary layer ozone levels and consequently
63 worsens surface pollution. Additionally, analysis of the backward trajectories and 3-
64 dimensional ozone concentration fields of 237 typhoons indicates that northward-
65 moving typhoons significantly enhance the downward transport of ozone,

66 consequently increasing the ozone concentration at the central point of Guangdong
67 Province by 2.5 – 14.0 ppbv (Type 2) and 0.3 – 14.5 ppbv (Type 3) within the 250 –
68 900 hPa layer.

69

70 **Plain Language Summary**

71 It is well established that typhoon tracks exert significant impacts on ozone
72 pollution. However, current research predominantly focuses on individual typhoon
73 case studies or isolated meteorological factors, leaving a gap in comparative analyses
74 of the mechanisms associated with different typhoon pathways. This study
75 categorizes the trajectories of 237 typhoons that occurred over the western Pacific
76 Ocean, specifically investigating the influence mechanisms of westward-moving
77 typhoons (Type1), distant northward-moving typhoons (Type2), and Proximal
78 northward-recurving typhoons (Type3) on ozone pollution in Guangdong Province.
79 The results demonstrate that close-in northward-moving typhoons induce the most
80 favorable conditions for ozone formation and the least favorable atmospheric
81 dispersion conditions in Guangdong, thereby promoting ozone pollution.

82 Additionally, northward-moving typhoons facilitate the subsidence of high-
83 latitude, high-concentration ozone into the boundary layer, leading to elevated ozone
84 levels. Finally, consecutive northward-moving typhoons trigger widespread and
85 persistent ozone pollution across Guangdong. During this process, cross-boundary-
86 layer transport via vertical motion contributes up to 16% of the ozone concentration
87 within the boundary layer, underscoring the substantial impact of northward-moving
88 typhoons on boundary-layer ozone through vertical transport mechanisms.

89 **1 Introduction**

90 Ozone (O_3) pollution has become one of the core challenges in atmospheric
91 environmental governance in China, particularly in the Pearl River Delta region. As a
92 typical secondary pollutant, the formation of O_3 is dually regulated by precursor

93 emissions (NO_x and VOCs) and meteorological conditions. (Dou et al., 2024; Gong et
94 al., 2025; Qiu et al., 2025; Yang et al., 2019). In recent years, despite continuous
95 strengthening of anthropogenic emission control measures, the increasing frequency
96 of extreme weather events has significantly amplified the complexity of O₃ pollution.
97 (Chen et al., 2022a; Lu et al., 2024; Wan et al., 2022; Wang et al., 2024a)。 Among
98 these factors, typhoons, as a crucial weather system during the East Asian summer,
99 exert profound impacts on O₃ formation, accumulation, and transboundary transport
100 through their track and intensity variations, which significantly modify regional
101 meteorological conditions (e.g., temperature, humidity, wind speed) and
102 atmospheric transport processes. (Chen et al., 2021; Qu et al., 2021; Shen et al., 2023;
103 Wang et al., 2022a)。

104 Typhoons affect ozone generation, accumulation, and vertical transport by
105 altering meteorological and circulation conditions. The peripheral subsidence flows of
106 typhoons frequently induce high temperatures, low humidity, and stagnant weather
107 conditions, which enhances photochemical reactions while suppressing pollutant
108 dispersion, consequently leads to localized O₃ accumulation. (Chen et al., 2022b).
109 Meanwhile, the heat-stagnation conditions stimulate biogenic emissions (e.g.,
110 doubling isoprene concentrations), providing additional precursors for ozone
111 formation (Xu et al., 2023). Observations and models indicate that typhoons can
112 increase biogenic emissions and cross-boundary ozone transport by 78.0% and 22.5%,
113 respectively, and more than double ozone formation efficiency (Wang et al., 2022a).
114 Additionally, typhoon systems may drive vertical transport, bringing ozone from
115 higher altitudes down to the surface, further exacerbating pollution (Chen et al.,
116 2021; Zhan et al., 2020; Chen et al., 2022c). However, the relative contribution of
117 vertical transport remains debated: some studies suggest that ozone increases are
118 primarily due to enhanced surface-level photochemical activity(Huang et al., 2021;
119 Jiang et al., 2024; Wang et al., 2025), with subsidence mainly acting to suppress
120 dispersion (Ding et al., 2023; Li et al., 2022; Ouyang et al., 2022), while others

121 confirm that processes such as typhoon-induced stratospheric intrusions can directly
122 elevate surface ozone concentrations by 10 – 15 ppbv (Chen et al., 2021).

123 Current research demonstrates that typhoon impacts on ozone pollution exhibit
124 significant path dependence. Westward-moving typhoons induce increased net
125 ozone production in the Pearl River Delta (PRD) core region prior to landfall, followed
126 by a rapid decline to near-zero levels on the landfall day(Ding et al., 2023). When a
127 typhoon approaches the land, the accompanying wind and rain effects can lead to
128 the removal of pollutants, leading to negative ozone anomalies over the Yangtze
129 River Delta region(Chen et al., 2021). When typhoons track northward across the
130 Taiwan Strait through the low-latitude western Pacific, they trigger sequential
131 regional ozone pollution episodes in both the Yangtze River Delta (YRD) and Pearl
132 River Delta (PRD) regions(Wang et al., 2022b). The northerly peripheral circulation of
133 the typhoons transports precursors from North China and the Yangtze River Delta
134 (YRD) southward, which, when superimposed with local emissions, triggers abrupt
135 ozone concentration increases(Shen et al., 2023). Successive northward-moving
136 typhoons can elevate O_3 concentrations by 30% across eastern China while
137 prolonging pollution duration(Wang et al., 2024b). Furthermore, the interaction
138 between typhoons and the subtropical high can form a compound weather system,
139 which exacerbates O_3 pollution intensity and prolongs its duration(Gao et al., 2020;
140 Han et al., 2020a; Qin et al., 2020).

141 However, current research predominantly focuses on individual typhoon cases
142 or isolated meteorological factors(Kumar et al., 2023; Li et al., 2023a; Zhan et al.,
143 2020), leaving significant gaps in comparative analyses of mechanisms associated
144 with different typhoon tracks. The key scientific questions include: How do different
145 movement paths of typhoons separately regulate meteorological conditions and
146 regional transport? How do large-scale circulation changes induced by varying
147 typhoon tracks influence the vertical distribution of ozone? The systematic
148 exploration of these issues will deepen our understanding of the interaction

149 mechanism between typhoons and ozone.

150 As a high-frequency typhoon landing region, Guangdong Province exhibits
151 particularly strong correlations between ozone pollution and typhoon activity
152 (Shuping et al., 2022; Yaoyao et al., 2022). Statistical analyses reveal that over 80% of
153 ozone exceedance days during Guangdong's summer-autumn seasons from 2015-
154 2021 were typhoon-associated (Shen et al., 2023). Under climate change scenarios,
155 observed trends of northward-shifting typhoon tracks and intensifying storm
156 strength may further alter regional ozone pollution patterns (Guo and Tan, 2022).
157 Consequently, elucidating the mechanistic links between typhoon paths and ozone
158 pollution holds dual significance: advancing regional atmospheric multipollutant
159 theory while providing scientific foundations for dynamic, precision-based ozone
160 control strategies.

161 This study systematically investigates all typhoons near Guangdong Province
162 from 2013 to 2023 by integrating multi-source observational data and numerical
163 simulations. Through comprehensive classification of typhoon tracks, we conduct in-
164 depth analyses of the relationships between meteorological factors, circulation
165 patterns, atmospheric transport, and three-dimensional ozone distribution under
166 different typhoon paths. Specifically, we examine the contribution of upper-level
167 transport to boundary layer ozone concentrations during typical typhoon events. The
168 research aims to elucidate the differential impacts of various typhoon tracks on O₃
169 pollution in Guangdong region, thereby providing scientific support for refined air
170 quality management strategies.

171 **2 Materials and Methods**

172 **2.1 K-means Clustering Analysis**

173 K-means represents one of the most prevalent partition-based clustering
174 methods. The algorithm categorizes n objects into K clusters based on a predefined
175 parameter K, aiming to minimize the within-cluster sum of squares (WCSS) while
176 maximizing the between-cluster sum of squares (BCSS). This ensures high intra-

177 cluster similarity and low inter-cluster similarity. The K-means algorithm has been
178 widely applied in atmospheric trajectory classification studies due to its effectiveness
179 in identifying characteristic transport patterns(Han et al., 2020b; Yufeng et al., 2024;
180 Zhu et al., 2023).

181 In this study, we performed two distinct clustering analyses using the K-means
182 method: typhoon track clustering and atmospheric transport pathway clustering. For
183 typhoon track clustering: 1. Targeted typhoon tracks over the western Pacific Ocean;
184 2. Employed Euclidean distance metric for data point allocation; 3. Determined the
185 optimal K value by identifying the elbow point where the rate of WCSS decrease
186 substantially diminished; 4. Selected K=3 as the optimal cluster number, yielding
187 three distinct typhoon track types (**Fig.S3**). For atmospheric transport pathway
188 clustering: 1. Analyzed 7-day three-dimensional backward trajectories; 2. Classified
189 atmospheric transport channels into four categories (**Fig.S4**); 3. Implemented similar
190 optimization procedures for cluster determination. The methodology ensures
191 statistically robust classification of both typhoon trajectories and associated air mass
192 transport patterns, providing a quantitative basis for subsequent ozone transport
193 analysis.

194

195 2.2 HYSPLIT Trajectory Model

196 HYSPLIT is a complete system for computing simple air parcel trajectories, as well
197 as complex transport, dispersion, chemical transformation, and deposition simulations.
198 A common application is a back trajectory analysis to determine the origin of air
199 masses and establish source-receptor relationships(Rolph et al., 2017; Stein et al., 20
200 15).

201 This study employs the NOAA HYSPLIT Trajectory Model (https://www.ready.noaa.gov/HYSPLIT_traj.php) to conduct backward trajectory simulations for 237 typhoon
202 s in the Western Pacific region between 2013 and 2023. The meteorological data use
203 d is GDAS (1-degree resolution). The source location is set at 113.5°E, 23.6°N

205 , with the backward trajectories initiated at 14:00 (local time) on the day
206 of peak ozone pollution during each typhoon event. The backward simulation runs fo
207 r 168 hours (7 days) , with trajectory heights set at 500 m, 1000 m, and
208 2000 m above ground level (AGL).

209

210 2.3 WRF-CMAQ

211 The WRF-CMAQ modeling system was employed to simulate meteorological
212 fields and ozone concentration variations during the typhoon process. The WRF
213 (Weather Research and Forecasting) model version 3.9 was configured with the
214 following parameterizations: Microphysics , WSM6 Scheme ; Cumulus
215 Parameterization : Grell-Freitas (GF) Scheme ; Radiation : RRTMG Scheme ;
216 Boundary Layer : YSU Scheme ; Surface Layer : MM5 Similarity Theory ; Land
217 Surface: Noah LSM. The large-scale meteorological fields and boundary conditions
218 were derived from NCEP's Global 6-hourly FNL forecast data. The CMAQ (Community
219 Multiscale Air Quality) model version 5.0.2 was implemented with the IPR (integrated
220 process rate) analysis module. The CB05 mechanism was selected for gas-phase
221 chemistry, while the AE6 mechanism was adopted for aerosol chemistry.

222 The modeling system utilized a triple-nested grid configuration (see **Fig.S1**) with
223 Lambert conformal projection centered at 114°E, 28.5°N and two standard parallels
224 at 15°N and 40°N. The outermost domain (D01) had a horizontal resolution of 27 km
225 × 27 km, covering China, Southeast Asia and the western Pacific region. The
226 intermediate domain (D02) featured a 9 km × 9 km resolution encompassing South
227 China, while the innermost domain (D03) employed a 3 km × 3 km resolution
228 focusing on Guangdong Province and surrounding cities. The vertical structure
229 consisted of 14 layers with the model top set at 200 hPa. For the first and second
230 nested domains, the air pollutant emission inventory adopted was the 0.25°×0.25°
231 MEIC (Multi-resolution Emission Inventory for China) developed by Tsinghua
232 University for the year 2020. For the third (innermost) domain, a higher-resolution 3

233 km×3 km emission inventory compiled by the research team (Li et al., 2023b) was
234 utilized. The simulation period spanned from 00:00 UTC on 24 August to 00:00 UTC
235 on 31 August 2020.

236 In the present study, O₃ was used as a model pollutant to analyze the effects of
237 atmospheric processes on the pollutants' value in deep convection events by using
238 Integrated Process Rate (IPR) analysis. The IPR analysis in CMAQ can be used to
239 calculate the influence of different atmospheric processes on the values of pollutants,
240 and to quantify the importance of each process in the evolution of the pollutant
241 value(Chen et al., 2018; Chen et al., 2022a). The processes include gas-phase
242 chemistry (CHEM),vertical advection (ZADV), horizontal advection (HADV), vertical
243 diffusion (VDIF), horizontal diffusion (HDIF), dry deposition(DDEP) and cloud
244 processes (CLDS).

245 **3 Data**

246 **3.1 Typhoon track data**

247 The typhoon track data were obtained from the CMA Best Track Dataset
248 (tcdata.typhoon.org.cn) maintained by the Tropical Cyclone Data Center of China
249 Meteorological Administration. This dataset provides 6-hourly positional and
250 intensity records of tropical cyclones in the Northwest Pacific (including the South
251 China Sea, north of the equator and west of 180°E) since 1949, covering all typhoons
252 approaching/making landfall in China, with a spatial resolution of 0.1°×0.1° (Lu et al.,
253 2021; Ying et al., 2014). For this study, we extracted all typhoon track data from
254 January 1, 2013, to December 31, 2023, including temporal, geographical coordinates
255 (longitude and latitude), and intensity information. After interpolating the data, we
256 performed typhoon track classification using the K-means clustering method.

257

258 **3.2 Ozone data**

259 The ground-level ozone monitoring data were obtained from the China National
260 Environmental Monitoring Center (CNEMC). This dataset contains hourly

261 concentrations of SO_2 , NO_2 , CO , O_3 , PM_{10} , and $\text{PM}_{2.5}$ from 1,657 monitoring stations
262 across China. For this study, we extracted hourly O_3 data from 105 stations within
263 Guangdong Province (station locations are shown in **Fig.S2**). Following the "Technical
264 Regulation on Ambient Air Quality Index (on trial)" (HJ 663-2013), we calculated the
265 daily maximum 8-hour average ozone concentration (MDA8 O_3). Days with MDA8 O_3
266 concentrations exceeding $160 \mu\text{g}/\text{m}^3$ (approximately 75 ppbv) were identified as
267 ozone exceedance days.

268 The TROPESS Chemical Reanalysis O_3 Increment 6-Hourly 3-dimensional Product
269 V1 dataset from NASA was utilized to investigate the three-dimensional spatial
270 distribution of ozone under typhoon conditions
271 (https://disc.gsfc.nasa.gov/datasets/TRPSCRO3I6H3D_1/summary). The data are part
272 of the Tropospheric Chemical Reanalysis v2 (TCR-2) for the period 2005-2021. TCR-2
273 uses JPL's Multi-mOdel Multi-cOnstituent Chemical (MOMO-Chem) data assimilation
274 framework that simultaneously optimizes both concentrations and emissions of
275 multiple species from multiple satellite sensors. The data files contains a year of data
276 at 6-hourly resolution, and a spatial resolution of $1.125^\circ \times 1.125^\circ$ at 27 pressure
277 levels between 1000 and 60 hPa. This study extracted data from January 1, 2013 to
278 December 31, 2021 for spatial analysis of ozone distribution.

279

280 3.4 Meteorological data

281 Meteorological data from ERA5 (the fifth-generation European Mesoscale
282 Weather Forecasting Center reanalysis of global climate and weather for the past
283 four to seven decades) was also adopted in order to understand the pollution
284 characteristics. The temporal resolution of the data is hourly and the spatial
285 resolution is $0.25^\circ \times 0.25^\circ$. The parameters extracted herein include 2-m temperature,
286 surface relative humidity, total cloud cover, downward UV radiation at the surface,
287 total precipitation, mean sea level pressure, the u-component and v-component of
288 wind at the 10m, 175hPa and 900hPa level, boundary layer height, vertical velocity at

289 the 850 hPa level, the Geopotential at the 175hPa and 900hPa level.
290 (<https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels?tab=overview>).
291

292

293 3.5 ground-level ozone reanalysis dataset

294 The ground-level MDA8 O₃ concentrations across China were obtained from the
295 China 1km High-Resolution Daily Ground-Level Ozone (O₃) Dataset (2000–2023), a
296 high-resolution (1 km) product developed by Wei et al. and hosted on the National
297 Earth System Science Data Sharing Platform (<http://geodata.nnu.edu.cn>) (Wei et al.,
298 2022). This dataset was generated through an ensemble learning approach
299 combining multi-source data, including hourly O₃ measurements from ~940 to 1,630
300 monitoring stations (2013–2020) under China's Ministry of Ecology and Environment
301 (MEE) network, OMI/Aura total-column O₃ and tropospheric NO₂ retrievals,
302 downward solar radiation (DSR) and surface air temperature (TEM) from ERA5
303 reanalysis (0.1° resolution), emissions of NO_x, VOCs, and CO from MEIC inventory,
304 land cover from MODIS, elevation from SRTM, and population density from LandScan.
305 The subset of data from January 1, 2013, to December 31, 2023, was temporally
306 aligned with recorded typhoon tracks to assess the spatio-temporal variability of O₃
307 during periods with distinct typhoon track types.

308 **4 Results**

309 4.1 Characteristics of ozone pollution under different typhoon paths

310 4.1.1 Typhoon track clustering

311 Through k-means clustering analysis, the 237 typhoon tracks over the western
312 Pacific from 2013 to 2023 were classified into three distinct types (**Fig1.a-c**). Type 1
313 comprises typhoons that form in the western Pacific, move into the South China Sea,
314 and subsequently make landfall in South China or pass through its southern maritime
315 areas (total: 105 cases). Type 2 consists of typhoons originating from low-latitude

316 regions of the western Pacific that approach China before recurring northward,
317 traversing Japan and Korea before returning to the western Pacific basin (total: 77
318 cases). Type 3 represents typhoons generated in low-latitude western Pacific regions
319 that approach China and recurve northward, ultimately making landfall in China or
320 dissipating near Japan/Korea (total: 55 cases).

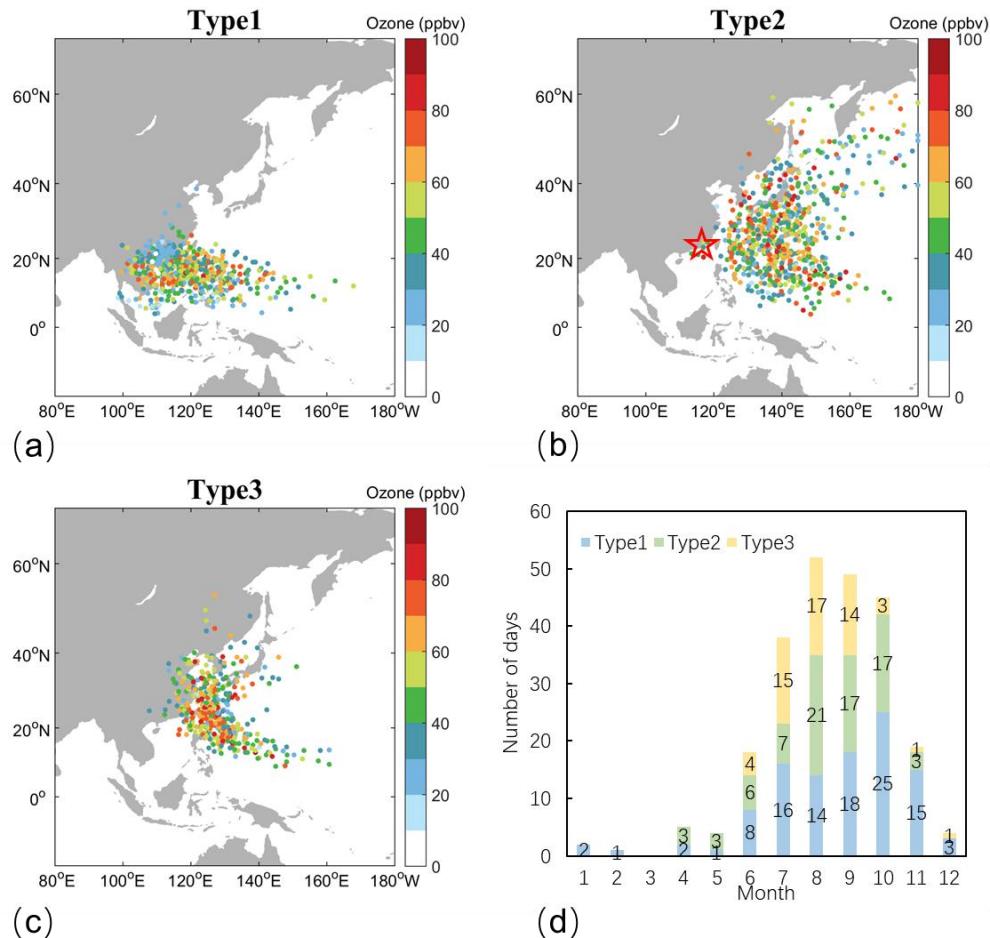

321 For clarity, these three typhoon types are respectively designated as: Type 1:
322 Westward-moving typhoons; Type 2: Distant northward-recurving typhoons; Type 3:
323 Proximal northward-recurving typhoons. Temporal distribution analysis (**Fig1.d**)
324 reveals that both Type 1 and Type 2 primarily occur from July to November, with
325 peak frequency in autumn, while Type 3 is predominantly observed from July to
326 September, showing maximum occurrence during summer.

327 4.1.2 Characteristics of ozone pollution

328 Figures 1a-1c illustrate the temporal evolution of maximum daily 8-hour average
329 ozone (MDA8) concentrations in Guangdong Province in relation to typhoon track
330 movements. From the perspective of ozone pollution characteristics, during the
331 approach of Type 1 typhoons toward mainland China, ozone concentrations in
332 Guangdong Province exhibit a gradual increase. If the typhoon does not make
333 landfall, ozone concentrations remain elevated until the typhoon dissipates. However,
334 if the typhoon makes landfall, ozone concentrations decrease rapidly due to
335 precipitation and strong winds (**Fig. 1a**). Recent studies highlight the dual effects of
336 typhoons on ozone: initial stages often enhance ozone through photochemical
337 processes and stratospheric intrusions, whereas landfall phases suppress it via
338 convective activity and precipitation(Chen et al., 2021; Li et al., 2021). Typhoons of
339 Type2 can affect the ozone concentration in Guangdong Province from a relatively
340 distant location from the mainland. The paths of typhoons causing ozone pollution
341 mainly fall within the range of 130-150°E and 15-40°N. (**Fig.1b**). This phenomenon
342 may be associated with large-scale transport of ozone and its precursors. Typhoons
343 of Type3 tend to induce ozone pollution in Guangdong when approaching eastern

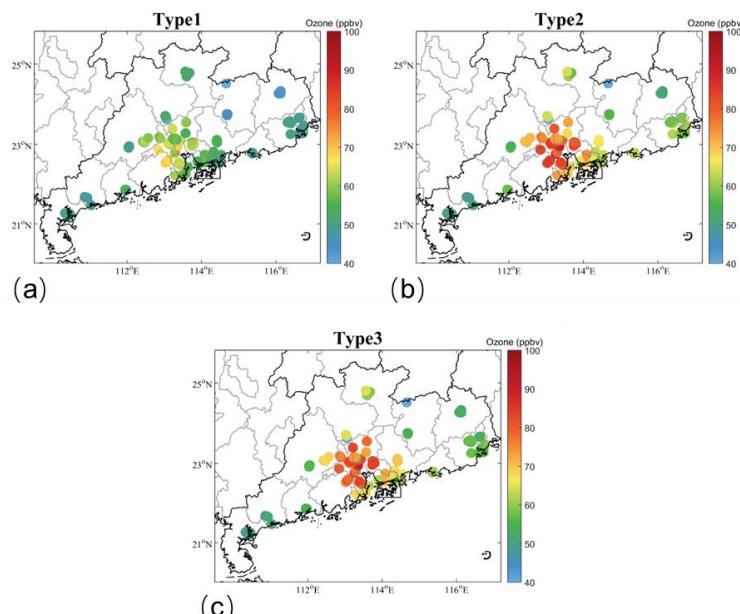

344 China, with peak ozone concentrations occurring when the typhoon reaches
345 approximately 25°N latitude. Following typhoon landfall or eastward deflection,
346 ozone concentrations decrease (**Fig. 1c**).

347 We extracted the MDA8 O₃ concentrations during each typhoon event and
348 calculated Type-specific averages to examine ozone distribution patterns in
349 Guangdong under different typhoon types (**Fig. 2**). The results demonstrate that:
350 Type 1 corresponds to MDA8 O₃ concentrations ranging 9.2-70.9 ppbv, with an
351 average of 20 monitoring stations exceeding standards. Type 2 shows MDA8 O₃
352 concentrations of 12.2-90.3 ppbv, averaging 34 exceedance stations. Type 3 exhibits
353 MDA8 O₃ concentrations of 3.3-89.7 ppbv, with 35 stations exceeding limits on
354 average. The spatial analysis reveals that ozone hotspots for all types consistently
355 cluster in central Guangdong, indicating similar spatial distribution patterns despite
356 varying intensity. Type3 exhibited the highest number of non-compliant monitoring
357 sites, while Type1 showed the lowest count.

358

359 Figure 1. (a-c) Maximum daily 8-hour average (MDA8) ozone concentrations in Guangdong
 360 Province (marked by red pentagrams) under different typhoon tracks(Different colors of dots
 361 represent the average ozone concentration at all monitoring stations in Guangdong Province
 362 when the typhoon is at that location), and (d) the corresponding temporal distributions of
 363 typhoon occurrences for each track type.

364

Figure. 2 Distribution of ozone pollution under different typhoon paths

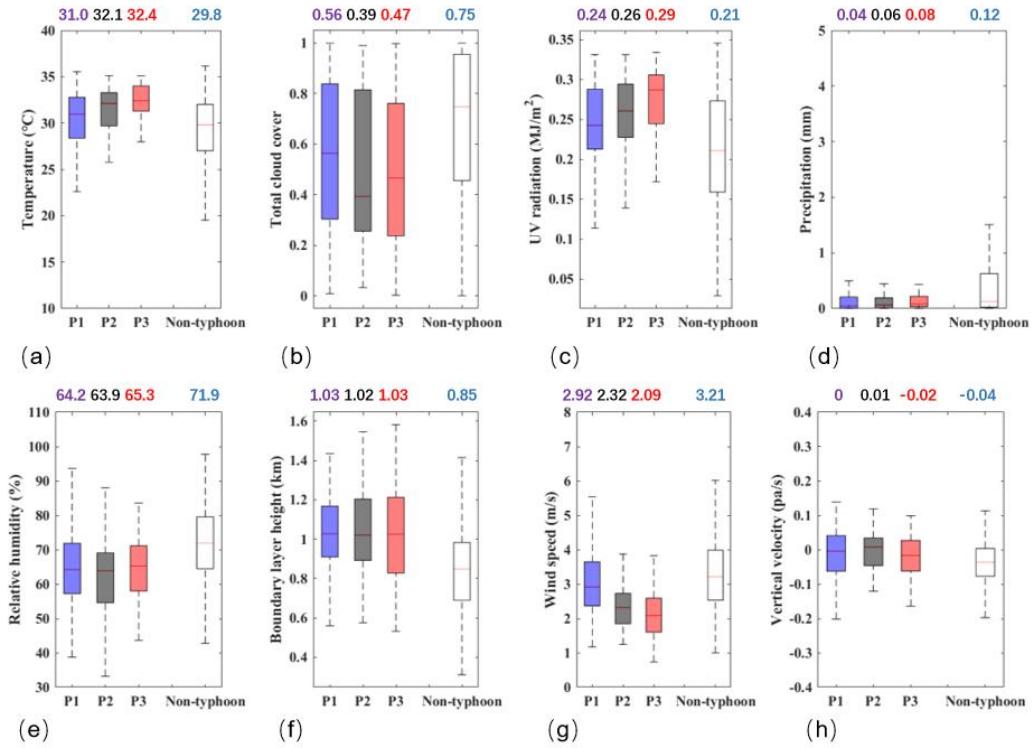

366 4.1.3 Meteorological characteristics

To investigate the influence of meteorological factors on ozone pollution in Guangdong Province under different typhoon tracks, we compared the differences in meteorological conditions between three types of typhoon weather and non-typhoon weather in Guangdong. Typhoon conditions refer to the day with the most severe pollution during the typhoon event, while non-typhoon conditions correspond to the remaining periods after excluding the entire typhoon process. Select the period from June to November when typhoons are most frequent to compare the meteorological differences between typhoon and non-typhoon weather conditions. The meteorological factors analyzed included surface temperature, total cloud cover, surface solar radiation, precipitation, surface relative humidity, boundary layer height, 10m wind speed, and vertical velocity at 850 hPa. All meteorological data were extracted from ERA5 at 14:00 local time for comparative analysis.

379 The results indicate that, compared to non-typhoon weather, typhoon weather
380 in Guangdong is characterized by higher temperatures, stronger solar radiation,
381 lower cloud cover, reduced precipitation, lower relative humidity, higher boundary
382 layer height, weaker surface winds, and suppressed vertical motion (**Fig.3**). The
383 peripheral circulation of typhoons modifies the thermodynamic and dynamic
384 structure of the boundary layer, creating an "ideal reactor" for ozone formation.
385 Near-surface conditions of high temperatures, low humidity, and weak winds foster a
386 stable boundary layer structure, significantly enhancing photochemical reaction rates
387 (Ding et al., 2023). Additionally, increased solar radiation and elevated boundary
388 layer height further expand the spatial domain for ozone production.

389 A comparison of meteorological characteristics across different typhoon track
390 types reveals that Type 3 corresponds to what may be termed "extreme"
391 meteorological conditions. It brings high temperature(32.4°C), high radiation
392 (0.29MJ/m^2), low cloud cover (0.47), low precipitation (0.08mm), low relative

393 humidity (65.3%), high boundary layer height (1.03km), low wind speed(2.09m/s),
394 and less vertical movement (-0.02pa/s) meteorological conditions, which are more
395 likely to cause ozone pollution in Guangdong Province. Compared to non-typhoon
396 conditions, Type 3 exhibits a temperature increase of 2.6°C, a cloud cover reduction
397 of 0.28, a radiation intensity enhancement of 0.08 MJ/m², and a boundary layer
398 height elevation of 0.18 km. It demonstrates the poorest horizontal diffusion
399 conditions, with a near-surface wind speed of 1.12 m/s lower than non-typhoon
400 conditions. The severe ozone pollution observed in Guangdong Province results from
401 the combined effects of strong ozone production rates and poor diffusion conditions,
402 creating a synergistic amplification of pollution levels. The photochemical reaction
403 conditions in Type2 are slightly weaker than those in Type3; however, reduced
404 precipitation inhibits the wet scavenging of ozone and its precursors. Additionally,
405 strong subsidence at the 850 hPa level not only suppresses the vertical diffusion of
406 pollutants within the boundary layer but also transports ozone from higher altitudes
407 downward, further increasing surface ozone concentrations. Compared to the other
408 two typhoon types, Type1 exhibits weaker ozone formation conditions and better
409 dispersion, resulting in the least severe ozone pollution.

410

411

412 Figure 3. Comparison of meteorological conditions between typhoon and non-typhoon
 413 weather. (a-f) represent 2m temperature, total cloud cover, surface solar radiation, precipitation,
 414 relative humidity, boundary layer height, 10m wind speed, and vertical velocity at 850 hPa,
 415 respectively. P1, P2, and P3 denote three distinct typhoon tracks, while Non-typhoon refers to
 416 non-typhoon conditions. The numerical values above each boxplot indicate the median of the
 417 corresponding dataset.

418 4.2 Effect of regional transport on ozone distribution

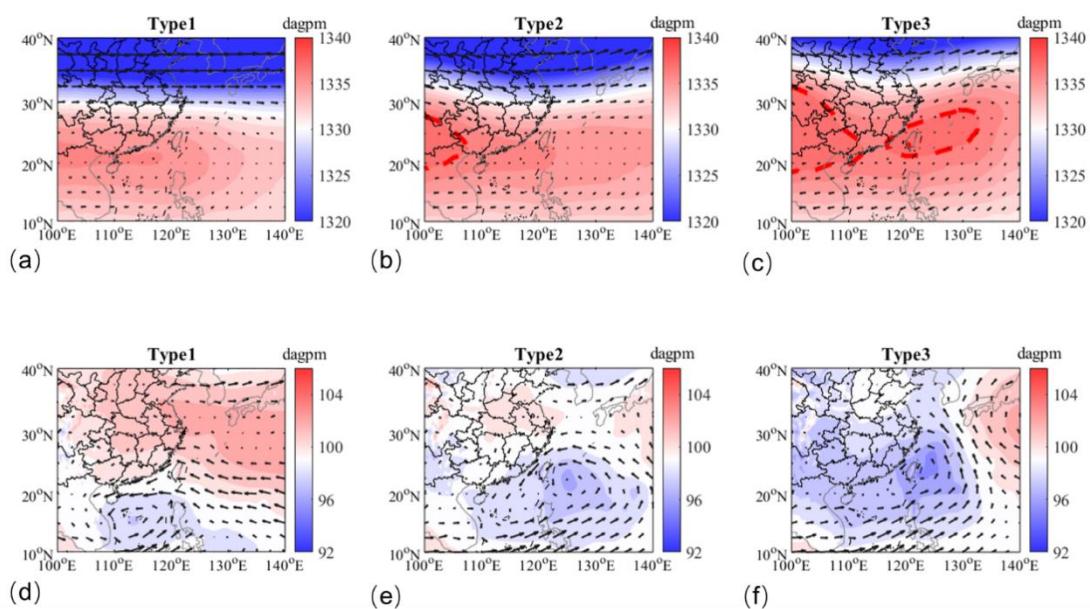

419 4.2.1 Three-dimensional spatial distribution of ozone

420 The impact of typhoons on ozone extends beyond creating favorable
 421 photochemical conditions. The regional transport induced by large-scale circulation
 422 plays a pivotal role in determining ozone concentration distribution(Chen et al.,
 423 2022b; Wang et al., 2018). Typhoon tracks modify regional airflow patterns,
 424 facilitating cross-regional transport of ozone and its precursors(Chen et al., 2021).
 425 This study employs three-dimensional reanalysis O₃ data (2013-2021) coupled with
 426 wind fields and geopotential height to examine how typhoon-induced regional
 427 transport affects the three-dimensional spatial distribution of ozone concentrations

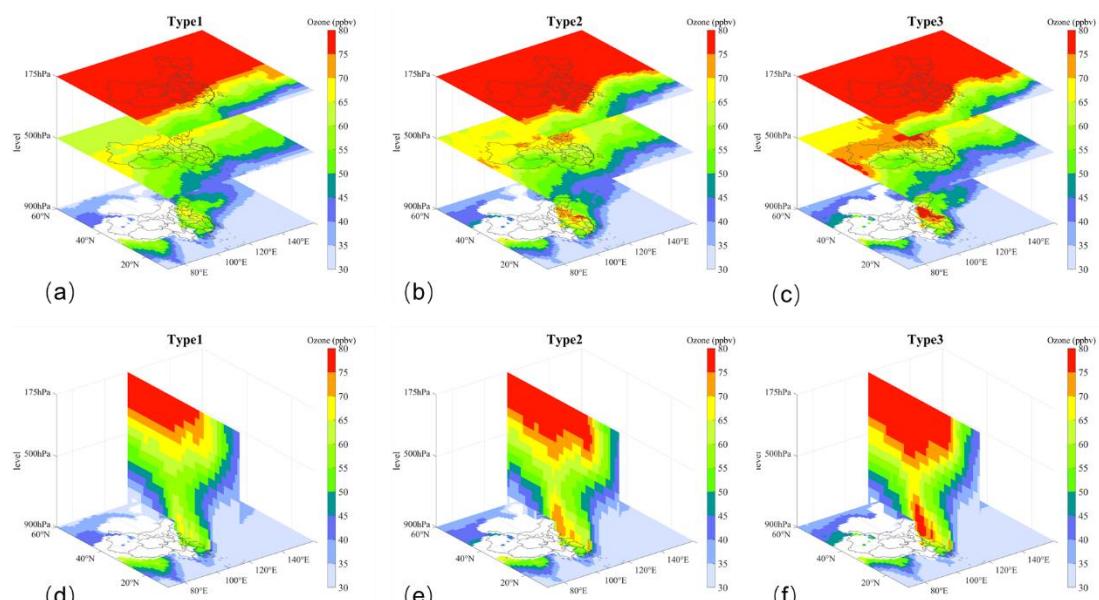

428 (Fig4-5). When the typhoon moves northward (type 2 and type3), a high-pressure
429 center emerges over western China at the 175 hPa level, aligned with the westerly jet
430 to the north, an ozone transport pathway is established, extending from high to low
431 latitudes and accompanied by subsidence (Fig. 4b, c). Specifically, figure 4c shows a
432 configuration featuring two distinct, separated anticyclones (the South Asian High
433 (SAH) over the Tibetan Plateau and the western Pacific Subtropical High (WPSH) aloft)
434 with a prominent saddle zone and upper-level convergence between them at 175
435 hPa. Dynamically, such a setup provides a classic pathway for significant stratospheric
436 ozone intrusion. A tropopause fold, often triggered on the northeastern flank of the
437 SAH where it interacts with the enhanced westerly jet stream, injects a substantial
438 volume of ozone-rich, dry stratospheric air into the upper troposphere. Subsequently,
439 the pronounced subsidence within the saddle zone—induced by the convergence
440 between the SAH and WPSH—effectively transports this intruded air mass downward
441 and southward, directing it toward eastern China and the adjacent oceanic regions.
442 The periphery of typhoon with type 3 tracks could enhance the southward and
443 downward transport of stratospheric ozone, which enhances stratosphere-to-
444 boundary-layer transport of ozone-rich air from the mid-high latitudes (Meng et al.,
445 2022). Through this transport channel, stratospheric ozone with high concentrations
446 (>75 ppbv) is advected southward to approximately 20°N and descends below the
447 500 hPa level (Fig. 5e, f). In contrast, westward-propagating typhoons (Type 1) do not
448 generate perturbations in the westerly jet, and no pronounced southward transport
449 or subsidence of upper-level ozone is evident (Fig. 5a, d).

450 As demonstrated by recent studies (Wang et al., 2022b; Yufeng et al., 2024), the
451 peripheral circulation of western North Pacific typhoons can effectively transport
452 ozone and its precursors from source regions (including the Yangtze River Delta,
453 Fujian, and Anhui provinces) to Guangdong through well-organized atmospheric
454 transport pathways. Analysis of ozone distribution at the 900 hPa level reveals that
455 northward-moving typhoons not only induce ozone pollution in Guangdong, but also

456 lead to elevated ozone concentrations in the Beijing-Tianjin-Hebei and Yangtze River
 457 Delta regions (**Fig. 5b,c**). During the typhoon's northward progression, the low-
 458 pressure center traverses China's eastern coastal areas, where cyclonic circulation
 459 facilitates southward transport of pollutants along the coast, ultimately impacting
 460 Guangdong Province (**Fig. 4e,f**).
 461

462
 463 Figure 4. Comparison of circulation patterns under different typhoon tracks. (a-c) show
 464 geopotential height and wind fields at 175 hPa (upper panels) and 900 hPa (lower panels),
 465 respectively. The red curves indicate the positions of high-pressure centers.

466
 467 Figure 5. Three-dimensional spatial distribution of ozone under different typhoon tracks.

468 (a-c) Horizontal ozone distributions at 900 hPa, 500 hPa, and 175 hPa for the three typhoon track
469 types. (d-f) Horizontal ozone distributions at 900 hPa and corresponding vertical cross-sections
470 along 114°E for each typhoon type.

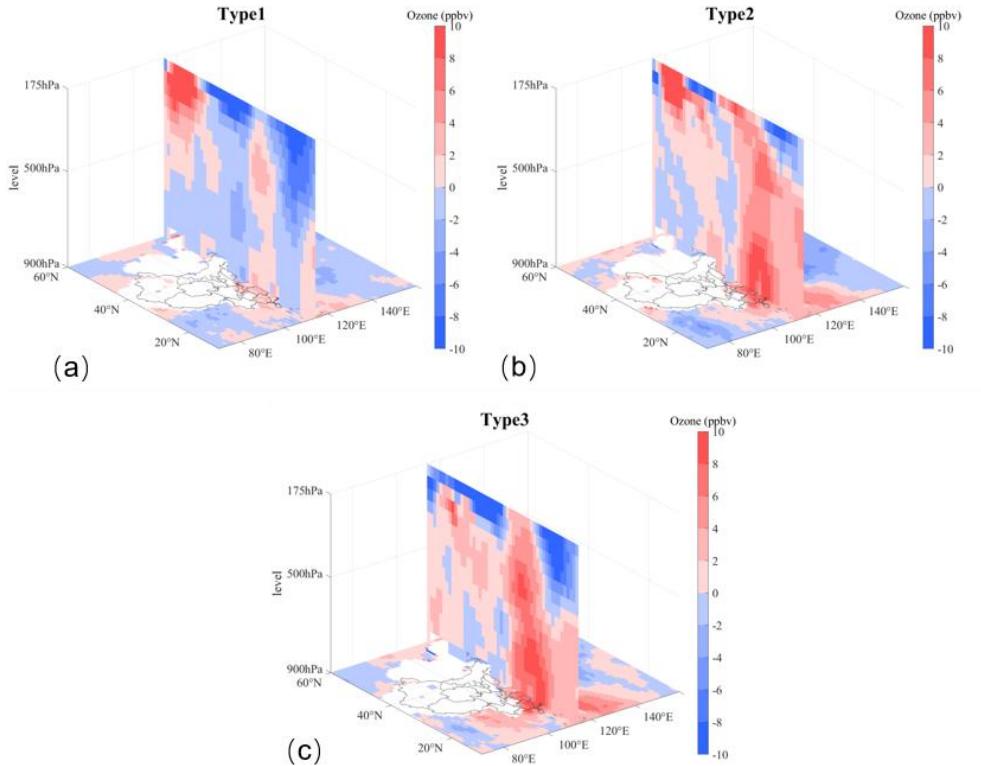

471

472 **Figure S5** presents the spatial distribution of ground-level MDA8 O₃
473 concentrations across China, as derived from the reanalysis 1 km high-resolution
474 daily dataset, under three distinct typhoon track types (type 1, type 2, and type 3).
475 The analysis focuses on typhoon events, characterized as the date with the highest
476 number of ground monitoring sites exceeding the 160 $\mu\text{g}/\text{m}^3$ (~75 ppbv) MDA8 O₃
477 threshold during the entire typhoon track.

478 Being consistent with spatial distribution of ground monitoring O₃
479 concentrations in section 4.1.2, here reveals significant spatial heterogeneity in O₃
480 concentrations across typhoon track types, particularly in Guangdong Province,
481 where the mean MDA8 O₃ follows the order: Type 2 (56.9 ppbv) > Type 3 (54.6
482 ppbv) > Type 1 (51.25 ppbv). This variability is attributed to differences in regional
483 transport pathways and precursor availability. Specifically, type 2 typhoons exhibit
484 elevated O₃ levels in eastern China but reduced concentrations in northern and
485 central regions compared to type 3. The enhanced O₃ under type 2 conditions is
486 driven by two synergistic mechanisms: (1) intensified low-tropospheric transport
487 along China's eastern coastal region, as evidenced by atmospheric circulation
488 patterns (**Fig. 4e**), and (2) the advection of O₃-rich air masses from northern and
489 central China, which supply abundant precursors to Guangdong, particularly its
490 eastern sector. Type 3 typhoons facilitate a more direct, meridional transport of O₃
491 from northern and central China, coupled with pronounced stratospheric intrusions
492 that enhance upper-tropospheric O₃ contributions (**Fig. 5c and 5f**). While type 2
493 systems lack the robust northern transport pathway observed in type 3, they
494 compensate via secondary O₃ delivery through coastal advection, which
495 subsequently propagates inland. This dual transport mechanism culminates in the
496 highest O₃ concentrations in Guangdong, especially the eastern and coastal part,
497 during type 2 events.

498 Collectively, integrating atmospheric dynamics (**Fig.4**), three dimensional
499 evolution of O₃ (**Fig.5**), and ground-level O₃ distributions (**Fig.S5**), underscores the
500 critical role of typhoon-track-dependent transport pathways in modulating regional
501 O₃ pollution. These highlight the necessity of considering multi-scale meteorological
502 processes in air quality forecasting and quantifying their contributions to O₃
503 concentrations across different vertical levels.

504 To further investigate typhoon-induced ozone variations, spatial ozone
505 concentration differences between typhoon conditions and non-typhoon conditions
506 were calculated (**Fig.6**). To eliminate seasonal influences, the anomaly in ozone
507 concentrations between typhoon days and non-typhoon days was first calculated on
508 a monthly basis, after which the different types of statistics were conducted. The
509 results indicate that northward-moving typhoons (Type 2 and Type 3) can
510 significantly increase the ozone concentration at altitudes ranging from 250 to
511 900hPa (**Fig. 6b,c**). Within this altitude range, the variation of ozone concentration at
512 the center point (113.23°E, 23.16°N) changes ranged between 2.5-14.0 ppbv (Type 2)
513 and 0.3-14.5 ppbv (Type 3). In contrast, Type 1 did not cause significant high-altitude
514 ozone increases, with central point ozone concentration changes ranging from -3.5 to
515 2.5 ppbv. Studies indicate that when gravity waves break in the upper troposphere
516 and lower stratosphere on the western side of typhoon centers, intense turbulence
517 occurs, leading to stratosphere-troposphere exchange (STE) (Huang et al., 2024).
518 Subsequently, typhoons approaching landfall significantly enhance cross-regional
519 ozone transport from North China to South China through STE (Wang et al., 2024c).
520 This suggests that after Types 2 and 3 typhoons move northward, their cyclonic
521 circulations transport high-concentration ozone from the tropopause to lower
522 latitudes and altitudes through STE, causing significant changes in ozone vertical
523 distribution and increased ozone concentrations within the boundary layer.

524

525 Figure 6. Ozone concentration changes induced by different typhoon types (a-c: horizontal
 526 distribution changes at 900 hPa and vertical cross-section changes along 114°E for each typhoon
 527 track type respectively).

528 4.2.2 Boundary layer ozone

529 To investigate the ozone transport pathways within the boundary layer over
 530 Guangdong Province under typhoon conditions, and to examine the differences in
 531 ozone sources associated with distinct typhoon tracks, this study conducted HYSPLIT
 532 backward trajectory analysis for 237 typhoon events. The analysis focused on 7-day
 533 air mass origins at 500m altitude over central Guangdong (**Fig.S6**). For each typhoon
 534 type, cluster analysis of air mass origins was performed. After K-value screening, the
 535 air mass origins were classified into four trajectory clusters (**Fig.7**). **Table S1** presents
 536 statistics for each trajectory type, including: (1) The percentage of different
 537 trajectories, (2) mean ozone concentrations along trajectories (data from **TROPESS**
 538 Chemical Reanalysis O_3), and (3) corresponding surface ozone concentrations.

539 Under Type 1 conditions, air masses in the target area mainly originated from
 540 within the boundary layer, accounting for 60.8%, with air transported from the South

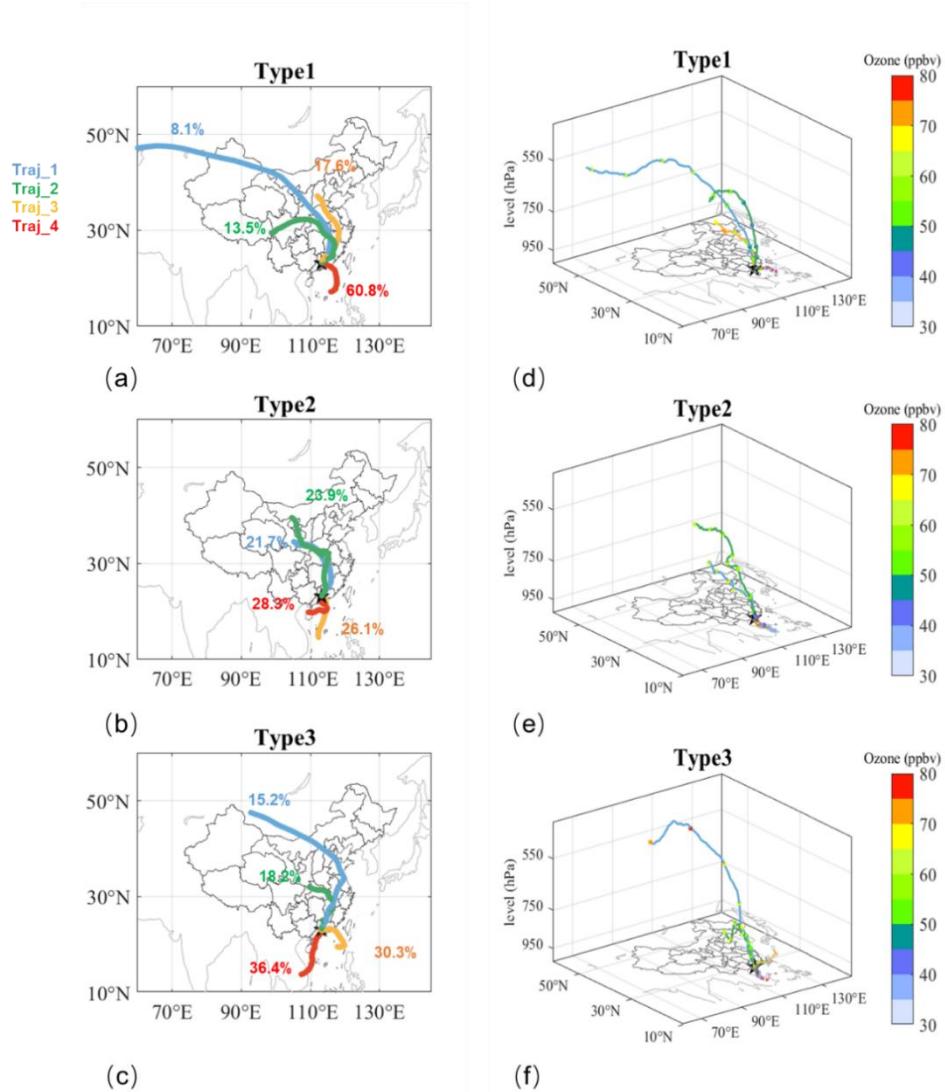

541 China Sea below 841 meters to Guangdong Province (Traj_4). Analysis of the
542 subtropical high's influence shows that under this typhoon type, Guangdong
543 experienced the highest surface pressure and was closest to the subtropical high
544 (**Fig.S7**). Research indicates that under the influence of the subtropical high, O3
545 pollution is primarily affected by local emissions (Chen et al., 2024). This aligns with
546 Traj_4's characteristics of short transport distance and low altitude. The other three
547 trajectories originated from northwest China (Traj_1, 8.1%), western China (Traj_2,
548 13.5%), and central China (Traj_3, 17.6%) respectively (**Fig.7a**). The trajectory with
549 the highest surface ozone concentration was Traj_2, which descended from 3794.1
550 meters with an average ozone concentration of 50.3 ppbv along the trajectory(**Fig.7d**,
551 **Table.S1**). Under Type 2 conditions, nearly half of the air masses in the target area
552 originated from northwest China (Traj_1, 21.7% and Traj_2, 23.9%), while the other
553 half came from the South China Sea region (Traj_3, 26.1% and Traj_4, 28.9%)(**Fig.7b**).
554 Among these, Traj_1 and Traj_2 air masses descended from above 2000m, whereas
555 Traj_3 and Traj_4 air masses were transported within the boundary layer(**Fig.7b**). The
556 trajectory with the highest surface concentration was Traj_1, which descended from
557 2646 meters with an average ozone concentration of 61.9 ppbv along the trajectory
558 (**Fig.7e, Table.S1**). Under Type 3 conditions, Traj_1 carried high-concentration ozone
559 (>75 ppbv) from high-altitude (6356m) over high-latitude areas through North China
560 to the target region, corresponding to the highest surface ozone concentration
561 (15.2% proportion) (**Fig.7f, Table.S1**). The other three trajectories originated from
562 central China (Traj_2, 18.2%) and the South China Sea region (Traj_3, 30.3% and
563 Traj_4, 36.4%)(**Fig.7c**).

564 A comparative analysis of air mass trajectories from different directions
565 demonstrates that marine air masses originating from the South China Sea are
566 characterized by lower altitudes and extended residence time over Guangdong
567 Province, thereby constituting local ozone pollution sources. Conversely, continental
568 air masses exhibit longer transport pathways and higher altitudes, representing

569 regional ozone transport sources. Quantitative analysis reveals that the proportional
570 contributions of local pollution sources under different typhoon tracks are 60.8%,
571 55.0%, and 66.4%, respectively. Analysis of long-range transport trajectories reveals
572 that different typhoon types can respectively deliver ozone from maximum altitudes
573 of 7,468 meters (~380 hPa), 8,927 meters (~320 hPa), and 9,980 meters (~250 hPa)
574 into the boundary layer. Type 2 and Type 3 exhibit significantly greater proportion
575 from upper-level air mass transport (23.9% and 15.2% respectively) compared to
576 Type 1. These typhoons can transport ozone from altitudes down into the boundary
577 layer. Combined with the high ozone concentrations along the atmospheric transport
578 pathways, this results in boundary-layer ozone increases of 10.7 ppbv and 12.3 ppbv
579 for these two types, respectively (**Fig6.b-c**).

580

581

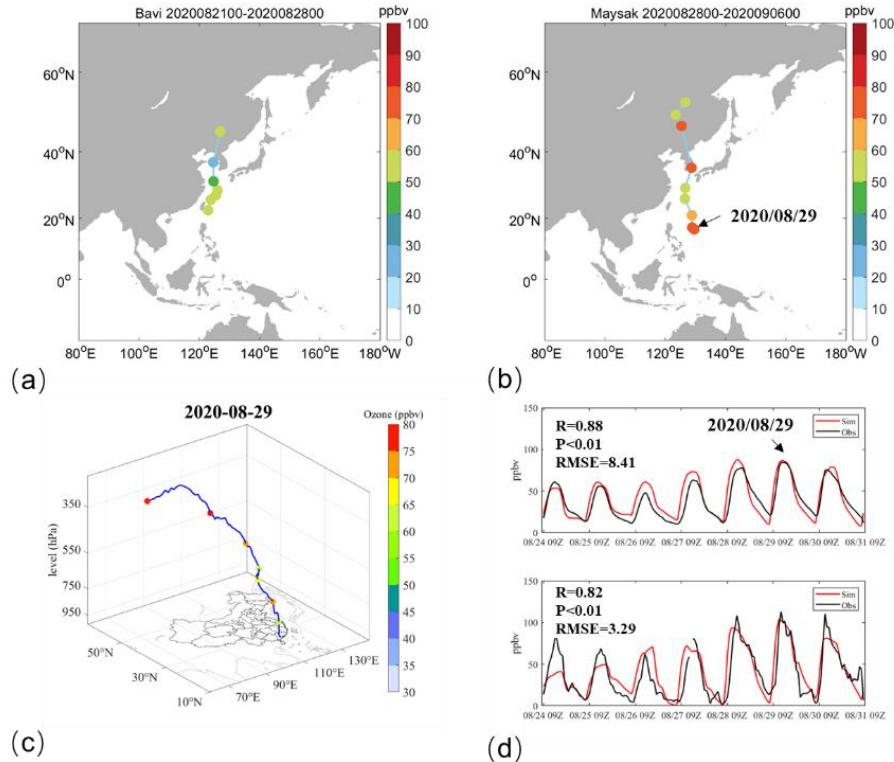

582
 583 Figure 7. Comparison of boundary-layer air mass trajectory sources under different typhoon
 584 tracks: (a-c) two-dimensional views with trajectory percentages indicated numerically; (d-f)
 585 three-dimensional views showing ozone concentrations (ppbv) along trajectories (marked by
 586 colored points); target regions are denoted by black pentagrams on maps.

587 4.3 Contribution of typhoons to the vertical transport of ozone

588 During the period from August 21 to September 6, 2020, the consecutive
 589 occurrence of two northward-moving typhoons (Bavi and Maysak) triggered
 590 prolonged ozone pollution episodes in the Beijing-Tianjin-Hebei and Yangtze River
 591 Delta regions, with over 50% of monitoring stations exceeding ozone standards(Cong
 592 et al., 2024; Hu et al., 2024). Our study reveals that Guangdong Province similarly
 593 experienced extended ozone pollution episodes, particularly between August 28-30

594 and September 1-3, when more than 40 out of 105 monitoring stations (38.1%)
595 recorded exceedances. The most severe pollution occurred on August 29, with 57
596 stations (54.3%) exceeding standards and an average MDA8 ozone concentration of
597 80.6 ppbv (**Fig.8a-b**). Backward trajectory analysis for August 29 identified a 7-day
598 vertical transport pathway from upper levels to the boundary layer, suggesting
599 potential downward mixing of high-ozone air masses (**Fig.8c**). This section examines
600 the period from August 24 to August 31, 2020, employing the WRF-CMAQ model to
601 simulate the spatial distribution of ozone. Integrated Process Rate (IPR) analysis is
602 applied to investigate the formation mechanisms of surface ozone pollution in
603 Guangdong Province under the influence of consecutive northward-moving typhoons,
604 with a quantitative assessment of the impact of vertical transport on ozone
605 concentrations within the planetary boundary layer.

606 The WRF-CMAQ model was used to simulate ozone variations in Guangdong
607 Province from August 24 to 31, 2020, with evaluation results showing excellent
608 performance (**Fig.8d**). For all 105 monitoring stations across the province, the
609 correlation coefficient between observed and simulated ozone concentrations
610 reached 0.88 ($p<0.01$), with a root mean square error (RMSE) of 8.41 ppbv. Focusing
611 on the Sanshui station (112.8°E, 23.15°N), which exhibited both high ozone levels
612 and a clear increasing trend, the correlation coefficient was 0.82 ($p<0.01$) with an
613 RMSE of 3.29 ppbv. These results demonstrate that the WRF-CMAQ model
614 successfully captured the spatial distribution and temporal evolution of this ozone
615 pollution event in Guangdong, with statistical metrics meeting operational air quality
616 modeling standards. The model's strong performance, particularly in reproducing
617 both regional patterns and local pollution trends, provides reliable support for
618 subsequent analysis of ozone formation mechanisms under typhoon conditions.

619

620 Figure 8. Consecutive northward-moving typhoon tracks, backward trajectories, and
 621 ozone variations. (a-b) Typhoon paths with corresponding MDA8 ozone concentrations in
 622 Guangdong province; (c) Backward trajectories at 1300 LST on August 29, 2020; (d) WRF-CMAQ
 623 simulated ozone variations (upper panel: average across 105 Guangdong monitoring stations;
 624 lower panel: Foshan Sanshui station (112.8°E, 23.15°N) observations, with red lines indicating
 625 simulated values and black lines representing monitored concentrations).

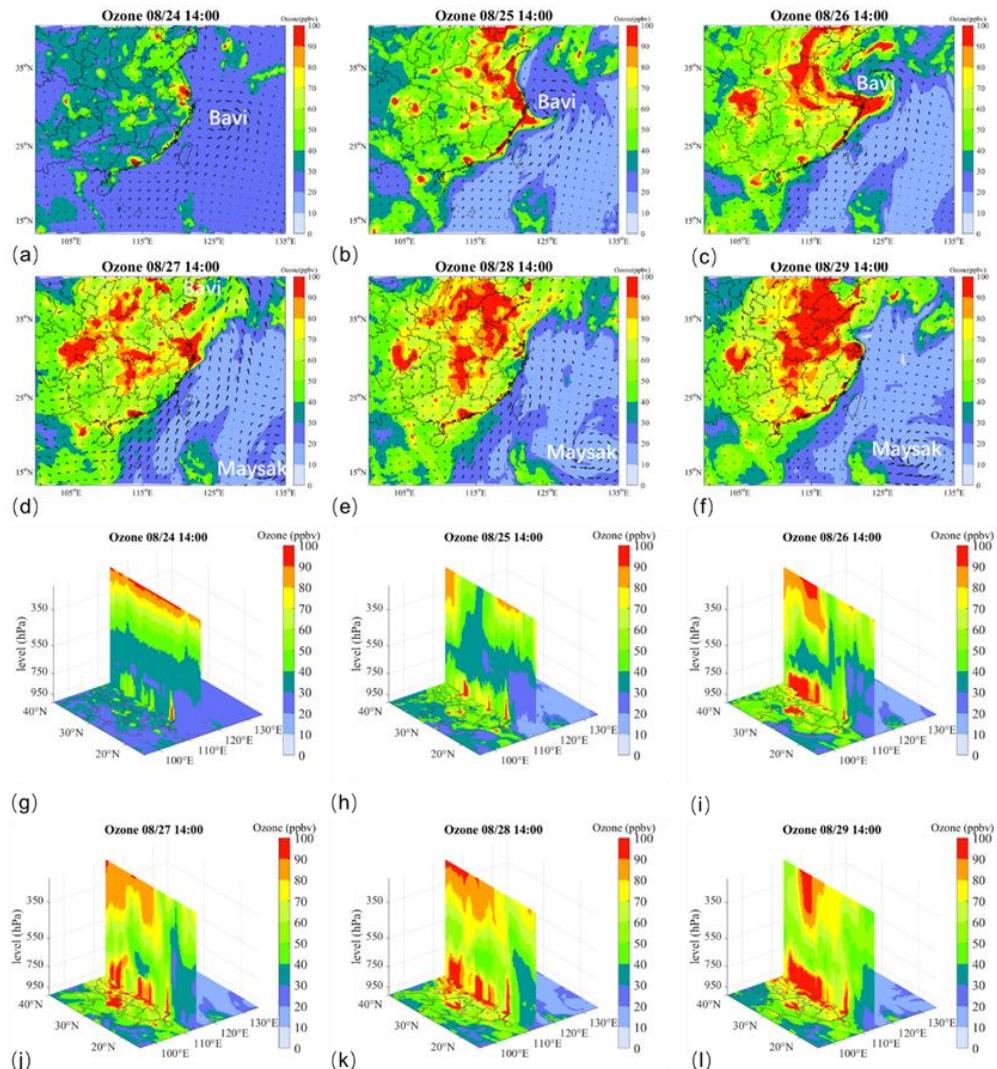

626

627 From August 24 to 27, Typhoon Bavi was located along the eastern coastal
 628 region of China, moving northward before gradually dissipating. From August 28 to
 629 31, Typhoon Maysak emerged in the South China Sea and progressively approached
 630 the Chinese mainland. During this period, we analyzed variations in surface ozone
 631 concentrations and their vertical distribution under the influence of these
 632 consecutive northward-moving typhoons, based on model simulation results (Fig.9).
 633 The results show that the variation in surface ozone distribution can be divided into
 634 two stages: The first stage occurred under the influence of Typhoon Bavi, when
 635 surface ozone concentrations rapidly increased in the Beijing-Tianjin-Hebei region,
 636 Yangtze River Delta, and Pearl River Delta, and was rapidly transported to
 637 southwestern China by circulation. The second stage occurred under the influence of

638 Typhoon Maysak, when ozone concentrations continued to rise across most regions
639 of China. Compared with the first stage, horizontal ozone transport was not
640 significant during the second stage (Fig. 9a-f). In the vertical dimension, the
641 consecutive northward-moving typhoons triggered a sustained downward transport
642 process of ozone. Beginning on August 25, downward ozone transport was observed
643 in the upper atmosphere between 35°N and 40°N. From August 26 to 29, the zone of
644 ozone subsidence gradually expanded southward, leading to a significant increase in
645 ozone concentrations over Guangdong Province (Fig. 9g-l).

646 The IPR process analysis results elucidate the impacts of photochemical
647 reactions and atmospheric transport on ozone concentration variations during this
648 event (Figs. S8-S9). The photochemical reactions correspond to the CHEM
649 contribution in the process analysis. The atmospheric transport represents the
650 combined contributions of horizontal diffusion (HDIF), horizontal advection (HADV),
651 vertical diffusion (VDIF), and vertical advection (ZADV) in the process analysis. The
652 results indicate that the increase in surface ozone was primarily driven by
653 photochemical reactions. During the period dominated by Typhoon Bavi (August 24-
654 27), photochemical reactions intensified rapidly over Guangdong Province,
655 contributing more than 30 ppbv to surface ozone concentrations in the central region
656 (Figs. S8a-d). Under the influence of Typhoon Maysak (August 28-29), the positive
657 contribution from photochemical reactions was slightly lower than in the previous
658 phase, but still exceeded 16 ppbv in the central Guangdong region (Figs. S8e-f). The
659 contribution of atmospheric transport varied significantly across different altitudes,
660 exhibiting predominantly negative effects below 850 hPa and positive effects above
661 850 hPa. Vertical cross-sections of daily mean atmospheric transport contributions
662 reveal a gradual southward transport of ozone from higher to lower latitudes.
663 However, its positive contribution to ozone concentrations was substantially lower
664 than that of photochemical reactions, with daily mean contributions remaining
665 below 4.5 ppbv (Fig. S9). The downward transport of upper-level ozone inhibited

666 vertical diffusion of surface ozone while simultaneously transporting high-
 667 concentration ozone downward into the boundary layer, further intensifying ozone
 668 pollution levels. In summary, during this ozone pollution event caused by consecutive
 669 northward-moving typhoons: Chemical processes were the main cause of surface
 670 ozone pollution in Guangdong Province, Atmospheric transport was a secondary
 671 contributing factor.

672
 673 Figure 9. Temporal evolution of (a–f) horizontal distributions of surface ozone and (g–l) vertical
 674 distributions (along 114°E cross-section) of ozone from 1400 LST 24 August to 1400 LST 29 August
 675 2020.

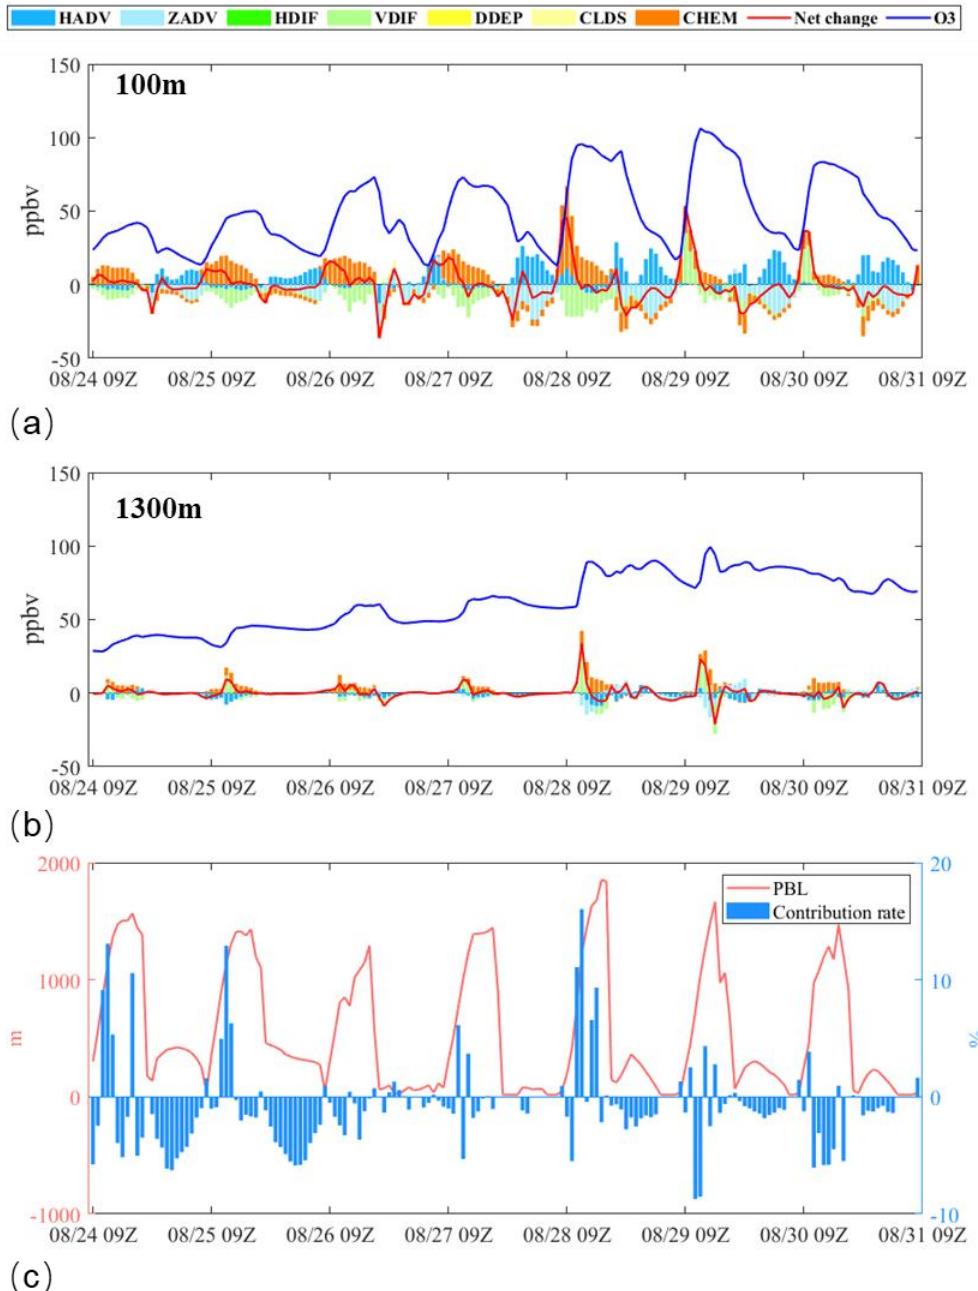

676 To quantitatively analyze the contribution of vertical transport to ozone
 677 concentrations within the boundary layer, we employed the IPR (Integrated Process
 678 Rate) analysis method to decompose ozone sources and sinks across the study area.

679 A detailed analysis was conducted using results from the Sanshui station at 100m and
680 1300m altitudes (**Fig.10a-b**). Subsequently, we calculated the contribution rate of
681 cross-boundary-layer vertical transport to ozone concentrations in the boundary
682 layer at each time point (**Fig.10c**) using the following formula (Chen et al., 2022a):

683
$$\text{Contribution rate} = (IPR_{v,pbl} \times Z_{pbl}) \div \left(\sum_{j=1}^{pbl} O_{3,j} \times Z_j \right) * 100\%$$

684 where $IPR_{v,pbl}$ indicates the IPR value corresponding to vertical transport
685 (VDIF+ZADV) on the Boundary layer height. that is, the change in the values of
686 pollutants caused by the vertical diffusion, Z_{pbl} represents the height of the layer in
687 the model that is close to the height of the boundary layer. $O_{3,j}$ indicates the ozone
688 concentration in layer j , Z_j represents the height of j layer.

689 Detailed analysis of process contributions at different heights within the
690 boundary layer shows that while near-surface atmospheric transport exhibited
691 negative contributions to daily mean ozone concentrations, the decomposition of
692 individual processes at 100m height revealed positive contributions from vertical
693 diffusion (VDIF) during 0900-1100 LST on 29 August, with magnitudes of 39.9 ppbv,
694 26.4 ppbv, and 12.3 ppbv respectively (**Fig. 10a**). Further analysis of process
695 contributions at 1300m height reveals distinct positive signals from vertical transport
696 during the morning hours of both 28 and 29 August (**Fig. 10b**). This confirms that
697 upper-level ozone can be transported into the boundary layer, thereby influencing
698 ozone concentrations within the boundary layer. Calculation of cross-boundary-layer
699 vertical transport contributions revealed six distinct ozone transport events during
700 this consecutive northward-moving typhoon episode, occurring on 24, 25, 27, 28, 29,
701 and 30 August. The maximum contribution rate to ozone concentrations within the
702 boundary layer reached 16%.

703

704 Figure 10. Process contributions to ozone concentrations at 100m and 1300m altitudes,
705 and cross-boundary-layer vertical transport contribution rates. (a-b: Contributions from
706 horizontal diffusion (HDIF), horizontal advection (HADV), vertical diffusion (VDIF), vertical
707 advection (ZADV), chemical processes (CHEM), dry deposition (DDEP), and cloud processes
708 (CLDS). c: Red lines indicate net ozone change, while blue lines show ozone concentration
709 variations.)

710 **5 Conclusions**

711 This study systematically investigated the mechanisms by which different
712 typhoon tracks influence ozone pollution in Guangdong Province through

713 meteorological factors, atmospheric circulation patterns, transport trajectories, and
714 vertical transport contributions, based on 237 typhoons in China's adjacent waters
715 from 2013-2023. The key findings are:

- 716 1. Historical typhoons were classified into three types using the K-MEANS
717 clustering method: westward-moving typhoons (Type 1), distant northward-
718 moving typhoons (Type 2), and proximal northward-recurving typhoons
719 (Type 3). Among these, near-track northward-moving typhoons are more
720 likely to induce ozone pollution in Guangdong Province due to their more
721 extreme meteorological conditions, including higher temperatures, stronger
722 solar radiation, lower cloud cover, reduced precipitation, decreased relative
723 humidity, elevated boundary layer height, weaker surface winds, and
724 suppressed vertical motion.
- 725 2. Under the influence of northward-moving typhoons (types 2 and 3), an
726 anticyclone develops over western China at the 175 hPa level, positioned to
727 the south of the westerly jet. This configuration leads to a more pronounced
728 southerly wind anomaly in the right exit region of the westerly jet. This
729 process triggers the subsidence of high-concentration ozone from the upper
730 troposphere, accompanied by pole-to-equator transport. Comparative
731 analysis between typhoon and non-typhoon conditions reveals that both
732 types of northward-moving typhoons induce significant ozone enhancement
733 throughout the vertical column, with increases ranging from 2.5 to 11.6
734 ppbv (Type 2) and 0.3 to 12.3 ppbv (Type 3).
- 735 3. For Type 1 typhoons, the associated ozone pollution is primarily controlled
736 by the subtropical high system, with significant contributions from local
737 pollution sources. In contrast, Type 2 and Type 3 typhoons exhibit the
738 highest proportions of upper-level transport trajectories (23.9% and 15.2%,
739 respectively), capable of delivering air masses from as high as 9,980 m (~250
740 hPa) into the boundary layer. Coupled with the elevated ozone

741 concentrations along these transport pathways, these mechanisms result in
742 ozone enhancements of 10.7 ppbv and 12.3 ppbv at boundary layer
743 altitudes for Type 2 and Type 3, respectively.

744 4. Under the influence of two consecutive northward-moving typhoons from
745 August 21 to September 6, 2020, Guangdong Province experienced a
746 prolonged ozone pollution episode. On August 29, ozone exceedance was
747 observed at 54.3% of monitoring stations. The primary cause of this ozone
748 pollution event was enhanced photochemical production, with secondary
749 contributions from upper-level ozone transport. Process analysis revealed
750 that during 09:00-11:00 LST on August 29, the positive contributions of
751 near-surface vertical transport to ozone concentrations were 39.9 ppbv, 26.4
752 ppbv, and 12.3 ppbv, respectively. During this typhoon event, cross-
753 boundary-layer transport via vertical mixing contributed up to 16% of the
754 ozone concentration within the boundary layer.

755

756 **Data availability**

757 All raw data can be provided by the corresponding authors upon request.

758 **Author contributions**

759 Xi Chen, Xiaoyang Chen, and Xuemei Wang planned the research; Long Wang,
760 Shucheng Chang and Minhui Li runned the model; Xi Chen analyzed the data; Xi Chen
761 and Xiaoyang Chen wrote the manuscript draft; Chenghao Liao, Yongbo Zhang, Mei
762 Li, and Xuemei Wang reviewed and edited the manuscript.

763 **Competing interests**

764 The authors declare that they have no conflict of interest.

765
